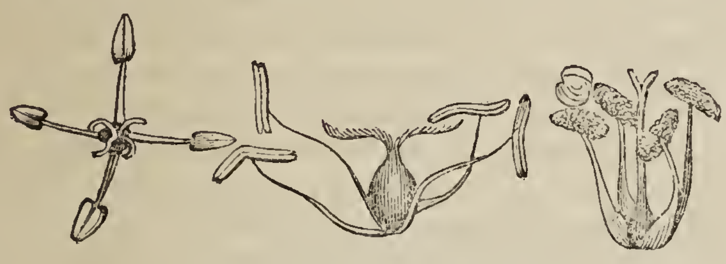
The fourth class is TETRANDRIA, containing all plants having four stamens of *equal length*. This distinction should be specially kept in mind by the student, because the fourteenth class (*didynamia*) has also four stamens, but in this last two are longer than the others.

This class is divided into three orders, namely, MONOGYNIA, DIGYNIA, and TETRAGYNIA, according to their number of pistils respectively. The whole contains above one hundred and nineteen genera and one thousand and twenty-seven species in the recently published lists. Many of the genera of the first order are beautiful shrubs and trees, chiefly natives of the Cape of Good Hope and New Holland, as the *Proteas, Hakias, Banksias*, and the splendid waratah or *Telopia speciosissima*. Several fine ornamental Chinese shrubs, as the ixoras, for instance, belong to this class, as well as many hardy plants, both shrubs and herbs, natives of Europe.

The second order contains only four genera, one of which is a British annual, *Buffonia tenuifolia*, named after the celebrated naturalist the Count de Buffon. The witch-hazel, a hardy North American tree, is also placed in this small order.

The third order, TETRAGYNIA, is also small, containing only eleven genera. Among these, however, we find the well-known holly, or holme-tree, as it used to be called in former times. This as a hedge plant is unrivalled; and as an ornamental evergreen, none are more worthy a place. Its timber, when it has attained full size, is solid, white, and of remarkable fine grain, and much used by musical instrument makers and other artists. The common pond weed, *Potamogiton*, so frequent in our slow running rivers, also belongs to this order.



Orders of the fourth class.

The fifth class of the system is PENTANDRIA, that is, flowers having five stamens. It is divided into six orders, namely, MONOGYNIA, DIGYNIA, TRIGYNIA, TETRAGYNIA, PENTAGYNIA, and POLYGYNIA. This class contains, perhaps, more phœnogamous plants than any other in the sexual system. The genera amount to above five hundred and twelve, and the described species are above four thousand and seventy-three. The first order is particularly abundand both in genera and species; every description of flowering plant is found here, trees, shrubs, and herbs, terrestrial and aquatic, trailers, creepers, and climbers, annuals, biennials, and perennials, deciduous and evergreen, tender and hardy. Among this great crowd of vegetable beauties, it is difficult to particularise any one as more typical of the class and order than another. Suffice to notice that among the herbs the primrose and convolvulus are conspicuous, among the shrubs are the beautiful azaleas, and of trees the allamanda and Portlandia are the most splendid in the tropical groves. Of medical plants there are many; one only need be mentioned, namely, the Jesuits' bark tree, *Cinchona officinalis;* and of dietetic plants there are many; instance the plantain tree of India, and the cultivated potato of Europe.

The second order, DIGYNIA, contains all plants having five stamens and two pistils. This is also a large order, and comprises many beautiful and useful plants. Here we find the *Asclepias*, with its curiously constructed flowers, and the no less remarkable *Stapelia*, a family of leafless plants, but bearing flowers of uncommon character both in shape and colour, and moreover diffusing a scent so loathsome that blow-flies lay their eggs on the petals! Here also we find the remarkable English parasitical plant, the dodder, *Cuscuta Europæa*, and the stately elm tree, so useful both for ornament and timber. Many medicinal plants are also in this order, and not a few are useful to the cook and confectioner.

The third order, TRIGYNIA, contains only eighteen genera, some of which are well-known plants. The laurestine is one of the most ornamental, and the elder, though a common intruder, is nevertheless useful in some respects; both wood and pith are employed in the arts, and the fruit supplies the labourer with a homely kind of wine. The sumach family, so variously useful in the arts, is also ranked here, with several other genera of inferior note.

The fourth order, TETRAGYNIA, contains one genera only, and which happens to be a British plant, a beautiful inhabitant of our bogs and marshy ground, known by the name of grass of Parnassus. There are four species of this plant already described; three of them are natives of North America.

The fifth order, PENTAGYNIA, contains nineteen genera, among which we find the highly ornamental family of *Crassula*, a tribe of succulent plants, chiefly from the Cape of Good Hope. Here also we find the superlatively useful flax, which furnishes the raw material of the linen manufacture; the neat thrift, used for the edgings of walks in gardens, and the showy sea lavender.

The sixth and last order, POLYGYNIA, that is having many pistils, is a small order containing only three genera, two of which are exotics, and the other a native of Britain, common in corn-fields, called *Myosurus minimus*, or mouse-tail.

Class Pentandria.

The sixth class is HEXANDRIA, and is divided into four orders, namely, MONOGYNIA, DIGYNIA, TRIGYNIA, and POLYGYNIA. It contains two hundred genera and above one thousand seven hundred and twenty-seven species. This class contains the greater number of our bulbous flowering, and culinary plants, as the showy narcissus, the splendid lilies, the long-lifed American aloe, the magnificent erinums, and pancratiums; the unequalled fruit the pine-apple, and the equally useful onion, asparagus, &c. &c. The plants are chiefly herbaceous, are found in every clime from the torrid to the arctic zone, in the burning sands of Africa, and from under the snows of Siberia.

The first is by far the largest order, containing nine-tenths of the whole class.

The second order, DIGYNIA, contains only three genera, but one of them is most important to the inhabitants of tropical countries, and to those of the warmer parts of the temperate zones. Rice is the staff of life in India, and is cultivated on every spot of level ground where there is a command of water for irrigating the crop. Its quality as a grain is highly nutritious, and at the same time easily prepared for use. A wooden pestle and stone mortar is only necessary to free it from its rough husk; and when winnowed, simple boiling with the addition of a little salt prepares it as a principal article of food for both rich and poor. This plant is a true cereal, and has been properly placed by Jussieu among the grasses. The only British plant in this order is the *Oxyria reneiformis*, mountain sorrel.

The third order, TRIGYNIA, contains a few bulbous and tuberous stemmed plants, as the birds' tongue, the elegant trillium, and the meadow saffron, a common English plant, as well as the well-known dock.

The fourth order is POLYGYNIA, comprising only four genera, among which we find one of the most beautiful British genera, namely, the water-plantain. It is only found in pools or turfy bogs, and if cultivated it must have a place in the aquarium.

Class Hexandria.

In studying the plants of this class care must be taken not to confound them with those of the fifteenth class (*Tetradynamia*), which also has six stamens. The distinction is this: in *Hexandria* the stamens are of equal length, whereas in the fifteenth class four are longer than the other two. But besides, the structure of the flowers of this latter class sufficiently distinguish them from the former.

The seventh class is HEPTANDRIA, and contains four orders, which together comprise fifteen genera and forty-eight species. The first order is the largest, and contains two nearly allied genera of trees, viz., the æsculus and pavia, better known by the name horse-chestnut. They are among the most ornamental of our forest trees, though they are not native foresters. The flowers of the common sort are well known, and one or two of the pavias have bright red flowers, which are most striking objects in ornamental scenery. The common horse-chestnut yields great crops of nuts; but except deer, no other domestic animal will touch them.

Class Heptandria.

Class Heptandria.

Order second, DIGYNIA, contains only one genera, namely, the *Limeum Africanum*, a perennial herb from the Cape of Good Hope.

The third order, TETRAGYNIA, comprises only two genera, *Saururus*, lizard's tail, and *Astranthus*, a new genus lately introduced from China.

The fourth order is HEPTAGYNIA, that is plants having seven stamens and seven pistils. It is remarkable that among above three thousand genera only one should occur with seven stamens and seven styles; indeed, as J. J. Rousseau says, nature has neglected the number seven in her arrangement of vegetable structure.

Class eight is OCTANDRIA, which contains four orders, seventy-seven genera, and one thousand and fifty-nine species. Many beautiful plants are ranged here; of those the heaths are the most conspicuous and numerous. Of this family alone there are five hundred and forty-three species already described, chiefly natives of the southern parts of Africa. A few are found in Britain, and several in other parts of Europe. The curious *Rhexia*, the gay, and night-flowering *Œnothera*, and the elegant *Fuchsia*, are found in this class. So also is the well known mezereon, and many exotic genera of great beauty.

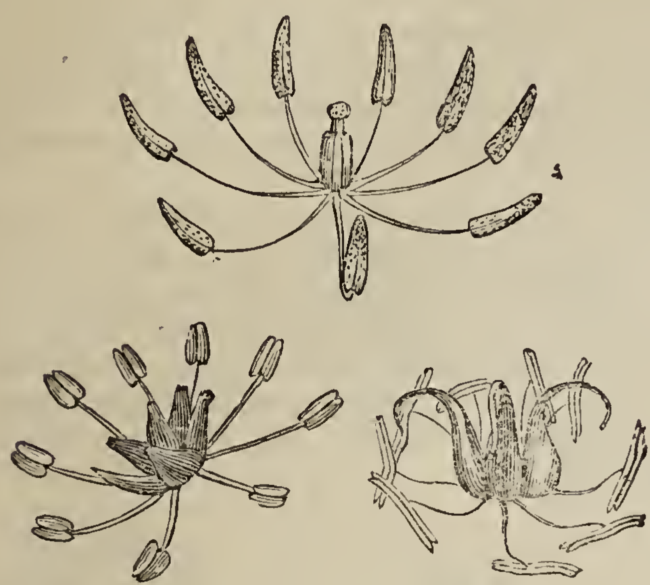
The second order, DIGYNIA, contains only five genera, all exotics, *Weinmannia* being the chief.

The third order, TRIGYNIA, comprises nine genera, among which the sea-side grape, and soap-berry of the West Indies, are the most remarkable.

The fourth order, TETRAGYNIA, contains six genera, among which is the curiously organised *Bryophyllum*, which bears viviparous progeny on the edges of its leaves. The two little interesting British plants, *Paris* and *Adoxa*, are also placed in this class and order.

Class Octandria.

The ninth class, ENNEANDRIA, is furnished with nine stamens, and contains but a limited number of plants. It is divided into three orders, comprising, together, ten genera and seventy species. In the first order, Monogynia, we find the useful and fragrant cinnamon, and the famous genus laurel, whence so many medicinal oils, and other useful substances are extracted.

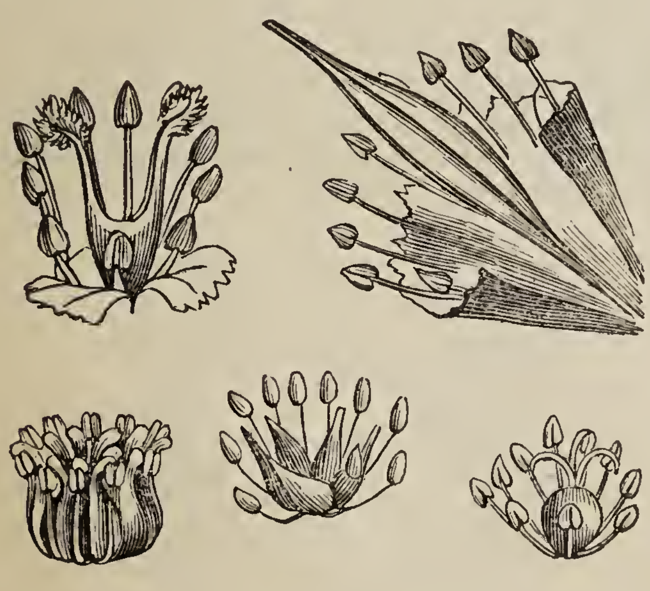


Class Enneandria.

In the second order, Trigynia, we find the excellent medical and now culinary plant rhubarb, with only one other congener, the *Pleca,* a rush-looking genus from Carolina.

The last order is Hexagynia, containing but one genus, of which there are only two species, the flowering rush of Britain and the broad-leaved ditto from Nepal.

The tenth class is numerically named Decandria, and contains five orders, one hundred and eighty-six genera, and above one thousand six hundred and forty-eight species. This class comprises a great many of our finest flowering shrubs and trees, especially those splendid kinds from North America, commonly called *par excellence* American plants. In the first order Monogynia, we have the *Kalmias, Ledums, Rhododendrons, Andromedas,* &c., plants as generally admired as they are universally cultivated: we have also the arbutus, clethra, the fine aromatic scented storax tree, and many other exotics of the greatest beauty.



Decandria and orders.

In the second order, Digynia, we find the well-known *Hydrangea,* the extensive genus *Saxifrage,* and the equally extensive family of *Dianthus,* which include the highly estimable carnation, pink, sweet-william, and other species and varieties of that favourite tribe.

The third order, Trigynia, contains a great many plants which are allied to the *Dianthus* family. They are mostly slender annual weeds, though many are pretty and a few ornamental. The catchflies, stitchworts, and sandworts are all found here, and constitute a great majority of the order.

The fourth order, Pentagynia, contains a good many plants, both native and foreign. The *Cotyledons* and *Oxalises* of the Cape of Good Hope, and the *Sedums* of Europe are most numerous. The lychnis and mouse-ear chickweed, together with the common spurrey, are also placed here.

The fifth order, Decagynia, that is, plants having ten pistils as well as ten stamens, contains only one genus, and that a foreigner, namely, *Phytolacea,* of which there are nine or ten species.

The eleventh class is called Dodecandria, there being no plant yet discovered with eleven stamens, and all those of this class have at least twelve. It contains seven orders, forty-nine genera, and four hundred and twenty-four species. The first order, Monogynia, among many fine tropical plants, includes the celebrated fruit tree, mangosteen, said to be the most delicious and wholesome fruit in the world. The garlic-pear, and the showy British plant which ornaments the banks of our rivers during summer, the *Lythrum salicaria,* are also in this order.

The second order, Digynia, contains only two genera, of which the British plant agrimony, common on road-sides, is one.

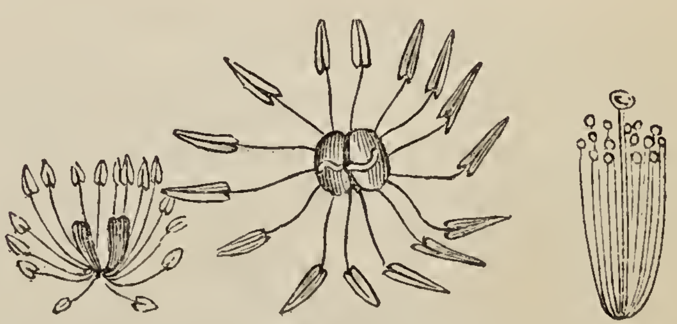
The third order, Trigynia, contains the genus *Reseda,* some species of which are used by the dyer for producing a yellow colour: another species is the universal favourite, mignonette, cultivated entirely for its scent. This order also contains the remarkable and extensive family of *Euphorbia* or *spurge,* a majority of which are exotics, though there are twelve or thirteen found wild in Britain, of which the caper-spurge and wart-wort are well known.

The fourth order, Tetragynia, contains only one genus, viz. the *Calligonum pallasia,* a native of the Caspian.

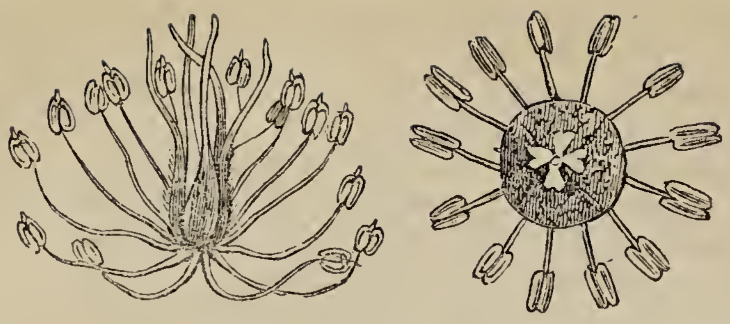
The fifth order, Pentagynia, contains only three genera, of which the *Blackwellias* are the principal. They are all, except one, tropical shrubs.

The sixth order, Hexagynia, contains a single genus, viz. *Cephalotus,* but that a very curious one; its leaves being formed into elegant pitchers, furnished with lids, like those of the *Nepenthes.*

The seventh and last order, Dodecagynia, contains only two nearly allied genera, viz., the sempervivum or house-leek, and the monanthus, a succulent plant, from the Canary Islands, bearing but one flower at a time.



Dodecandria and orders.

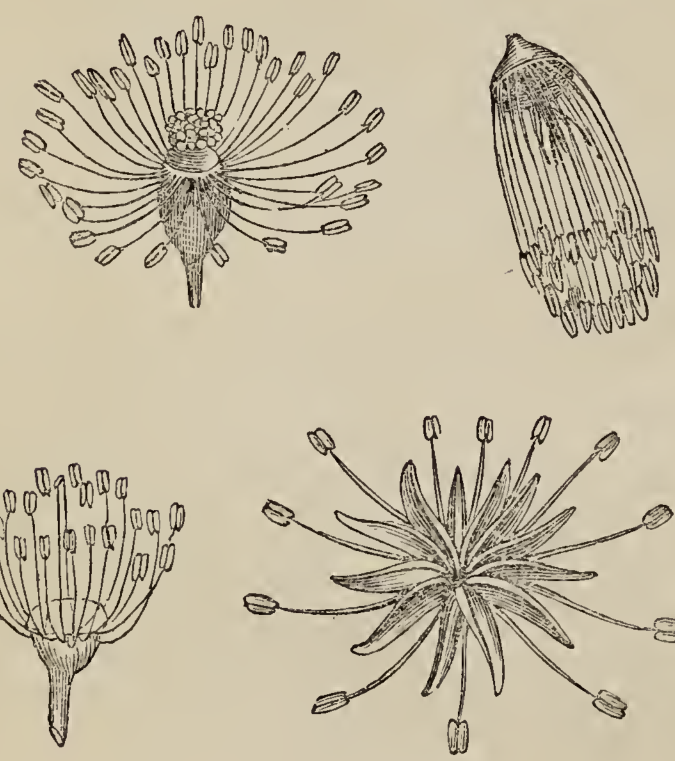


Class Dodecandria and orders.

The twelfth class, Icosandria, contains all such plants as have twenty or more stamens seated upon the corolla or calyx. It is divided into three orders, comprising sixty genera, and one thousand two hundred and ten species. This is one of the most important classes of the Linnæan system, as containing many of our most useful fruits, as well as most esteemed flowers. In the first order, Monogynia, we have the gorgeous *Cacti*, *Cereus*, *Epiphyllum*, and *Opuntias;* the myrtle, *Eugenia* and *Eucalytus;* of fruits we have the guava, pomegranate, and several of our best wall-fruit.

In the second order, Di-Pentagynia, that is, plants having from two to five pistils, we have the pear, apple, quince, &c.; likewise the extensive genus *Mesembryanthemum*, of which there are three hundred and thirteen species, besides numerous varieties described by the late lamented Mr. Haworth.

In the third order, Polygynia, we have the unrivalled rose, the exquisite strawberry, raspberry, and many others of great worth and beauty.



Class Icosandria and orders.

The thirteenth class is Polyandria; that is, all plants having an unlimited number of stamens distinct from each other, and seated on the receptacle. This class contains one hundred and seven genera, and nine hundred and fifty-six species.

The first order, Monogynia, comprises, among many others, the caper-tree, the well-known poppy, the curious sarracenia, and the magnificent water-lily.

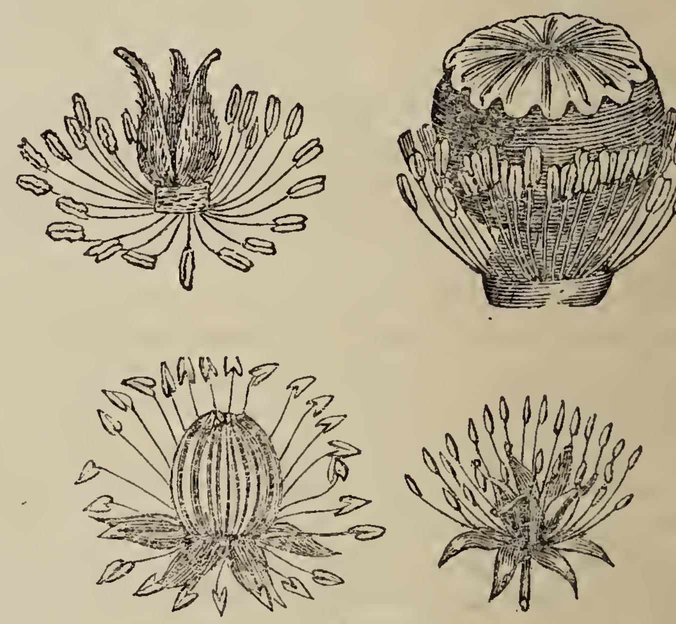
The second order, Digynia, is well typified in the splendid peony, a genus which has been lately much increased by new varieties received from China and Siberia.

The third order, Trigynia, contains the beautiful larkspurs, the dangerous aconite, and the inodorous Hibbertia.

The fourth order, Tetragynia, contains only two genera; the butter nut, a tropical fruit; and the *Drimys winteri*, a tree alied to the magnolia.

The fifth order. Pentagynia, contains ten genera, of which the well-known columbine may be taken as a type.

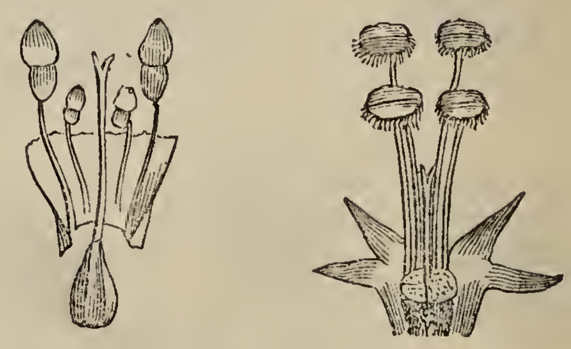
The sixth order, Polygynia, contains a great many fine flowering plants, both shrubs and herbs; among the former, the magnolia is most conspicuous; among the latter, the anemone and ranunculus are confessedly beautiful. Of early, or winter flowering plants, the aconite and hellebore are examples, and the globe-flower and marsh-marigold are showy plant.



Class Polyandria.

The fourteenth class is called Didynamia, because of four stamens two are superior, and contains two orders, one hundred and seventy genera, and one thousand four hundred species. The flowers are generally ringent.

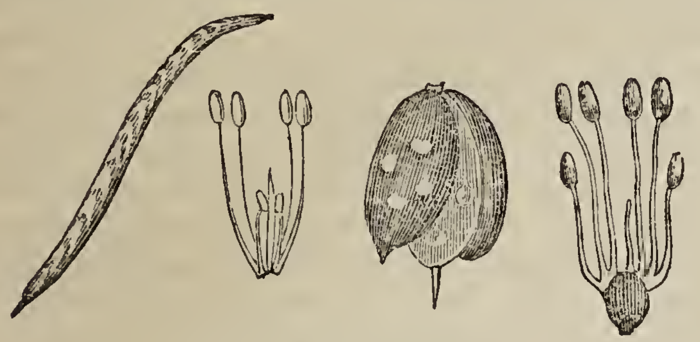
In the first order, Gymnosperma, the calyx is persisting, and becomes the seed-vessel, in which the seeds lie naked. In this order we find the germander, lavender, mint, and dead-nettle, and many others of similar character: several of them are useful in cookery.



Class Didynamia and orders.

The second order, Angiosperma, so called because, though the stamens are the same in number and position, the seeds are differently disposed, being contained in a capsule. Many of the plants in this order are very beautiful; for instance, the bignonia, volkameria, antirrhinum, mimulus, &c. The common fox-glove, so conspicuous in our hedge banks, also belongs to this order, and is a good type of the whole.

The fifteenth class is TETRADYNAMIA, so called because of six stamens four are longer than the other two. There are no orders in this class, the orders siliculosa and siliquosa being exploded; all the flower being similar in structure, and is a truly natural association, and forms the order *Cruciferæ* in Jussieu's system. Many of the plants are dietetic,



Class Tetradynamia.

as the cabbage, turnip, radish, &c.; and some are finely scented and favourite flowers, as the wall-flower, stock, arabis, rocket, &c. The seeds of several cruciferous plants yield oil of excellent quality.

The sixteenth class is called MONADELPHIA, because the stamens are united in one set. It is divided into seven orders, founded on the number of the stamens, not on that of the pistils, as in other classes; the whole containing one hundred and thirty-nine genera, and one thousand four hundred and thirty-six species.

The first order, TRIANDRIA, contains all such flowers as have three united stamens. In this we find several beautiful Cape bulbs; as the *Feraria*, *Tigridia*, *Herbertia*, &c. The flowers are not only of uncommon forms, but curiously spotted or streaked with dark colours.

The second order, PENTANDRIA, has five stamens united in one set. Of this order the passion-flower is the most remarkable type. There is also the *Erodium* or heron's-bill, a section of plants formerly united with the geraniums.

The third order, HEXANDRIA, has six stamens united in one set. This order contains but one genus, and is so distinct in itself, that it forms an order in the natural system. It is a bulbous-rooted plant, having grass-like leaves and curious flowers. This plant was unknown to Linnæus.

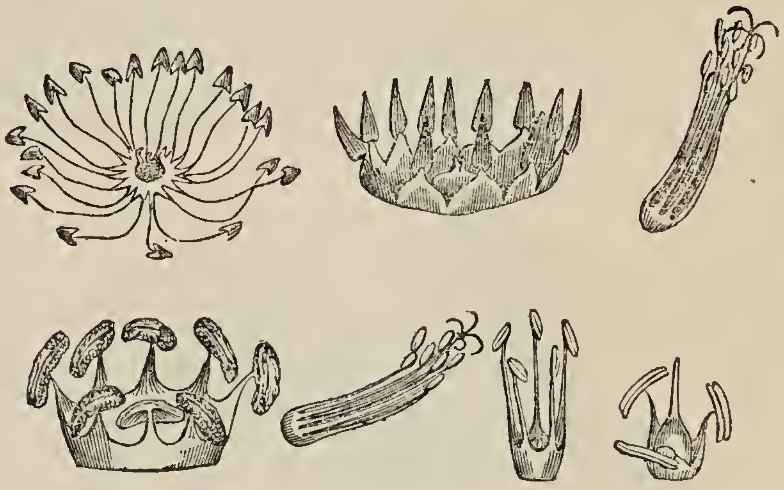
The fourth order is HEPTANDRIA, plants furnished with seven stamens united together at the base. The order contains the pelargoniums, commonly called geraniums; a genus of plants unequalled for immense variety of forms and colours. Of pelargoniums there are above two hundred and thirty-eight species, and between three and four hundred varieties already enrolled in books. They are chiefly natives of the Cape of Good Hope, and have long formed a large majority of our green-house plants. They are, perhaps more than any other tribe, very susceptible of hybridisation, and consequently every day presents new varieties or subvarieties. Many of them have tuberous roots, by which they are easily propagated, but the greater part are under shrubs.

The fifth order of the class is OCTANDRIA, and contains only two genera, which have eight stamens united in one set or brotherhood. The first genus is *Aitonia*, named by Linnæus in honour of the late William Aiton, esq., royal gardener at Kew. The second is *Comosperma*, hairy-seeded shrubs from New Holland.

The sixth order is DECANDRIA, plants having ten stamens in one set. Here we find the true geraniums or crane's-bill. These are chiefly herbaceous plants, and found in many parts of the temperate latitudes. The herb-Robert, is a common British plant, and is a good type of the genus. This order is, however, rich in showy plants of very differently constructed flowers, called *Papilionaceous*, or butterfly-shaped, and their seed-vessels being pods. Hence we findhere the crotalarias, the common furze, broom, genista, laburnum, rest-harrow, lupine, and many other beautiful plants, as well trees, shrubs, and herbs.

The seventh order is DODECANDRIA, containing plants which have twelve stamens in one brotherhood. This order comprises twelve genera, some of them highly ornamental, but they are all tropical plants.

The eighth order is POLYANDRIA, that is, flowers having many stamens united in one set. Here many of our gayest flowering plants are arranged—as the althea, lavatera, hibiscus, sida, silk-cotton-tree, the tea-tree, and its magnificent congener the camellia, now so common an ornamental favourite in British gardens.



Class Monadelphia and orders.

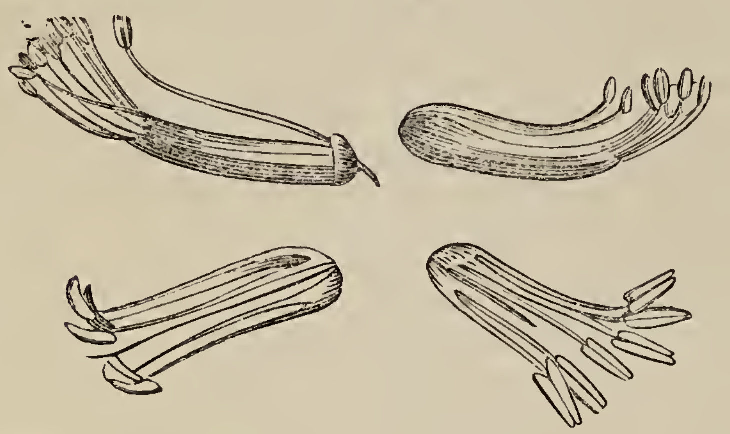
The seventeenth class is DIADELPHIA, that is, all flowers having two sets or brotherhoods of stamens. In general nine are united together, with a single one by itself, which is accounted the second brotherhood. This class contains one hundred and twenty-nine genera, and one thousand five hundred and six species. The flowers are chiefly butterfly-shaped and the whole class has a very distinct character.

The first order is PENTANDRIA, that is, five stamens united in two sets. This order contains only a single genus, namely, the *Monniera trifolia*, an African annual of no great beauty.

The second order is HEXANDRIA, consisting of plants bearing six stamens in two brotherhoods. This order contains six genera, of which the common weed fumitory is a good example.

The third order of this class is OCTANDRIA, containing flowers having eight stamens in two sets. This order comprises only four genera, of which the beautiful milkwort is the most numerous and conspicuous. The common one of this country is oen of the most interesting; found on chalk hills or other dry places.

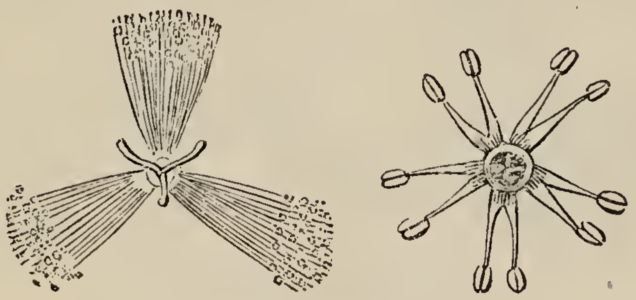
Order the fourth is DECANDRIA; plants having ten stamens united in two sets, usually nine together, and one by itself above the others. The order contains the greater number of the leguminous plants, or such as bear pods. They have all butterfly-shaped flowers; and comprise almost all our most useful kinds of pulse, forage plants, dyes, and many beautiful and valuable shrubs and trees. The pea, bean, tare, indigo, are examples of the order.



Class Diadelphia and orders.

The eighteenth class is POLYADELPHIA, containing all plants having their stamens arranged in many brotherhoods. It is divided into two orders, and contains twenty-one genera and one hundred and eighty-seven species.

The first is DECANDRIA; flowers with ten stamens in several distinct bundles or sets. Here are only four genera, all tropical plants; among them we find the *Theobroma*, which yields the useful chocolate nut.



Class Polyadelphia.

The second order is POLYANDRIA, comprising plants whose flowers have many stamens in many distinct sets. This disposition of the parts on which the order is founded, is exemplified in the St. John's wort, a plant common in our fields as well as gardens. And in green-houses the useful and beautiful fruit-tree, the orange, affords a ready example.

The nineteenth class of the Linnæan system is SYNGENESIA, and contains all the compound flowers or *Compositæ* of Jussieu. The meaning of the title signifies to generate together: the seed-bearing florets being all crowded together on the same base or receptacle: or, more probably, from the circumstance of the stamens being united in a cylinder, and surrounding the style near its apex. The peculiar arrangement by which syngenesious flowers are distinguished from all others is this, that besides the union of the anthers, the flowers or florets, instead of standing singly, are here congregated; instead of each having a calyx and receptacle, one calyx and one receptacle is common to the whole, whatever that number may be. The whole together is called the flower, as that of a daisy: the separate parts composing the disk of it, are called florets. The flower is supported on its exterior by a number of scale-like leaves, by some called calyx, but by others *anthodium*, and mostly attached to the outer rim of the receptacle, which bears the florets on its upper surface. The florets however are not always perfect in themselves; some of them are of two sexes, others, male, or female, or neuter. On the difference of these in position and character, the orders of the class are founded. The florets are said to have a calyx which is superior, and becomes the crown of the seed; a corolla which is of one petal and superior; the limb campanulate, or ligulate; stamens five, filaments inserted into the tube of the floret; anthers united by their margins in all bisexual florets; germen inferior, being a naked seed crowned with the other parts; style erect; stigma in two parts, each revolute and divergent; seed single, either naked, or crowned with the calyx, or with a pappus to assist the dispersion. The dandelion and thistle are familiar examples. This class contains two hundred and seventy-seven genera, and two thousand six hundred and fifty species.

The first order is ÆQUALIS in which all the florets are of two sexes. This is a very extensive order and contains many very common plants, as the sowthistle, lettuce, hawkweed, burdock, artichoke, &c., &c. The chief part of them are herbs, and many are annuals.

The second order is SUPERFLUA, here we find plants the flowers of which have the florets of the disk

Superflua Æqualis.

bisexual, and those forming the rays female, but which are impregnated by the anthers of the disk. This circumstance was considered by Linnæus as superfluous, and hence the title. This is also a very large order, and contains many useful as well as beautiful plants. Of the first tansy and chamomile are examples, of the second the helichrysums, xeranthemums, and dahlias.

The third order is FRUSTRANEA, so called because the florets of the disk are bisexual, and those in the ray or margin neuter. These last, having sometimes the rudiments of a pistillum, but no other sexual organ, are said to be ineffectual or frustrated polygamy. The type of the order is the splendid sunflower, with which many of the same style of flowering plants are arranged, such as the rudbeckia, coreopsis, &c.

The fourth order is called NECESSARIA, because the florets of the disk or centre of the flower, being all male, it is necessary that those of the ray or margin should be female, in order that there may be perfect seed, and which is found to be the case in all plants ranked in this order. Calendula and arctotis, exotics chiefly from the Cape of Good Hope, are two of the most conspicuous genera in this order.

The fifth order of Syngenesia is called SEGREGATA, because the florets have each its proper calyx (different from the perianthe of the floret) besides the common anthodium or exterior calyx; or there are several florets contained in each calyculus. All the plants in this order are exotic herbs and undershrubs, the globe thistle being the most common in British gardens.

N. B. To the above five orders Linnæus added a sixth, called MONOGAMIA, in contradistinction to the other orders which are polygamous. The plants which stood in this sixth order were such as had their stamens united, as in the other orders of the class, but had simple flowers, not aggregated florets. The genus *Lobelia* was one, but which is, as well as all the others (except one) of the order *Monogamia*, now placed in the class *Pentandria Monogynia.*

The twentieth class is GYNANDRIA, containing all plants which have their stamens seated upon the pistillum. This class comprises one hundred and ten genera, and four hundred and thirty-seven species. The species are generally herbaceous, with tuberous roots, curious gouty, or climbing stems, many are epiphytes growing on trees, or flourishing in rotten vegetable matter in moist places. Some of their flowers are splendid, many highly fragrant, and all of remarkable conformation. The class is divided into three orders, viz.:—

Order one is MONANDRIA, containing plants which have one anther seated on the pistillum. This order comprises some of the most attractive wild British plants; as the orchis, ophrys, epipactis, &c. These, however beautiful, are excelled by those of the same tribe from America and other parts of the world.

The second order is DIANDRIA, flowers having two anthers seated on the pistillum. In this order we find one of the greatest British beauties, namely, the ladies' slipper, found in damp woods, and particularly in the north of England; but they never can be plentiful, because the moment the flowers appear they are gathered and torn up without mercy.

The third order is HEXANDRIA, containing plants which have six stamens seated on the pistil. This order has only one genus, namely, the *Aristolochia* or birthwort, a very curious family of climbing exotics; one only being found in Britain, viz., the *A. clematitis.*

Class Gyrandria.

The twenty-first class is MONŒCIA, consisting of plants which have male and female flowers separate, but on the same root. This class contains one hundred and forty-seven genera, and one thousand and fifty-two species. It may here be observed, that in syngenesious flowers the unisexual florets stand separately, but are included in the same cover; here they also are separate, but in distinct covers

This class is divided into ten orders, viz.—

Order one is MONANDRIA, that is separate male flowers bearing one stamen. Five genera are contained in this order, one of which is the celebrated bread fruit tree, a native of the South Sea Islands. The only British genus arranged here, is the *Zannichellia palustris,* the common pondweed.

Monœcia Monandria.

The second order is DIANDRIA, having distinct male flowers bearing two stamens. There are only four genera in this order, three of them exotic, and one British, namely, the common duckweed, the small floating plant which forms " the green-mantle of the standing pool."

Monœcia Diandria.

The third order is TRIANDRIA, consisting of plants, having separate male flowers bearing three stamens. Here are a few tropical trees, and a great many coarse European grass-like plants. The cat's-tail and bar-reed, are common aquatics, found in many parts of Britain. The maize or Indian corn also ranks in this order.

The fourth order is TETRANDRIA, includes all plants whose separate male flowers have four stamens. Here we find the alder and birch, forest trees; the box and mulberry trees; the common nettle, and the well known foreigner *Aucuba Japonica.*

The fifth order is PENTANDRIA, containing all monœcious plants whose male flowers bear five stamens. The amaranthus is most conspicuous here.

Monœcia Pentandria.

The sixth order is Hexandria, separate male flowers, furnished with six stamens. The plants of this order are chiefly palms, or allied to that tribe. The cocoa nut and sago palms are here, as well as the acrocomia and others.

The seventh order, Octandria, has separate male flowers, bearing eight stamens. This is a very small order, containing only one genus, the *Duvaua*, a lofty tree, indigenous to Chile. There are two species, one of them from *Owhyhee.*

The eighth order is Icosandria, containing plants which have male flowers separate, and bearing many stamens inserted into the calyx. Botanists have as yet discovered only one genus which can with propriety be placed here, and this a tree from New Holland, called *Atherosperma moschata.*

The ninth order is Polyandria, which contains plants whose male flowers are separate, and which bear many stamens, seated on the receptacle. This is a pretty large order, and comprises the beautiful *Begonia,* the chestnut, beech, hazel, walnut, and above all, the lordly oak. Here also we find the planetree, Salisburia, and humble yet numerous tribe of arums, &c.

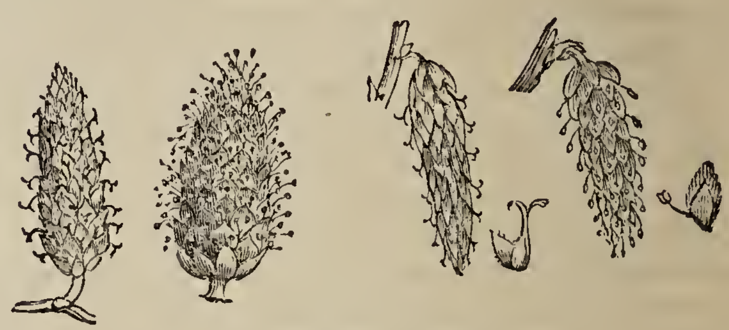
The tenth order is Monadelphia, that is, plants having male flowers distinct, and whose stamens are united at the base into one brotherhood. This is the largest order of the class, and contains some of the most magnificent forest trees, as the pines and firs, larch, cedar, cypress, &c. Here are also the enormous gourd, useful melon, and cucumber, the poisonous janipha manihot, and the medicinal palma Christi.

Monœcia Polyandria.

Monœcia Monadelphia.

The twenty-second class is Diœcia, which is composed of plants which have unisexual flowers, not on the same, but on different roots. In modern nomenclatures this class has arranged in it one hundred and three genera, and six hundred and sixty species. It is divided into no less than thirteen orders, which are as follow, viz.:—

The first order is Monandria, consisting of plants bearing unisexual flowers on different roots, those of the male plant having but one stamen. This is a small order, containing only two genera, one being the remarkable screw-pine; so called because the leaves resemble those of the pine apple, only much larger, and they issue from the stem in a very different manner; that is, neither opposite or alternately, but the last always a little to the left of the former, so that they are expanded spirally like the worm of a screw.



Diœcia Monandria.

The second order is Diandria, containing plants having unisexual flowers on different roots, the males bearing two stamens. This order contains four genera, of which the common willow is the principal; there being of this genus no less than one hundred and sixty-seven species already described. The *Valisneria spiralis,* so beautifully described by Dr. Darwin in his "loves of the plants," belongs to the order.

The third order is Triandria, having male flowers on one plant, and females on another, the former being furnished with three stamens in each. This order contains twelve genera, among which one is a common trailing plant, found on our moist moors—namely, the crow-berry. The date-bearing palm, so useful to the common people in Persia, and other countries where it grows naturally, also belongs to this order.

The fourth order, Tetrandria, consists of plants having flowers of one sex, but on distinct roots. The male plants have four stamens in each flower. This order contains fifteen genera, among them we find the candle-berry myrtle, one species of which is found wild in Britain, namely, the sweet gale. The parasite mistletoe is also common in England on oak trees, white-thorn, and particularly in apple orchards. It is said that the oaks on which mistletoe grew, were particularly valued by the Druids, and under them they performed their devotions.

Diœcea, Triandria and Tetrandria.

The fifth order is Pentandria, the male plants of which bear flowers having five stamens. This order contains thirteen genera: among which are the well-known culinary vegetable spinach, and the no less valuable hop. All the other genera are exotics. Respecting the hop, it has been said that it was formerly the custom to root out all the male plants from every hop-garden; but that now the custom is found erroneous; and one male plant to every twenty females is allowed by the growers, in order to give weight to the sample.

Diœcia Pentandria.

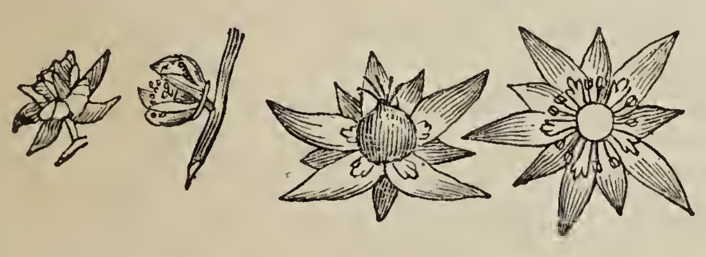
The sixth order is Hexandria, diœcious plants, bearing male flowers, having six stamens. This order comprises seventeen genera, among which are six palms, some of them of stately growth, and highly ornamental in their native countries. The genus *smilax* is also here, some of the species of which yield medical drugs. The only British genus is the black bryony.

Order seven is Octandria, containing diœcious plants, the males of which have flowers furnished with eight stamens. This is a very small order, containing only the genus poplar. Four species are natives of Britain, one of which, the white poplar, grows to a very large size when standing in its favourite soil, a moist peat earth.

The eighth order is Enneandria, the male plants of which bear flowers having nine stamens. This is also a small order, containing only three genera, two of which, the mercury and frog-bit, are British. The third triplaris is an American tree, useful for its timber.

Diœcia Octandria and Enneandria.

The ninth order is Decandria, the male plants of which have ten stamens. Another small order, containing five genera, all of which are exotics. One of the principal is the papaw, a large tree-like herb, bearing bunches of fruit resembling melons, much used in India.



Diœcia Decandria and Dodecandria.

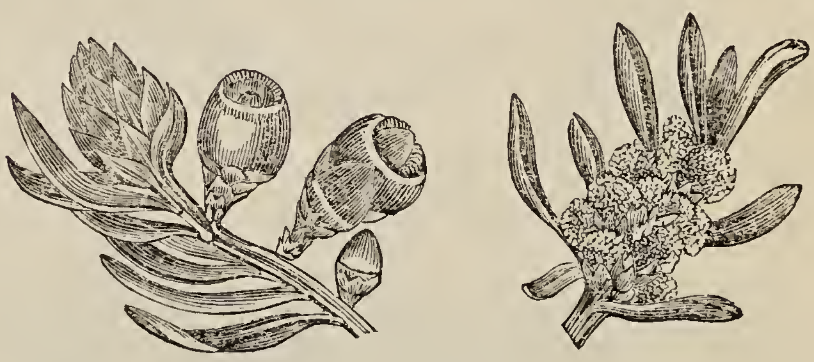
The tenth order is Dodecandria, the male plants of which are furnished with twelve stamens. This order contains six genera: among them we find only one British, an aquatic, called the water-soldier. Another is the menispermum or moon-seed, which, with all the others, are exotics.

The eleventh order of the class Diœcia is Icosandria, the male plants of which bear flowers having above twelve stamens inserted in the calyx. There are only three genera, none of which are British; in botanical collections they are inmates of the hot-house.

Diœcia Icosandria and Polyandria.

Order twelve is Polyandria, the male plants of which are furnished with many stamens, fixed on the receptacle. This order contains seven genera, all of which are exotics. Here we find *Cliffortia*, a genus common in our green-houses. Also *cycas* and *zamia*, plants of curious habit, to be met with in most collections.

The last order of the class is Monadelphia, the male plants of which bear flowers, in which the stamens are united in one brotherhood. This order comprises fifteen genera, of very various bulk and manner of growth. Here are the magnificent Bourbon palm, the lofty and symmetrical araucaria,—the humble butchers' broom—the pyramidal juniper—the dark yew—the fragrant nutmeg, and the curious pitcher plant, forming together a most interesting assemblage.



Diœcia Monadelphia.

The twenty-third class is Polygamia, signifying many marriages; that is, of plants having both

Polygamia Monœcia.

unisexual and bisexual flowers on the same, or on different roots. There is a good deal of uncertainty about placing plants in this division of the system, because some of the genera are not always constant in their modes of flowering; and even single plants will occasionally exhibit all the characters by which the different orders are founded.

This class contains sixty-eight genera, and seven hundred and thirty-six species, and is divided into two orders.

The first order is Monœcia, containing plants in which the polygamy is complete on one root, that is, where there are male flowers having stamens only, female flowers having pistils only, and flowers in which the stamens and pistils are united. This is a very extensive order, and contains many highly beautiful as well as useful plants. Here are the mimosas, the ingas, the acacias, the maples, the beautiful ailantus, and the fine fruit tree, the mango. There are also a good many of the gramineæ in this order.

The second order Diœcia contains plants which have the polygamy complete on two different roots. This order contains eighteen genera, among which there are the ash tree, so useful for its timber, the bread nut, the date plum, the anacardium, and the numerous family of the fig. Out of this last-mentioned genus Linnæus formed another order which he called Triœcia, having the polygamy complete on three distinct plants; that is, male flowers are found on one, female on another, and male and female flowers on a third; but as this circumstance has only been noticed on one species, viz. the cultivated fig, his followers have thought the order untenable, and it is therefore abolished.

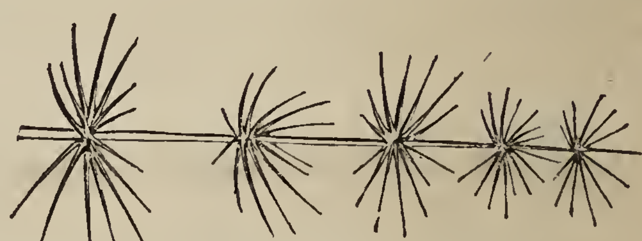
Polygamia Diœcia.

The twenty-fourth class is Cryptogamia, which signifies hidden marriages. This class is divided into nine orders, and contains three hundred and seventy-six genera, ,and two thousand six hundred and sixty-two species.

The first order is Filices, or ferns, having the sporule or seed conceptacles on the back of the fronds or leaves. These are a very curious and distinct tribe of vegetables. They have perennial roots, annually throwing up stems or fronds, which are evolved circinately; that is, the point of the frond, and its divisions, are rolled in upon their bases in their incipient state, and their develepement is an evolution or unrolling to complete expansion. In cold countries, the ferns are what the palms are between the tropics. their appearance being somewhat similar. Indeed, some of the ferns in South America vie with the palms in height, though not in duration; the former being much more fugitive. The fronds are kidney-shaped, linear, pinnate, or decompound; some are not more than an inch in height; others, in warm countries, arrive at many feet in height. According as the conceptacles, or spots whence the seeds or dust proceed are arranged on the frond, the generic characters are drawn; some, as the osmunda, have their fructification in a loose spike, quite different in form from the fronds. The habitat of ferns is on waste ground, damp rocks, or mossy stems of trees.

Filices.

The second order, Equistaceæ, contains only one genus, whence the name of the order is derived, namely equisetum, or horsetail, a common British plant found in pools and ditches. In some countries this plant is called frog-pipe, because they are found in the same situations. The horse tail is of most symmetrical growth; upright jointed stems, with verticillate fringes of linear leaves, bearing spikes of fructification on the summit.



Cryptogamia Equisetaceæ.

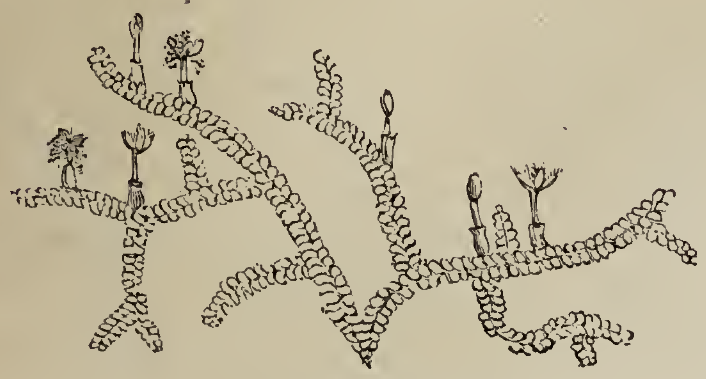
The third order is Lycopodeaceæ, containing only two genera. This is otherwise called club-moss, from the shape of the plants. This order of plants are found on peat bogs, and damp woods of peaty soil.

Cryptogamia Lycopodeaceæ.

The fourth order is Marsileaceæ, containing four genera. These are very inconspicuous plants, springing up on moist ground among moss or grass, having the appearance of tufts of small quills; others bear little round heads; hence they are called pillwort.

The fifth order is Musci, containing a great many genera and species. These flourish only in cold northern countries, and in shady damp situations. Bogs and moist ground are covered with them, forming a soft and compact carpet. They rank in the lowest order of vegetation, and serve for a protection or food for larger plants.

The sixth order is Hepaticæ, consisting of small creeping inconspicuous plants, having their leaves imbricated on each other, and quite distinct from the lichens, which they in some degree resemble. One of the genera, the jungermannia, is the most common, and met with on bogs, moist woods, and sides of mountains where springs ooze out.



Cryptogamia Hepaticæ.

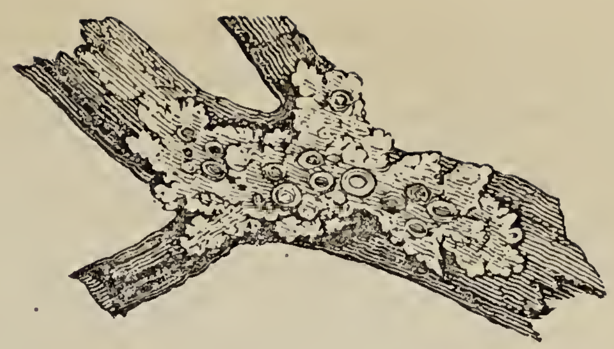
The seventh order is ALGÆ, containing seventy nine genera, which are chiefly aquatics inhabiting the sea, lakes, and rivers. In the second tribe of this order we find conferva, a numerous genus, and remarkable for its being sooner detected by its colour than its form. The green scum, which so soon appears on a glass of water, or on the surface of moist earth, or on the inside of water vessels, or on stones in brooks, is conferva of one species or other. The greater number of algæ inhabit the depths and shallows of the ocean, hence called sea-weeds.

Cryptogamia Algæ.

The eighth order is LICHENES, containing all those scaly, ash-coloured substances which grow on rocks, walls, buildings, or stems of trees. They assume very many forms; some are spread out in thin parchment like expansions, others rise from the surface on which they grow, and present shaggy tufts of a hoary appearance. Some of them are the food of animals,

Cryptogamia Lichenes.

as the reindeer of Lapland; others are medicinally useful, and a few are used by the dyer.



Cryptogamia Lichenes.

The ninth and last order is FUNGI, comprising all the mushroom tribes. There are above one hundred and fifty-nine genera, and upwards of one thousand one hundred and fifty-seven species already on the published lists; and no doubt many more exist undiscovered. The major part of the fungi grow on rotten wood, and other decayed vegetable and animal substances. Some of them are eatable, and much used in refined cookery, others poisonous, and much caution is requisite even in choosing those which are allowed to be wholesome. The dry rot in timber is said to be caused by different kinds of fungi.

Cryptogamia Fungi.

To these twenty-four classes the author of the sexual system added an appendix containing the order *Palmæ*, the flowers of which, in his time, were not sufficiently known to enable him to place them in the proper classes; this task, however, has been performed by modern botanists, who have distributed the palms among the different classes and orders according to the Linnæan rules, and where he himself would have placed them had he been acquainted with their manner of flowering.

The foregoing is an outline of the sexual system of botany. The annexed delineations of the numbers and dispositions of the sexual parts on which the system is founded, render longer descriptions of the classes and orders unnecessary. For by an attentive examination of the titles compared with the figures, as perfect a knowledge of the system may be acquired, as is necessary for any one seeking information on the subject.

For the easy classification of the various tribes of plants, the sexual system as is well calculated as any other artificial scheme that can be devised; and as a first step to gaining a knowledge of the different forms of flowers it is indispensable. But like all other artificial systems it has its defects; these are bringing together in the same class, plants which have neither resemblance or affinity with each other, save in the circumstance of their having the same number of stamens. Some of the true grasses for instance, are classed with genera having no kind of similitude or congeniality; indeed, many anomalies are found in the system, which show its artificial character, This, as before observed, was felt and acknowledged by the author himself, and has led to the new system of Jussieu, of which we now proceed to give as concise an account as is consistent with perspicuity.

The Jussieuian, or Natural System.

The author of this new system of botany seems to have taken a very comprehensive view of the vegetable kingdom, and has been fortunate in fixing on those greater characteristics of plants which distinguish them from each other, and which are the most invariable. Looking at vegetable membrane he found it was either uniformly simple, that is, consisting of tissues of cells of nearly equal size, or of tissues of which the cells were of various sizes intermixed with each other, and formed into fibres lying in straight or in spiral positions, and forming tubes and openings of different structure and consistence. This evident difference of structure served to divide the whole vegetable kingdom into two parts; the first he called *Cellulares*, the second *Vasculares*. He further observed, that all the plants of the first division sprung up destitute of seed leaves, (*cotyledons*), and those of the second division sprung up from the seed furnished with either one or two seed-leaves. This difference in the germination of the plants called vascular, served to separate this grand division into two very distinct classes, namely, Dicotyledoneæ, containing such plants as rise with two seed-leaves; and Monocotyledoneæ, those that rise with one. These classes are also very different in the manner of their growth; the first, *Dicotyledoneæ*, is increased annually by additions to the outside, hence called *Exogenes;* and the second, *Monocotyledoneæ*, receives additional matter from the inside, hence denominated *Indogenes.* Besides these very striking characteristics as regards the growth, the structure and appearance of their foliage is also obviously different. In a leaf of the first class the petiole is extended directly through the web, and as it proceeds, sends off branches towards the margin on both sides, whereas in a leaf of the second class there is no costa or mid-rib, the petiole being divided into several parts, which run in nearly parallel lines from the base to the apex of the leaf.

By these obvious distinctions in the manner of germination of the seeds, the modes of accretion, and in the structure of the stems and foliage, the two classes of dicotyledoneæ are clearly marked. But as there are great differences in the parts and positions of the floral members, the author of the system thought it expedient, in order to facilitate the study of it, to separate the first class into two subdivisions, and these again into sub-classes, as follow:—

The first grand division, Vasculares, of which the first class is *Dicotyledoneæ*, rising with two seed leaves. Of this class the first subdivision is *Dichlamydeæ*, that is, two coats or coverings, the calyx and corolla being distinct.

This subdivision is further divided into three sub-classes, viz., first, *Thalamifloræ*, containing flowers in which the stamens are seated under the pistillum.

This sub-class contains fifty-eight orders, all under proper titles derived from some one of the genera, which is assumed as the general type of the order. For instance, the first order is called *Ranunculaceæ*, because all the other orders of this sub-class resemble more or less in structure and form the flowers of the ranunculus, or crowfoot. Here we find associated the anemone, the peony, aconite, columbine, marsh-marigold, hepatica, adonis, &c., all of which show an affinity in their modes of flowering.

In applying this portion of botanical knowledge, the student has to ascertain whether the seedling rises with two seed-leaves, whether on seeing the flower it presents a calyx and corolla distinct from each other, and finds all the stamens seated below the germen—he may conclude that the plant belongs to this sub-class; and if not to the order *Ranunculaceæ* to some other allied order, with the character of which it may better agree in general habit, as to whether herb, shrub, or tree.

The second sub-class of this division is *Calycifloræ*, containing plants whose flowers have the stamens seated on the calyx.

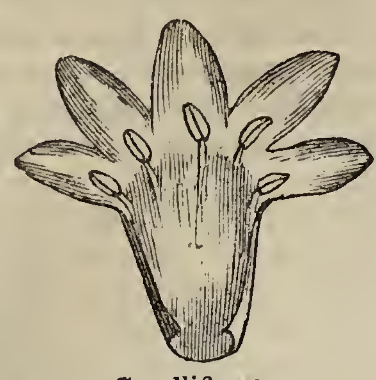
This sub-class comprises fifty-eight orders, one thousand one hundred and forty-nine genera, and eleven thousand four hundred and forty-five species. One of the most beautiful orders is the *Leguminosæ*, which contains all plants bearing pods and having butterfly-shaped flowers. So numerous indeed, and so varied are the genera in this single order that, it is divided into divisions, sub-orders, sub-divisions, tribes, and sub-tribes, in order that the numerous species composing it may be easier understood, and recognised. To the *Lejuminosæ* the order *Rosaceæ* is the next in importance. Its type, the common rose, is not more regarded for its beauty and scent, than are many of its associates for their excellent fruit.

Here we find the cherry, plum, apricot, and peach, the principal of our wall fruit of this country; besides many of our smaller fruit cultivated in gardens, as the gooseberry, currant, strawberry and raspberry. Nor should the fine serviceable fruits, the common apple and pear, be forgotten These also belong to this order; and for the use of the table, the kitchen, and for the manufacture of cider and perry, are inestimable.

The white thorn, with which our fields are divided from each other, and which enlivens with its snow-white blossoms the whole country during the month of May, also belongs to this order.

Besides the above, many other beautiful flowering plants are also placed here: indeed, all plants bearing rose-like flowers are put into this sub-class, as the myrtle, the Eugenia, the Barringtonia, together with those useful foreign fruits, the different species of guava. Here also we find the elegant passion-flower, and all those curious tribes of plants from foreign countries, the crassulas, mesembryanthemums, cactuses, cereuses, and the like. Here also is ranked the extensive European family of plants, the saxifrage or stonecrop, together with many other floral beauties, which it is unnecessary to mention.

The third sub-class of the natural system is *Corolliflorœ*, including all flowers which have the stamens attached to the corolla; the petals cohering in the form of a hypogynous (that is, seated below the germen) corolla, but separated from the calyx. This sub-class contains four hundred and eighty-five genera, and four thousand one hundred and ninety species. Among these the olive, as a useful fruit tree, and the jasmine for its beauty and fragrance, are well known. The *asclepias* is also here, and gives a title to one of the orders, and which order comprises many genera remarkable for the curious structure and colours of the flowers, and the uncommon rankness of their scent. The humble gentian, and the climbing bignonia and convolvulus, are also here; so is the order *Solaneœ*, which contains the wholesome potato and the poisonous night-shade; the intoxicating tobacco, and the pungent capsicum. The numerous order *Labiatœ*, is in this sub-class, containing so many of our useful aromatic herbs, as thyme, mint, balm, &c. Many floral beauties are also here: the order *Primulaceœ* embraces some of the most common, though at the same time most admired; namely, the primrose, cowslip, auricula, and anagallis or pimpernell.



Corolliflorœ.

The second subdivision is Monochlamydeæ, signifying two coats in one, the calyx and corolla being blended together; at least these members are not distinct. This subdivision contains twenty-seven orders, two hundred and fifty-six genera, and two thousand six hundred and twenty-eight species. Here are associated herbs, shrubs, and trees. Of the first the amaranthus and begonia are conspicuous: among the second the proteas and their alliances, the banksias, dryandras, and telopea stand pre-eminent; and among the trees the cinnamon, nutmeg, bread-fruit, and mulberry, are some of the most remarkable; and of forest trees, the whole orders *Coniferœ* and *Amentaceœ*, afford familiar examples.

Monochlamydeæ.

The second class of the natural system is Monocotyledoneæ, comprising all plants which rise from the seed, and exhibiting *one cotyledon* or seed-leaf only.

Monocotyledoneæ.

This class contains thirty-three orders, six hundred and thirty genera, and four thousand seven hundred and two species of beautiful, and, except the palms, herbaceous plants. Here we have all the bulbous and tuberous-stemmed flowering favourites, as the *Orchideœ*, *Irideœ*, *Tulipaceœ*, and *Amaryllideœ*, which include a great majority of our gayest bed, border, and green-house ornamental plants. The pine-apple, the plantain, and the various kinds of palms, all esteemed as yielding delicious fruit, are also here. Another order, perhaps the most useful of all, is ranked in this class, namely, the grasses, of which there are one hundred and fifty-eight genera found in different parts, but chiefly in the temperate regions of the earth. These furnish universal pasturage and provender for cattle; sugar, bread, and spirituous liquors for the use of man. Lower grades of plants are grouped with the grasses; as the careces and rushes, and most of the aquatic tribes.

The second grand division of the system is Cellulares, signifying plants composed of cellular tissue, and with but few instances of the existence of spiral vessels in their structure. They are reproduced by minute sporules discharged from their conceptacles, and rise from the earth without cotyledons or seed leaves: hence this division is also called *Acotyledoneœ*. It contains three hundred and seventy-six genera, and two thousand eight hundred and fifty-nine species, and which are divided into two classes.

The first class is Foliaceæ, containing such plants of the division as exhibit leaf-like expansions. Of this class there are six orders, viz:—

The first order is Filices, which contains all the different sorts of ferns. Of these there are fifty-three genera, and eight hundred and thirty-seven species, already described. Ferns have a perennial stem entirely under, or creeping on, the surface of the ground. The stems are increased in length and thickness by internal accretion, and by the persisting bases of former leaves. From the point of the stem, and from tubercles on the side, the fronds or leaves are produced, and in a peculiar manner; instead of simple elongation, the expansion takes place by evolution—the face of the leaves, and lateral divisions of the leaves, being unrolled from the bases to the points. Some of the ferns have simple leaves, and in many they are compound and much divided. In size these plants vary from a few inches to twenty feet in height.

The second order is Equisetaceæ, containing only one genus, and ten species. These are aquatics, and they grow on very damp clayey or loamy soils. Their forms are regularly elegant, though their foliage is very attenuated, and growing in whorls from the joints of the stem. The stems of most of the equisetums, or horse-tails, as they are provincially called, are succulent, erect, and regularly jointed; the reproductive organs being borne on a scaly kind of catkin at the apex of the stems.

The third order is Lycopodineæ, or club-moss. Of these there are two genera, and nineteen species, all herbaceous prostrate plants. Their leaves are simple, and lie imbricated over each other from the base upwards. They are usually found in damp woods and bogs, and they shed sporules like ferns.

The fourth order is Marsileaceæ, comprising four genera, and one species of each. They are simple leaved or floating plants, found in different parts of Europe. They are of no known use, nor are they met with in botanical collections.

The fifth order of this class is Musci, or mosses. Of these thirty genera, and three hundred and thirty species are described. They are a humble and common tribe, inhabiting cold damp places, and attaching themselves to rocks, stones, or moist buildings:

often growing among, and sometimes extirpating, the grasses of moist meadows.

The sixth order is Hepaticæ or liverwort moss, containing six genera, and ninety-four species. They are like some of the foregoing small creeping plants, and inhabiting the same damp and cold places. They are, however, very different in structure from the other genera of this class.

The second class of cellulares is called *Aphyllæ*, because they are entirely destitute of leaves or leaf-like expansions. This class has three divisions. The first is Algæ, containing seventy-nine genera, and four hundred and fifty-three species. Among the algæ the simplest forms of vegetation are to be found, and also some gigantic sea-weeds rising from great depths of the sea. Some of hair-like structure have a spontaneous motion like worms; some require a microscope to be seen, and of very different character as to duration, perennial, annual, or ephemeral. Some of the sea species are edible, their flavour being mild and rather grateful.

The second division are the Lichenes, containing thirty-five genera, and four hundred and twelve species. These are the plants which cause the weather-stains on old buildings; they creep on the naked rocks, and attach themselves to the trunks and branches of trees. Some of them are used in diet and in medicine, and several by the dyer. They flourish most in northern climates, and for some animals answer the purposes of forage.

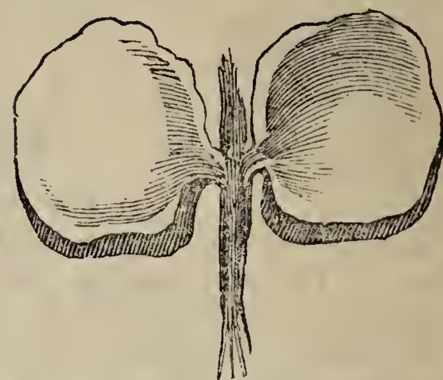
The third and last division of the class aphyllæ is the Fungi, which is by far the most numerous of all. Of these there are one hundred and fifty-nine genera, and one thousand one hundred and fifty-seven species. The mushroom is one of the best known genera, and lends its name to many that do not belong to the family. The toads' stool and other boleti are often mistaken for mushrooms by ignorant people, who not unfrequently use them at the peril of their lives. The mould on cheese and stale bread are fungi; so is the mildew on trees, and the rust on corn. Though so many of this division have been discovered, it is more than probable that hundreds remain unnoticed and unknown.

As the figures of the classes and orders of the second grand division Cellulares are all represented on the plate, they are omitted under their respective titles here, being easily referred to while the descriptions are read.

The foregoing is a very brief sketch of the Jussieuan system as improved by later writers. The descriptions of the divisions, classes, subdivisions, and subclasses, are all intentionally brief, because these, together with each order of the subclasses, have been or will be particularly noticed as they occur alphabetically in the body of this division of the Cyclopædia. Another reason for the brevity alluded to is the pictorial illustrations of Jussieu's divisions and subdivisions, which will be found at the end of this article, and which, when compared with the explanations of the titles of each subclass, cannot fail to convey a pretty clear idea of the grand features of this popular and nearly universally received system.

As there are many other terms employed in the Jussieuan system of botany that have not been used in the foregoing sketch, it may be necessary in this place, while giving a kind of summary of the whole, to notice them.

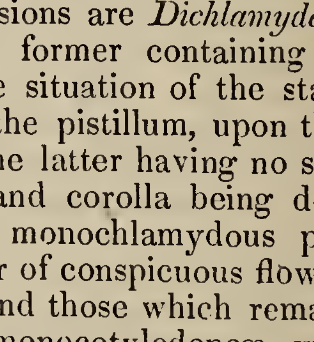
It has already been observed that Jussieu divides the vegetable kingdom into two grand and well defined parts, namely, Vasculares and Cellulares. The first is also called *Cotyledoneæ*, and the second is also called *Acotyledoneæ* for reasons assigned under those titles. Vasculares are, moreover, called *Phanerogamia* or *Phænogamia*, because they have visible flowers; and cellulares are called *Cryptogamia*, because they have no visible flowers.



Germination of Dicotyledons.

Vasculares are separated into two classes called *Dicotyledons* or *Exogenes*, and *Monocotyledons* or *Endogenes*, significant of their manner of growth; the former rising with two seed-leaves, and increasing by additions on the outside; the latter rising with one seed-leaf, and increasing by additions in the inside of their stems.

These greater features of the system being first fixed, the author next proceeded to determine what should be the signs for subclassing the vast number of plants then known to botanists. This subclassing was necessary on two accounts, viz., to follow nature in forming congenial groups, and to facilitate the study of the science. In doing this he was naturally led to the consideration of the structure of the flowers. Here he found that a very great majority had the two outer coats, namely, the calyx and corolla, perfectly distinct; and another considerable portion of flowers in which these members were united. This difference of structure afforded very obvious marks on which to found two subdivisions of the first class. These subdivisions are *Dichlamydeæ* and *Monochlamydeæ*. The former containing three subclasses founded on the situation of the stamens, as whether seated below the pistillum, upon the calyx, or upon the corolla; the latter having no subclass, the union of the calyx and corolla being deemed a sufficient distinction of monochlamydous plants. Thus the greater number of conspicuous flowering plants were disposed of; and those which remained, forming the second class monocotyledoneæ, were easily distinguishable by the circumstances of rising with one cotyledon only, and from the very different structure of their leaves and stems.



Dichlamydeæ; calyx and corolla distinct.

Thus were the phænogamous or flowering plants arranged; and it only remained to classify the cellulares or acotyledoneæ in some other way than by their flowers, which were unobvious or unknown.

This was accomplished by placing all that had leaves in one class called FOLIACEÆ, and all leafless cellulares in another which the author called APHYLLÆ.

That Jussieu has chosen for marks of distinction those particulars of structure and exterior conformation which are the least liable to variation is perfectly true; and perhaps no plan could be hit upon that would better distinguish the principal features of vegetation. This is so far well, because it enables the student to group plants with comparative ease, and which alone is a great advantage. At this point many amateur botanists may be disposed to stop, because in proceeding to be able to identify species, or even genera, is much more laborious, and requires a greater share of practical knowledge than Linnæan botany; and this very circumstance will probably keep the latter system longer in the schools than it would otherwise be.

BOTRYCERAS (Willdenow). An evergreen shrub from New Holland, resembling a laurel, and in the natural order *Proteaceæ*.

BOTTLE GOURD. Is the *Lagenaria vulgaris* of Seringe. This with several varieties obtained from it, are cultivated in the East Indies, their native habitat. They are annuals, and cultivated in this country for the curious form and colours of their fruit.

BOTTLE-TIT or LONG-TAILED TITMOUSE (*Vagans*, Leach; *Parus caudatus*, and *Longicaudatus*, auctorum). A very curious little bird, frequenting low wooded situations in all parts of Europe; very plentifully in Holland, and abundant and pretty generally distributed over Britain. It is a very small species, not exceeding in size and weight the common wren, but is much longer in the tail, and in structure nearly resembles some of the titmice (*Parus*), in which genus it has been commonly arranged.

The bill is black and very short, but appears more so in the adult bird, from its base being hidden in the feathers, which project forwards and conceal the nostrils, and are generally half erected on the head, of a more arcuated form than in the titmice, the upper mandible slightly curving over the under. Irides, in the adults, dark reddish hazel; bare skin around the eye, orange yellow; the forehead and crown of the head are white; from near the bill, passing over the eyes, are two streaks of black, which join at the nape of the neck, forming a broad streak which runs down the middle of the back; scapulars, which, in the birds that have moulted twice, form on each side a large broad spot, roseate; in the younger individuals there is less of this colour, and the spot is but ill defined. The quills black; secondaries deeply edged with a whitish colour. The under parts also are whitish, with a line of dusky spots across the breast, and are tinged about the flanks with rosy red. The tail is very long and wedge-shaped, except that the two middle feathers are shorter and sometimes narrower than the two next, which latter are, in the adult, longest of all, those on each side being successively shorter and shorter. Legs and toes blackish, rather more slender than in the titmice, with the claws very pointed and sharp, and the grasp of the foot amazingly strong.

The sexes in this bird are much alike, but the young in their first or nestling plumage are very different. In these the two mandibles of the bill are of equal length, black, excepting the tip of the upper, which is whitish, where, in about six weeks, it grows and curves over the under. The bill also appears considerably larger than in the old bird, from its base not being concealed in the plumage. The irides are at first dark greyish, like those of a young cuckoo; in the course of two or three weeks becoming much paler and brighter, and more inclining to blue; then gradually darkening, till in eight or ten weeks, they assimilate to the colour of the pupil, so as only to be distinguished when examined closely. The colour of the bare skin around the eye at first is brick red, afterwards becoming very bright and conspicuous about the time the irides are darkest, the upper part changing to orange-yellow in the autumn, the under not till late in the following spring. Crown of the head (a much larger portion of it than in the adult), together with the whole under parts and some of the lower scapulars, pure white, without a tinge of roseate, but appearing on the flanks greyish, or intermixed with black, the feathers of these parts being thin and puffy, and showing much of their blackish inner portions. Ear-coverts, which in the adults are whitish with a few dusky spots, black; line over the eye and the whole upper parts also black, the few white scapulars forming merely a narrow white line. The wings and tail marked as in the adult, but more indistinctly, the black being everywhere more dusky than in the old bird.

Bottle-tit.

The tail also of the young bottle-tit in its nestling plumage is considerably longer than that of the adult, the two feathers next the middle measuring three inches seven-tenths; those next again measuring about a tenth more; the middle ones wanting a tenth of three inches, being a mere trifle longer than the fifth. In the adult bird the proportions are, middle feathers the same as in the young; the two next, which are longest, only one-fifth of an inch more, the longest feather being thus seven tenths shorter than in the young; a difference which, however slight it may appear, is very striking when the two birds are seen together.

The above detailed descriptions are taken from a considerable number of specimens, amongst which there is no variation, at least beyond that already adverted to as resulting from disparity of age; and we have been thus particular in noting down all the minutiæ, having some reason to apprehend, from the descriptions of various authors, that two or three species, inhabiting different parts of Europe, are at present confounded together.

In describing the smaller feathered inhabitants of Britain, we have perhaps, in several instances, been rather more minute than the subject would altogether seem to require; but our object in being so has been to render the different species at once recognisable to all who wish to distinguish them in the fields. The study of birds offers peculiar advantages to those who have but little time for these pursuits. Quadrupeds, in a state of nature, are for the most part wild and wary, ever anxious to elude the eye of man; concealed during the day in holes and coverts, and in most instances coming out only by night when darkness veils them from our most vigilant research, they frequently defy the observation of the naturalist. In like manner are the inhabitants of the waters in great measure concealed by the medium in which they live, and insects are often hidden from us by their minuteness. Birds alone are ever before us; secure in their power of rising buoyant into the air, they move in confidence around, their beauty and familiarity pleasing the eye, whilst their melody, or even their most dissonant and harsh cries, from associations connected with them, delight the ear. And who is there that seeing does not admire these beautiful creatures, and that admiring does not feel a wish to become better acquainted with them? Moreover, there is a pleasure in verifying from our own observations the various accounts which we meet with in books; and nought is more likely to interest a young observer, and to incite him to fresh researches, than the qualification he feels in being able to judge from his own experience of the accuracy of at least a part of what is laid before him; he will endeavour, so far as is within his power, to assure himself by observation of the remainder, having already perhaps been often led astray by some of the erroneous compilations so much about; and in the course of his investigations will, not at all improbably, discover something worthy of notice that had previously escaped the attention of observers. Again, the meeting with a full description of objects which are continually within the range of our own observation not unfrequently awakens, in some minds, an interest about those objects which was entirely unfelt before; strange as it may seem, many persons seem to regard all common objects of natural history with feelings of great indifference, not to say contempt; and yet, from these very persons, we have often obtained much curious and interesting information respecting the habits of singular or uncommon species; information which our own subsequent researches have, in some instances, enabled us to verify and extend. Indeed it is not by any means unusual to meet with persons, collectors perhaps and preservers of the more curious British animals, who have a considerable acquaintance with the haunts and habits of many of our rare and less known species, but who are nevertheless absolutely ignorant of almost all that concerns many which are much commoner, though at the same time perhaps not so conspicuous. To these commoner animals we would wish to direct attention; their habits are often very interesting, and the study of them is alike accessible to all, yet they are not unfrequently still involved in much greater obscurity than many which but seldom come within the sphere of our observation; and this, from the comparatively little attention which has hitherto been bestowed upon them. We are not aware that the various peculiarities of the bottle-tit or long-tailed titmouse, the subject of the present article, have ever yet been pointed out, nor the distinctive peculiarities in which it differs from all the other members of the genus, in which it has usually been arranged.

There are few but must have observed sometimes, during the autumn and winter, a number of very small birds with long tails, following each other along the hedges, or from tree to tree, in a little troop, yet busily engaged the while in searching every twig and tuft of buds for insect food, hanging often with their backs downwards, and assuming every possible variety of curious and constrained attitude. "It seems," says an elegant and pleasing writer, Mr. Knapp, "the most restless of little creatures, and is all day long in a state of progression from tree to tree, from hedge to hedge, jerking through the air with its long tail like a ball of feathers, or threading the branches of a tree, several following each other in a little stream; the leading bird uttering a shrill cry of *twitter, twitter*, and away they all scuttle to be first, stop for a second, and then are away again, observing the same order and precipitation the whole day long. The space travelled by these diminutive creatures, in the course of their progresses from the first move till the evening roost, must be considerable; yet, by their constant alacrity and animation, they appear fully equal to their daily task."

This little bird subsists entirely upon the smallest insects in different stages of their growth; in this differing from the true titmice, as we would limit that genus, the different species of which (see Titmouse) are about the most omnivorous of little birds, and feed not only on insects, fruit, various kinds of grain, and even carrion, but sometimes also on such young and sickly birds as they can master, a fact of which the writer of this article has been more than once an eye-witness in different species. But the bottle-tit at no season touches aught but insect food, nor to obtain this does it ever, like the *Pari*, purposely approach our habitations, but keeps to hedges and thickets throughout the year. We have had occasion to examine numbers of them at all seasons, and in winter have almost invariably found in them the remains of a small species of beetle with pale brown elytra, but which we cannot exactly specificate from its being always so imperfect. It has, in common with the pari, the habit in winter of sometimes pulling off the buds of trees; but as stated in our account of the blue titmouse, we are very doubtful whether this is ever done but where the traces of insect food are discernible.

The tits, as we have already had occasion to observe (see Blue Titmouse and Bearded Reed Bird), are remarkable for their jay-like habit of constantly holding their food with the foot, or with both feet, whilst they pick it to pieces with the bill; but the bottle-tit at no time holds its food in this manner, nor has it the slightest notion of so doing. On giving one in confinement a large spider's nest, it was evidently at a loss to know how to pull out the eggs, tried to nibble out a small portion, and lay the remainder beside it on a perch, but was unsuccessful, and on returning to look at it after a few minutes' absence, it was found still carrying it about in its bill; but, on fastening it to a perch, it was demolished in an instant. Its strong muscular neck seems peculiarly adapted for pulling any thing upward by force, and it is thus that, in a state of nature, its food is mostly obtained.

In a recent publication*, after describing the minute insects on which the bottle-tit appears chiefly to subsist, some highly interesting remarks are introduced, on the relative degree of acuteness of vision in this and other species; from which it would appear that, in all probability, the sight of the bottle-tit is more peculiarly adapted for distinguishing very minute objects, than that of any other bird whatever. "It is probable," observes the writer, "that though this bird is a little larger than the gold-crested wren," the smallest of British birds, "it feeds on smaller prey. From the centre of the eyes to the tip of the bill is only four-tenths of an inch, while that in the golden-crested wren is one half more, or six-tenths. Hence it is probable that, in its vision, the long-tailed tit is the most microscopic of birds. Now it accords with analogy and with observation, as far as that can be carried, that the shortest focal length of the eye, that at which minute objects can be distinctly seen, is never much longer (if longer at all) than the distance from the eye to the tip of the bill; and nearer than that would be useless.

"Hence we have a very easy means of judging of the relative power of vision in those birds which feed upon very small substances, and which, being," at least comparatively, "hard billed, as the tits are, or not having the bill covered with a sentient membrane, or the nasal groove continued to the point of it, as is the case with that most singular of all birds the apteryx, or wingless bird of New Zealand, must feed wholly or chiefly by sight.

"In the average of human eyes, of good formation, and in a healthy state, the common focal distance for small objects, such as for reading very small print, is about seven inches and a half; and the microscopic distance, such as that at which a very delicate engraving is examined (and that requires a little time for the adjustment of the eye), is about one-third less, or five inches. The bird must often strike its prey without any time for adjustment, and therefore the distance from the eye to the bill may be taken as the ordinary short focal length; but call it microscopic, and the magnifying power in line being inversely as the focal length, the lineal dimensions of an object seen by the long-tailed tit will be to that of the same seen by the human eye, as five inches to four-tenths of an inch, or as twelve and a half to one. The surface will of course be as the square, or as $156\frac{1}{4}$ to 1, and the body or solid of an object, as the cube, or $1953\frac{1}{8}$ to 1. Thus an aphis or any other small insect that can come wholly within the field of vision, will appear very nearly as large to the long-tailed tit as *two thousand* of the same would to the human eye.

..... "The microscopic power of the eyes of those little birds which seek for minute prey on the bark of trees is, therefore," (the same author afterward continues, and we cannot do better than quote his observations,) "as wonderful as the telescopic range of the eyes of eagles and other birds which soar aloft, and scan a horizon of miles; and not the least wonderful part of the whole matter is the ease with which the eye changes from telescope to microscope. The eye of the eagle which can discern the motion of a small quadruped at the distance of more than a mile, can shorten its focus, so as to be keen and perfect at the distance of a few inches; and the tit, to whose near vision the eggs of flies must appear as large as musket bullets do to us, feels no difficulty at seeing a bush at the distance of more than a hundred yards. We may admire, but we cannot imitate that wonderful mechanical skill which can, in an organ not altogether larger than a pepper-corn, produce so many focal lengths in the same crystalline lens, instantly adapt the retina, or sentient tissue, to all of them, manage the admission of the proper light by the iris, and remove the colours and correct the aberrations by the other humours; all, as it were, in an instant, without effort, and (to use the common though unphilosophical terms) without *will* or *consciousness* on the part of the owner......

..... "Eyes have no doubt a wonderful flexibility in their focal length, so that the same eye is to a considerable extent both a telescope and a microscope. But still their flexibility or power of adaptation in that way has a limit; and as the focal length of the long-tailed tit's eye is not more than a twelfth that of the human eye, we may suppose that it cannot see so well at the distance of half a mile as man does at the distance of twelve miles."

Still, probable however as this last supposition may be in the case of the bottle-tit, the gold-crests, and a few other species, it certainly will not apply alike to the generality of small birds. The power of telescopic vision in most birds, even the smaller kinds, is very much greater than most naturalists seem to be aware of; and in this class of animals generally, as is indicated by the very flattened form of the crystalline lens, and as might perhaps be anticipated from the comparatively very large size of the eye, in proportion to that of the head, appears very greatly to exceed what it is in any other class. The great extent also to which diurnal birds can alter the apparent size of the retina, and consequently regulate the degree of light admitted into the eye, is very worthy of attention; and this may be easily observed by holding in the hand a whitethroat, or some other small species with pale irides, for it is curious that, when struggling to make their escape, they keep continually dilating and contracting the iris, often to its utmost; and after witnessing the extent to which they do this, we can no longer feel surprise that the eyes of diurnal birds are never dazzled by intense light. The eagle has been always famed for gazing with undazzled vision full at the sun, but she does this in common with every little bird; the sparrow, or the robin, or the common fowl, can face the sun as well as he; and this not, as is the commonly received opinion, by shielding the eye with the nictitating membrane, but simply by contracting the pupil, as any one, who will take the trouble to observe a common fowl, will readily perceive. With regard to distant or telescopic vision, the power of sight in most (even of the smaller) birds is far superior to that of most of the human race. The writer of this article has, in his garden, a number of small birds in confinement of various genera, and the whole of these he has

* "Feathered Tribes of the British Islands," by Robert Mudie. Article Long-tailed Tit.

repeatedly seen suddenly to cease from hopping about, and all gaze earnestly at some object in the sky; yet he has often strained his eyes in vain, and so have others that have been with him, and for many minutes, before they could just discriminate the minute speck which had so long riveted the attention of the birds; frequently, indeed, he has been unable to distinguish any thing, although to them a bird of prey was plainly perceptible, as the nature of their cries evinced. Other similar instances might here be added of this wonderfully acute vision of the feathered race in general, but it would too much extend the present digression. Of this, however, we are fully convinced, from repeated observation, that, piercing as the eye of a hawk may be, the majority of little birds see nearly, if not quite, as keenly from below; perhaps quite as much so in proportion, although they want the projecting super-orbital bone and attached muscular apparatus of the falcon family, an apparatus which is said to compress the eye and adapt it peculiarly for telescopic vision. (The osprey, by the way, however, one of the keenest sighted of this very family, is also without this projecting bone.) Indeed it is very well known that the common fowl, or the turkey, perceives the kite when far above the reach of human ken; and we think it will be found that this exquisite acuteness of vision is common to very nearly all the feathered tribes. The hawks, it may be remarked, which prey most on small birds, are those which come upon them unawares; of the high-flying species, the hobby attacks chiefly the lark, as it perceives it mounting to the sky; the kestril drops almost wholly upon mice; and the merlin (at least in winter in the cultivated districts, where only the writer of this has seen it) skims swiftly along the hedges, turns a corner, and comes suddenly on a flock of larks or finches, which, crouching or flying terrified in all directions, he singles out his victim, strikes it, and is gone in an instant.

Birds whose habits lead them to the open fields would be continually exposed to danger, were they not thus enabled by quick and powerful vision to guard against enemies from above; and those enemies would have no occasion for their extraordinary powers of enduring hunger and fatigue, and would multiply to the extirpation of their prey, if the constant vigilance of the latter did not prompt them to flee instantly to shelter, or to crouch and lay motionless like a portion of the surface, (the colour of which they always resemble, each species that of its appropriate haunt,) whenever the dreaded figure of a bird of prey first dimly presented itself hovering in the blue distance. It is even questionable whether the attention of predacious birds which seek their prey upon the ground is ever excited, but by perceiving some object to be in motion; and it is also extremely probable that, in every instance, the prey is first singled out when unawares. There are a considerable number of small land birds, however, which possess in very great perfection the faculty of distinguishing minute objects at an immense distance, but in which the immediate purpose of this faculty is not altogether so apparent; we allude to the mass of thrushes and warblers, which (from observations made on them in confinement) appear even to excel the ground birds in the promptitude with which they discover a distant foe. Now these are mostly the inhabitants of trees and bushes, amid the intricacies of which they can almost always effectually shelter themselves from the attacks of enemies from above; and the majority of them are never, like the fly-catchers, in the habit of watching the distant flight of insects through the air. Possibly, however, their powerful and acute vision may be of great and constant use toward finding their food, by distinguishing small caterpillars and various insects crawling among the foliage of a distant bough, and so enabling them to come at once upon their prey, which otherwise might be long sought for with little success.

But there are still certain other groups of species, the eyes of which are very full and convex, and which are consequently particularly adapted for very close or microscopic vision; and many of these, especially the gold-crest, evidently do not very clearly distinguish a large object, such as a human form, except it is in motion, when only they appear to evince alarm at its proximity. These are either bark birds, which creep about and subsist on the various insects which at all seasons lurk about the boles and larger branches of trees, or they are diminutive and hardy kinds, which examine the smaller twigs and sprays, and by constant exertion contrive to reap, both in winter and summer, an abundant harvest of small insects and larvæ, and of minute insect eggs which are deposited in such situations. These latter birds are the titmice and allied genera, which, brought together under the general term *Parinæ*, named from *Parus*, the typical genus, or that in which the more characteristic peculiarities of the group are most observable, form another of the marked leading divisions into which the *Sylviadæ* or great warbler family is divisible*.

The species of this division are mostly of diminutive size, but are generally of compact, short, well knit forms, and so warmly clothed with a dense covering of long puffy feathers (the webs of which are loose and discomposed), that they seem to bid defiance to all the rigours of winter. They are all of very social habits, except in the breeding season, and in several of the species the young follow their parents till the influence of that season prompts them to separate into pairs, at which time they are violently pugnacious. They nestle in the holes of trees or buildings, which are well lined, or they construct with wonderful art large and beautiful domed nests, which are warmly lined with a profusion of vegetable down, or soft feathers: a considerable degree of warmth seems here indispensable; and these hardy little residents, which brave the severest winters of our climate, prepare much warmer receptacles for their young than the mass of our small migrating summer visitants; but their broods are more numerous, eight or ten being about the usual average, and some species (as the subject of the present article) will sometimes lay as many as fourteen or even sixteen eggs, though twelve is a more common number: these, however, breed but once in the season. It would appear, therefore, that the heat generated by so small a body is insufficient to incubate so many, unless it be retained within a fabric of the most non-conducting materials; yet still it is by no means unusual to meet with one or more addled eggs in the nests of these birds, which appear to have sunk below the others into the downy yielding substance with which they are lined, and so to have been beyond the influence of the necessary heat generated by the sitting bird. We have particularly observed this in the nests of the bottle-tit and gold-

* For another of these divisions, the *Saxicoline*, or wheatear and robin group, see the article Blue-bird. These groups are hardly as yet sufficiently established to be placed in alphabetical order in the body of this work.

crest. The eggs of these birds are mostly white and semi-translucent, and are commonly more or less spotted with reddish-brown; and the young, in their first plumage, in general nearly resemble the mature birds, but are not so bright, and are never mottled or spotted. Their notes, which are often repeated and somewhat peculiar, are very characteristic, and have a considerable resemblance in all the species; and their songs (in the few instances which deserve the name) are short and monotonous. They seem fearless and familiar in their habits, though this may partly arise, in some instances (as in the gold-crests), from the decided indistinctness with which they appear to perceive large objects, and in others (as in the true *Pari*), more from the all-engrossing eagerness with which they seek their food, and in others again, perhaps, from both of these causes in conjunction. It does not, however, invariably follow that those species, the vision of which, according to the rule above laid down, would appear to be most microscopic, are also, in consequence of this, the least able to perceive small objects at a distance; for we have ascertained, by direct and careful experiments with these birds in confinement, that the bottle-tit can perceive a fly held to it at more than twice the distance that the gold-crest can; and that the blue and cole titmice can thus distinguish a small object clearly, very much farther than the bottle-tit. We have even varied these experiments several different ways, and have invariably obtained the same results.

As in most other *Sylviadæ*, small insects form the principal food of the *Parinæ*, but the members of the typical genus, *Parus* (see Titmouse), as before observed, are very omnivorous in their diet; and many species of this genus display the remarkable instinct of hoarding up stores of food in holes and other places, to which they resort in times of necessity. This has also been stated of the nuthatches (*Sitta*), a genus belonging to another family, but which is somewhat allied to the true titmice; but the statement has been always received with much doubt, and it has even been said, that the hoards of dormice, and other small mammalia, have been mistaken for the stores of these birds. M. Bechstein, however, who appears to have amused himself by keeping some nuthatches in captivity, expressly says, that "if these birds are left at liberty in the room, they are accustomed, like the tits, to hide the greater part of what is given them, to keep it for another meal;" and afterwards, speaking of the attractive qualities of the nuthatch in confinement, observes, that "its plumage, liveliness, agility, and great cunning in catching and hiding its food, are its most agreeable qualities." In this we see the utility, in studying the habits of animals, but especially birds, of keeping them for a time in captivity; of course, a natural history deduced only from such a source, would be a very meagre production indeed; but many curious and interesting peculiarities of various species, are only thus to be observed, which often throw considerable light on their wild habits; and besides, the very accurate acquaintance with their various notes and songs, which is thus easily obtained, is a very great assistance to the naturalist in his out-door researches, by enabling him, without difficulty, to recognise at once the different species even before they make their appearance. In the present case, we question much whether this habit of birds storing up their food, would ever have been noticed at all, had it not been observed in some that were in a state of confinement: it is a habit common to very many omnivorous species, and (as far as the observation of the writer of this goes) is peculiar to those which are omnivorous; consequently, though very observable in the cole and marsh titmice (*Parus ater* and *P. palustris*), which subsist on various kinds of food, we look for it in vain in the bottle-tit, and other species which are wholly insectivorous.

Few birds are so preeminently distinguished for the very beautiful structure of their nests, as the little bottle-tit is; and the nest of this species forms, without exception, the most exquisite fabric of the kind which is found in the British islands: several weeks are occupied in its construction, and yet it is often finished by the close of the month of March, or beginning of April; but in this case, as can be shown pretty clearly, it is never the production of birds of the preceding year. Bottletits, we know, remain in families till the return of spring; and an individual of this species is never seen, as the titmice often are, solitary, excepting when it has a nest to provide for. Now, it invariably obtains, among birds, that the older individuals are the first to feel the influence of the vernal season; and consequently, the old bottle-tits are found to pair, and leave their progeny, some weeks before the latter cease to be gregarious: and have thus often concluded the laborious work of nidification before the younger ones commence. This is not mere theory, for, as the bottletit that has twice moulted is very easily distinguishable from a younger individual by its superior beauty, we have been enabled to ascertain the fact, by shooting a few detached pairs in early spring, whilst the younger birds were still in society: and it therefore follows, as an almost necessary consequence from this fact, that when the bottle-tit pairs, it pairs for life; that is, the same pair remaining always together, and in company with their offspring till the following spring, invariably feel, some time before their progeny, the genial influence of the season, and they consequently then separate from their families of the preceding year, and again commence together the business of nidification. It is true that, during the winter months, three or four families of these birds sometimes seem to unite, and to follow in each other's train, thus forming an almost endlessly long succession of them from tree to tree; yet, each family at night appears to separate again from the others, and to retire to its own particular resting place.

Even here we may perceive a difference in habit between the bottle-tit and the true titmice: the latter invariably go to roost in holes; and so marked is this habit, that a marsh titmouse (*Parus palustris*), which we long kept in confinement, used for many months always to pass the night in a tin seed pan attached to the cage, as inconvenient a couch to all appearance as can well be imagined: but the bottle-tit always retires at night to the horizontal branch of some thick evergreen, a holly or spruce fir, where the family roost together in a line; and an amusing sight it is to see them settle, to see the family arrive straggling to the spot, chirrupping forth as they approach their peculiar *twittr*, *twittr;* but changing this note as they alight, one after another, to a low, scarcely audible soft *twittr*. They are a long time, however, composing themselves to rest, for, like numerous young *Sylviadæ*, the two on the outside keep continually flying up and working their way into the centre, and then the two next succeed and do the same, and so they continue till it is almost dark, twittering their soft note all the time, till on a sudden all is quiet.

To return, however, to the nest. It is of an oval form, and about the size of a large pine-apple, with a very small opening on one side near the top. Most writers have described it to have two openings, which is erroneous; and the great number of works into which this statement has found its way, shows how very much authors have been in the habit of copying from one another. It has even been said that the two holes serve for ingress and egress, and that when the bird is sitting, its long tail may always be seen projecting through one of the orifices. This no doubt is very fanciful and pretty, and answers extremely well to fill out and embellish the natural history of the bird; but as it certainly is not founded on fact, it only serves, like many other such careless statements about trifling matters, when found to be incorrect, to cast a doubt upon more important assertions; and when a work is found to contain many little similar inaccuracies, it never can be looked up to as an authority; as it is from trifles that we are accustomed to judge of matters of graver import. The fact is, that so far from this bird taking care of its fine tail, the very reverse is the case; which is perhaps the reason that the singular form of its tail has so escaped the observation of naturalists. Search when you may, it is rather a difficult matter to procure a bottle-tit with a perfect tail, and even immediately after the autumnal moult, many will be found with some new tail feathers injured, before others are properly developed; and at nesting time particularly, the tails of both male and female are invariably much curled and crumpled, and rarely more than half their proper length; which would perhaps imply, that both sexes perform by turns the office of incubation. So many respectable naturalists, however, have described the nest of this bird to have two apertures, that it is only after careful inspection of several dozens of them, that we here venture positively to assert that this never is the case.

An accurate and minute description of it, however, is given by Aldrovand, of which the following is a quaint translation:—"It was of an oblong figure, like a pine-apple; of two palms length, and one broad; round, built of sundry materials; namely, both tree and earth moss, caterpillars' webs, and other woolly-like matter and fibres, arranged with that order and art, that the chief and middle strength of the work, or texture of the walls, was of that yellowish-green moss, the common hairy moss, that silk-like substance, and tough threads, resembling those filaments suspended in the air, and flying up and down like spiders' webs, which are accounted signs of fair weather; connected and interwoven, or rather entangled so firmly together, that they could hardly be plucked asunder. Of the interior capacity, all the sides, it seemed, as well as the bottom, were covered and lined with feathers, for the more soft and warm lying of the young. The utmost superficies round about was fenced and strengthened with fragments of that leafy moss which every where grows on trees, firmly bound together. On the fore part, respecting the sun-rise" (which latter, however, is purely fortuitous), "and that above (where an arched roof, of the same uniform matter and texture with the sides and bottom, covered the nest), was seen a little hole, scarce big enough, one would think, to admit the old one."

This singular and curious fabric, the interest of which is doubly excited, when we contemplate the little bill which is the only instrument employed in its construction, is generally situate on the forked branch of an evergreen, about eight or ten feet from the ground; sometimes, however, in a large hawthorn bush; and we have more than once seen it beautifully placed amid the thickly blossomed twigs of a wild crab. The eggs average about ten or twelve, rarely less, but sometimes more; are of a semi-transparent white, and generally with a few small rusty-coloured spots, at the larger end; they are subject, however, to considerable variations; and they require about twelve days to hatch.

The bottle-tit is almost destitute of song; but in the spring months it utters, in addition to its usual chirrup, a very pleasing soft ringing note, very similar to the vernal call of the blue titmouse. At other times, it has no other call but that which we have here already endeavoured to express in writing, and which, serving to keep the family together, is continually repeated by them as they flit among the trees and bushes.

Being desirous of observing the habits of these curious little birds in confinement, we once procured a nest containing ten young ones, which were all easily reared upon chopped meat and egg, and very soon learned to feed of themselves. They became in a short time extremely quarrelsome, and fought with each other most cruelly; being very active, and so many together, one would sometimes fly up against another, and nearly overturn it, on which the latter would always attack whichever happened to be nearest, seizing it by the bare skin around the eye, and in an instant each would have its claws on the other's head, and both would fall together to the ground; here they would lie struggling for many minutes, uttering all the time a shrill twitter, and clinging so tightly that it was no very easy matter to separate them; after trying in vain to part them without tearing them to pieces, we have even tossed them from one end of a room to another without their ceasing to fight. Sometimes three, or even four, would thus lie entangled together on the ground, and yet, strange to say, they never seemed to hurt each other much. The chief point of attack was always the bare skin around the eye.

This quarrelsome propensity may be observed in most young birds, its obvious purpose being, seemingly, to promote their dispersion; at least, so one would imagine. Yet this explanation of it cannot exactly apply to the bottle-tit, as the families keep together till the following spring. It certainly was not want of space that caused it, for they were in a very large cage, and even when loose about the room it was just the same; without any apparent cause, one would often follow another and attack it. It lasted, however, only about ten days, or a fortnight, and afterwards they lived together very peaceably. We have often observed similar and equally violent combats among these birds in the spring, about the time when the young of the preceding year are pairing.

The power which the bottle-tit has of grasping with the feet, is very considerable, fully equal in proportion to that of a woodpecker; and when the individuals we are now describing were young and playful, it was no uncommon sight to see one clinging (sometimes by one leg) to the long tail of another, and not to be easily shaken off. They seemed to bathe less frequently than the different titmice, but were extremely fond of sunning themselves; that is, of extending themselves towards the sun, with neck stretched out, every feather erect, and tail and sunward wing spread wide. An observer, unaccustomed to the sight, would fancy they were dying, or that something very bad was the matter: this is a habit common to many of the *Sylviadæ*.

When they became fully able to take care of themselves, they were turned into a large cage, containing various other birds of this family; and here they unexpectedly found a protector. A tree pipit (*Anthus arboreus*), which had long been in confinement, fed and tended them with all the care of a parent. They had for some weeks picked up their own food, but still had no objection to be fed; and it was often an interesting sight to see the pipit (so incongruous a species), with food in his mouth, looking up earnestly at the active young bottletits, and waiting patiently till one of them could find leisure to come and take it.

This interesting little family had thriven so well, that we began to fancy we should be overstocked with them. Some were given away, and soon after one of them died of obesity; then another, and another, till the stock was at length reduced to four: this number continued for some time, till one morning, without any apparent cause, three of them were found lying dead. The sole remaining one survived the others two or three months, and at length died when it had nearly finished moulting. It is worthy of remark, that this individual would hardly ever touch meat, of which all the others were very fond; and to this, we think, may be attributed its comparative longevity. It fed principally on bread and milk, and upon crumbled bun and bruised hemp-seed; would sometimes just taste a little fruit, but did not eat it like the true titmice; and it was at all times very active and lively, and out of its cage troublesomely tame.

The writer of this has described the habits of these birds in confinement somewhat in detail, as he is not aware of any previous instance of their being kept in a cage; nor, as the birds which are captured old will never live, are there many who will take the trouble to keep them, as they must necessarily be reared from the nest. It is only thus, however, that the writer has been able to satisfy himself that this species should be arranged separately from *Parus*, though previous observation of it in its wild haunts had long led to the supposition. Now, however, he is fully convinced, from a due consideration of the many peculiarities of its structure, manners, habits, food, the character of its plumage, and various other minor particulars, that it cannot properly range in the same minimum division with the true titmice, and that consequently Dr. Leach was perfectly right, in removing this very singular species from the genus *Parus*, and forming of it a separate division.

BOTYS (Latreille). A genus of lepidopterous insects belonging to the nocturnal division of moths, and to the family *Pyralidæ*. The body is long and slender, the antennæ short and simple in both sexes. The wings form a triangle when shut, the tongue is very apparent and serves for the ordinary purposes of a tubular haustellum. The larvæ are naked, with sixteen legs, and the pupa is inclosed in a cocoon of silk spun within a rolled up leaf. The type of the genus is the *Pyralis urticata* of Linnæus, a pretty and common British species, known to collectors by the name of the small magpie moth. The thorax and tip of the body are yellow, the wings white with bands of black spots. The larva resides in folds of the leaves of the nettle, bindweed, &c. It remains nine months in the cocoon previous to assuming the pupa state.

BOURBON PALM. Is the *Latania borbonica* of Commelin. This fine ornamental palm belongs to *Diœcia Monadelphia* of the sexual system, and to its own order of course. Generic character: spadix many leaved; calyx three-leaved; petals three; stamens from fifteen to twenty; drupe coated, containing three seeds. The fronds are plaited like a fan; the terminal lobe is longest, which makes the whole appear as if winged.

BOUVARDIA (Salisbury). A genus of three species, and three varieties of green-house shrubs, natives of Mexico. Class and order *Tetrandria Monogynia*, and natural order *Rubiaceæ*. Generic character: calyx four parted, with intersecting teeth; corolla, tubular, limb four-cleft, filaments are joined to the tube, anthers as high as the top of the tube; style simple, stigma two-lobed; capsule, two-celled, seeds margined. Some of these are beautiful plants; particularly the *B. triphylla* and *B. versicolor*.

BOWICA (Haworth). A genus of two species of half shrubby plants, natives of Southern Africa. They belong to the class and order *Hexandria Monogynia*, and the natural order *Hemerocallideæ*. The flowers are very curious in structure, and the plants are easily managed.

BOX ELDER. The English name of a tree formerly called the Ash-leaved Maple. It was then *Acer negundo*, but has been made a new genus by Moench, under the name *Negundo Fraxinifolium*; and by Decandolle, as *Negundium Americanum*. In ornamental planting the tree is useful; it not only grows quickly, but its foliage is of a light yellowish green, contrasting well with deeper tinted trees. It has, however, two defects: the timber is inferior, and so brittle, that the tree is frequently demolished by high winds. There is a variety of it called *N. crispa*, or curled leaved, cultivated in nurseries for the ornamental planter. The tree is raised from seed like the common maple.

BOX THORN is the *Lycium* of Linnæus. A genus of handsome shrubs and climbers from the south of Europe and other parts of the world. Class and order, *Pentandria Monogynia*, and natural order, *Solaneæ*. Generic character: calyx bell-shaped, five-toothed, often cut in the sides; corolla funnel-shaped; stamens inserted in the tube of the corolla; filaments hairy at the base; berry two-celled, many seeded. Some of these plants, especially those from the Cape, are fine flowering plants. *L. Barbarum*, though a native of Barbary, succeeds in the open air in England; and, from its quick growth, is useful for covering arbours and the like. Some of the species bear thorns on their branches; hence the English name.

BOX TREE. This well-known plant is the *Buxus sempervirens* of Linnæus, who placed it in the twenty-first class, and fourth order of his system, viz., *Monœcia Tetrandria*. In the natural system it is associated with *Euphorbiaceæ*. There are four species; three are exotics, and the fourth, *B. sempervirens*, is indigenous to England, and of which there are two varieties, the narrow-leaved and the subshrubby.

BRABEJUM (Linnæus), is the African Almond. It belongs to *Polygamia Monœcia*, and to the highly ornamental order *Proteaceæ*. This is an elegant flowering plant; the racemes of blossoms are aptly compared to a sceptre.

BRACHELYTRA (Cuvier; MICROPTERA, Gravenhorst). A group or sub-section of beetles of considerable extent, belonging to the section, having five joints in all the tarsi (*Pentamera*), and corresponding with the Linnæan genus *Staphylinus*. The insects composing this sub-section are distinguished easily by the shortness of the wing-covers, which, although they entirely conceal the organs of flight, when folded up, are yet seldom more than one-third of the length of the abdomen, the remainder of which is consequently exposed. The wings themselves are of a large size (whence the impropriety of the name given to the insects by Gravenhorst, signifying small wings); but by means of numerous folds, and owing to their very thin and delicate structure, they are easily shut up and hidden beneath their two short covers. Unlike the ground beetles, *Carabidæ* (to which these insects are related, according to Latreille), the lower jaws are armed only with a single pair of palpi, or feelers; or, more strictly speaking, the terminal exterior portion of these organs, instead of exhibiting the form of a palpus, as it does in the latter insects—a peculiarity of organisation beautifully dependent upon correspondent peculiarity of economy—is either entirely soldered to the organ of which it is a part, or appears in the form of a dilated and inarticulate appendage; the antennæ are short, and either of an equal thickness throughout, or thickened at the tips, and composed of moniliform, or cup-shaped joints.

By Linnæus these insects are arranged at the end of the *Coleoptera*, and by some authors they have been considered as forming a passage to the next order, the *Orthoptera*, at the head of which the earwig (*Forficula*) is placed. It is not to be denied that there is great similarity in appearance between some of the moderate-sized species of this sub-section of the earwigs, especially in the shortness of the wing-covers and the exposed abdomen, as well as in the terminal appendages of the body, which, although they are of a large and forceps-like construction in the ear-wig, are evidently represented by the pilose setæ which the brachelytra possess at the same part of the body. In their habits there is likewise considerable similarity, as well as in their peculiar movements; but it is with the necrophagous beetles (*Silpha*, Linnæus) that the greatest number of relationships may be perceived, and which become so striking amongst some of the smaller species, that entomologists have been perplexed to assign them to their true location. The genus *Micropeplus* may be cited as an instance. The head is generally large and flat; the jaws strong; the thorax as broad as the abdomen; the wing-covers cut off square at the extremity, and the abdomen, instead of having its upper surface of a membranous or coriaceous texture, as it is in those beetles which have this part of the body entirely covered by the wings and wing-cases, is scaly both on its upper and under side.

The Devil's Coach-horse, as the insect is often termed, *Staphylinus* (*Ocypus*) *olens* of Linnæus, may be mentioned as one of the most common, and at the same time largest, species of the sub-section. It is of a dull black colour, with pale reddish wings, and is about an inch long. It is often to be seen running along footpaths, and in obscure places, such as outhouses, damp cellars, &c. When alarmed at the approach of danger, it assumes a most ferocious attitude; the jaws, which are very large and hooked, are opened wide, ready to seize the approaching object; the abdomen is thrown over the back, and from its extremity are protruded not only the pair of conical pilose appendages above noticed, but also several

Gærius Olens.

white fleshy vesicles, from which a subtle vapour is emitted, which has a very disagreeable scent. M. Dufour, whose researches upon the internal anatomy of insects are almost unrivalled, and have been already alluded to in this work under the article BOMBARDIER BEETLE, has published a description of the apparatus producing this vapour in the 8th volume of the "Annales des Sciences Naturelles." The abdomen is endowed with very considerable powers of motion, being capable of inflexion in almost every direction; and it is by its assistance that the large wings are folded and unfolded with surprising quickness. We have noticed some of the philonthi, &c., expand their wings, and take flight almost as quickly as a common fly; when on the wing they are equally agile, and they run with great swiftness. It has been stated that these insects feed upon others which they find in the places of their resort, carrying on a continual war with them, sometimes surprising them in their retreats, and at other times pursuing them with great ferocity. That they are very voracious is unquestionable; and their activity, and the powerful structure of the different parts of their mouths, fully confirms this opinion; but their voracity appears to us to be applied, not to living, but to dead animal or vegetable matter; and hence a minute examination of their mouth, and especially of their lower jaws, prove that they possess a very different structure from that which insects which prey upon others in a living state are known to possess. They are found under ground, in manure, under dung, and on fungi, beneath stones, &c.; and the opinions relative to their habits of feeding upon decaying animal or vegetable matter are confirmed by some circumstances connected with this kind of habitation. We are aware that the opposite opinion has been maintained by the great observer of insects, Dr. Geer, who relates, that having presented a fly to a large species of staphylinus, the latter seized it at once, and at length tore it in pieces with its teeth; but we do not hesitate to state, that if one of these insects be confined, and even a bit of wood or paper be presented to it, the result would be the same. The circumstances to which we would more particularly allude result from the geographical distribution of insects, and the analogy existing between the manners of the brachelytra and other insects which feed upon decayed vegetable or animal food.

Who is there that has not, in his twilight rambles, observed the shard-borne beetles (*Geotrupes stercorarius*) flying about some particular spot, unconscious of every object, and dashing against whatever may be in their way, with all the blindness of a beetle, their numbers increasing every minute? This assemblage is occasioned by the attraction afforded by the scent of some new-laid dung upon or near the spot, and upon which they feed with avidity. It is precisely in the same manner that the species of the brachelytra swarm in the same situations. How often is it that, in walking along some shady lane in the heat of the summer, we have been half blinded by these little torments flying unconsciously into our eyes, occasioning a smarting pain, greatly increased by the emission of the fluid or vapour which, as above stated, these insects have the means of discharging, and which has terminated only by the extraction of the little animal, which, instead of a choice repast*, has found, in all probability, a watery grave. This continued searching after their food has caused these insects to be termed rove-beetles in our common language; and the circumstance, that a group of insects should have received a general vernacular term in England, (that of rove beetles,) whilst the numerous continental entomologists have not conferred upon it any other than its scientific denomination, is one which, although it may appear to be unworthy of notice, is a striking indication of that peculiarity in the geographical distribution of these insects to which we have above alluded.

In Great Britain, we possess nearly eight hundred species, described by Mr. Stephens. Now, De Jean, in the new edition of his Catalogue of Coleoptera from all Quarters of the Globe (1833), does not enumerate more than this number. From the tropical climes of Asia and America we possess scarcely any species. In fact, Great Britain has been regarded as the metropolis of the group; and it is a singular circumstance, that not a single insect of the brachelytra was collected by Dr. Horsfield during his long researches in Java. That they sparingly exist in that country cannot perhaps be doubted, because, both from India and New Holland have species been received, but in all those parts of the world their numbers are very trifling indeed. Let us look, however, at the cause of this, and its apparent singularity vanishes. "In Java, as in all other tropical climates, the surface of the earth is almost exclusively occupied by ants; and, according to Dr. Horsfield, when the common ants are not found, the termites, or white ants, possess the territory. These two tribes, which are constantly at war, or rather, which clear away and destroy each other as their numbers respectively predominate, have in a great measure divided the surface of the island among themselves. From their incredible numbers, particularly of the common ant, little is left on the surface for other insects. Swarming in every spot, and incessantly in motion, they attack and devour whatever *animal* matter they meet with in a much shorter period than would be thought possible by a person who had not witnessed the fact. But, nevertheless, whenever, in his excursions, Dr. Horsfield observed the carcass of any animal, he and his assistants carefully examined it, and, from the care they took in such labours, he is convinced that, had silphidæ, staphylinidæ, and such *carrion*-feeding families of insects occurred in any tolerable abundance, they would scarcely have escaped his researches. With respect to such genera of brachelytra as inhabit flowers, he scarcely conceives, had they been common, that they would have escaped him, as he was in the constant habit of collecting on plants and flowers."—MacLeay, *Annulosa Javanica*. This author, it will be seen, speaks only of carrion feeders, and those inhabiting flowers; but the fact of their feeding upon decaying vegetable matter is known to every practical entomologist. Indeed, from this circumstance one of the genera has derived its name. See the article BOLETOBIUS.

Some species, forming the genera *Pæderus* and *Stenus*, are generally found upon the margins of streams or standing water, whilst others, of a small size, as the *Omalia*, frequent flowers in the perfect state.

The larvæ nearly resemble the perfect insects in shape, being long and narrow, with the head broad and large, but the wings and wing-covers are entirely wanting; the legs, which are six in number, are attached to the first three segments of the body, which gradually becomes more slender to the extremity, terminating in an elongated tube, armed at each side with a long and slender hairy jointed filament. These larvæ are found in the same situations, and prey upon the same substances as the perfect insects.

In the Linnæan system only twenty-six species belonging to this sub-section were described under the genus *Staphylinus*. As, however, the group became better known, and the number of species greatly augmented, various generic groups were detached by Fabricius, Gravenhorst, and others. The group was, however, restored to its original limits, by its establishment as a distinct sub-section, comprising numerous genera, and by the distribution of the latter, according to the comprehensive views of Latreille, into several tribes; namely, 1. the *Fissilabres* (cleft-lipped); 2. *Longipalpi* (having long palpi); 3. the *Denticrura* (having toothed tibiæ); 4. the *Depressa* (flattened bodies); and 5. the *Microcephala* (small-headed). To these tribes the Count Mannerheim, in a valuable memoir upon this family, contained in the first volume of the Memoirs of the Imperial Academy of Sciences of St. Petersburg, has added another, under the name of the *Aleocharides*, a step which we had long previously proposed in a memoir upon these insects, published in the Zoological Journal. To these another group is also referable, namely, the extraordinary family of *Pselaphidæ*, which, from having been supposed to possess only two joints in the tarsi, had been formed by Latreille into a distinct primary section of the *Coleoptera*, under the name of *Dimera*. As, however, their general structure agrees with some of the minute brachelytra, and as some of the latter have only three joints in the tarsi, the grounds for their separation become untenable, and they have accordingly, by Messrs. MacLeay and Stephens, been introduced into the brachelytra.

As the work of Count Mannerheim is the latest containing a general revision of the group, and moreover, as it is in the hands of very few English entomologists, we have thought that the following slight synopsis of the classification contained in it may not be uninteresting to our readers, premising only, that some other genera have been described by Mr. Stephens in his Illustrations of British Entomology, and of which the Count Mannerheim was ignorant.

Tribe 1. STAPHYLINIDES (*Fissilabra*, Latreille).

The head is separated from the thorax by a narrow neck, so as to be entirely disengaged; the thorax is square, semi-oval, rounded or truncate-cordate; the

* Practical collectors of insects are well aware that the most advantageous method of obtaining these insects is to immerse pieces of dung, or such like matters, in a pail of water, when the beetles rise to the surface, and are easily secured.

upper lip is divided by a deep slit in the centre into two lobes.

Genera: 1, *Oxyporus*, Fabricius; 2, *Astrapæus*, Gravenhorst; 3, *Velleius*, Leach; 4, *Creophilus*, Kirby; 5, *Emus*, Leach; 6, *Staphylinus*, Linnæus; 7, *Cafius*, Leach; 8, *Physetops*, Mannerheim, new genus, from Tartary; 9, *Gyrohypnus*, Kirby; 10, *Eulissus*, Mannerheim, new genus, from Brazil; 11, *Platyprosopus*, Mannerheim, new genus, from Caucasus; 12, *Lathrobium*, Gravenhorst; 13, *Cryptobium*, Mannerheim, new genus, from Sweden; 14, *Achenium*, Leach.

Tribe 2. Stenides (*Longipalpi*, Latreille).

The head is disengaged, but the labrum is not notched; the palpi are as long as the head, terminated in a club at the extremity of the third joint, the fourth being very minute.

Genera: 1, *Pæderus*, Fabricius; 2, *Rugilus*, Leach; 3, *Eristhetus*, Knoch; 4, *Dianous*, Leach; 5, *Stenus*, Latreille.

Tribe 3. Oxytelides (*Denticrura*, Latreille).

The palpi are much shorter than the head, with four distinct joints; the anterior tibiæ toothed or spinose on the outside; the tarsi fold back upon the tibiæ, with the basal joints minute, or even obliterated; the last joint very long.

Genera: 1, *Bledius*, Leach; 2, *Platystethus*, Mannerheim, new genus (*Oxytelus cornutus*, Gyll, &c.); 3, *Oxytelus*, Gravenhorst; 4, *Trogophlæus*, Mannerheim, new genus (*Oxytelus corticinus*, Gravenhorst).

Tribe 4. Omalides (*Depressa*, Latreille).

The head is disengaged, the lip entire, the palpi short and four-jointed; but the tibiæ are simple and unarmed, and the tarsi evidently five-jointed.

Genera: 1, *Phloeocharis*, Mannerheim, new genus, from Finland; 2, *Tænosoma*, Mannerheim, new genus, from Russia; 3, *Omalium*, Gravenhorst; 4, *Anthobium*, Leach; 5, *Acidota*, Kirby; 6, *Lesteva*, Latreille; 7, *Proteinus*, Latreille; 8, *Micropeplus*, Latreille.

Tribe 5. Tachinides (*Microcephali*, Latreille).

The head is immersed as far as the eyes in the thorax, upper lip rounded, legs spiny, antennæ inserted in front of the eyes.

Genera: 1, *Hypochyptus*, Schuppell; 2, *Tachyporus*, Gravenhorst; 3, *Tachinus*, Gravenhorst; 4, *Myectoporus*, Mannerheim, new genus, from Sweden; 5, *Boletobius*, Leach.

Tribe 6. Aleocharides, Mannerheim.

Lip entire, squared in front; legs not spined; antennæ inserted beneath the eyes; head sometimes having a distinct neck.

Genera: 1, *Dinarda*, Leach; 2, *Lomechusa*, Gravenhorst; 3, *Gymnusa*, Karsten; 4, *Aleochara*, Knoch; 5, *Sphænoma*, Mannerheim; 6, *Oxypoda*, Mannerheim; 7, *Microcera*, Mannerheim; 8, *Oligota*, Mannerheim; 9, *Trichophya*, Mannerheim; 10, *Homalota*, Mannerheim; 11, *Gyrophæna*, Mannerheim; 12, *Boletochara*, Mannerheim; 13, *Drusilla*, Leach; 14, *Calodera*, Mannerheim; 15, *Falagria*, Leach; 16, *Autalia*, Leach.

Tribe 7. Psilaphides.

This tribe is not comprised in Count Mannerheim's work. Reference must be had to M. Aubé's Memoir, recently published in Paris, upon this tribe.

BRACHINIDÆ (Mac Leay; Truncatipennes Latreille). A family of coleopterous insects, belonging to the section *Pentamera*, and separated from the great Linnæan group of *Carabus*. In this family, which comprises numerous and very differently constructed insects, the maxillary palpi are not terminated by a minute conical joint, as in the *Bembidiidæ;* the anterior tibiæ are not entire and without a notch, as in the *Carabidæ;* the anterior tarsi are not dilated in the males, as in the *Harpalidæ;* and the fore legs are not formed for burrowing, nor the thorax separated from the elytra by a sort of neck, as in the *Scaritidæ*. A character which is found in the more typical genera is to have the elytra squared off at the extremity, whence Latreille's name; but there are many of the genera in which they do not exhibit this structure. The head and thorax are narrower than the elytra, and the labium is seldom accompanied by lateral filaments.

Many of the species are much more elegantly ornamented with various colours than the majority of the Linnæan *Carabi*, and the species do not appear to be so voracious in their habits as the *Scaritidæ*, *Harpalidæ*, &c. Of the habits of the exotic species, however, but little is known. The British species of some of the genera (as *Odacantha*, *Polystichus*, &c.) frequent sandy districts on the sea-shore, or the meres of Huntingdonshire and Cambridgeshire; others, as the *Brachini*, prefer damp situations on the margins of rivers, &c., whilst some are generally found in gravel pits or beneath the bark of trees, as the *Dromii*, some of which hybernate in the latter situation. We have already, under the article Bombardier Beetle, given an account of the habits of the genus *Brachinus*. Many of the species are destitute of wings.

Messrs. Audouin and Brulle, in their valuable "Histoire Naturelle des Insectes" (of which the publication in parts has recently commenced), have divided this family into six minor divisions. 1, *Trigonodactyliens;* 2, *Odacanthiens;* 3, *Zuphiens;* 4, *Lebiens;* 5, *Brachiniens;* and 6, *Graphipteriens*.

The *Brachiniens* are distinguished by their short filiform palpi, and the convexity of their bodies. In this division are placed the genera *Brachinus*, Weber; *Aptinus*, Bonelli; *Pseudaptinus*, Laporte; and *Corsyra*, Steven. The first of these (which is the only genus found in this country) is distinguished by the presence of a pair of large wings beneath the elytra, and by the mentum having a deep notch without any central tooth. The claws are not toothed, and the body is thick and convex, with the elytra but slightly truncate. There are five British species of this genus, of which the type *Brach-crepitans*, Linnæus, is the most common and best known.

BRACHIONUS. One of those singularly interesting genera of microscopic animals discovered in infusions of vegetable or animal matter, therefore named by Linnæus *Infusoria*, and by that great naturalist placed in the fifth order of the class *Zoophyta*, forming the last division of the animal kingdom. The brachionus is nearly invisible, or only appears as a moving atom; its motions are various; it is seen to attack, or fly from an enemy, and in a second voluntarily to change its shape, being constantly occupied in search of food, or performing its other animal functions; the body is highly contractile, covered with a shell with rotatory cilia, and in many the internal structure is visible. The burecolaris is the only species yet described; it is found most frequently in stagnant waters.

The prodigious improvements microscopes have undergone in their construction, and the power given them by the application of the united flame of hydro and oxygen gases, have led to discoveries in the animal creation, beyond the imagination of man to conceive; a single drop of water is now seen to possess countless numbers of organised beings, each pursuing the functions of life ; each endowed with its own peculiar habits or purposes, and all playing parts in their sphere of life, no less important in the scale of creation than those of the unwieldy elephant or the gigantic whale. Could more be required to exhibit the infinite wisdom of Nature's God, were every other proof to fail ? This subject, so interesting in every point of view, will be most amply treated under the article INFUSORIA.

BRACHIURUS. A section of American monkeys, found chiefly or exclusively in the woods of the warmer parts of that continent. The chief distinguishing character is that upon which the name is founded, the tail shorter than the body. There are two species described, one with the body yellow, and the extremities, the head, and the tail black ; and the other with the head black, and all the rest yellow. The first is *Brachiurus auaraki* of Spix, and figured in Plate VIII. of his great work ; the other is *Simia melanocephala* of Baron Humboldt.

BRACHYCERUS (Fabricius). A genus of coleopterous insects belonging to the section *Tetramera*, or beetles having four joints in all the tarsi, to the subsection *Rhyncophora*, or those having the face prolonged into a snout, and to the family of the weevils, *Curculionidæ*, in which family it forms a group of species distinguished from all the others by having the antennæ, which are but slightly elbowed at the extremity of the first joint, short, composed of nine joints, and inserted near the tip of the snout, and the tarsi not cushioned beneath. They are destitute of wings, the body is very convex, the abdomen and elytra being nearly globular. These insects, which are amongst the largest of the weevils, do not frequent flowers, nor are they ever found upon trees and plants, like the majority of the family. Their wingless state compels them to remain on the ground, where they creep along with great heaviness, and without the least agility. Here, therefore, we have a perfect contrast with the equally wingless ground beetles, as many of the *Carabidæ*, which, in order to compensate for the want of organs of flight, are endowed with an increase in the power of locomotion in their legs. The legs of the *Brachyceri* are, indeed, as thick and as long as in many of the latter insects; but it would almost seem that it was merely for the purpose of supporting, rather than bearing along, their heavy and unwieldy bodies. Let us however look at the habits of the two groups, and perhaps we may be aole in some measure to account for the difference ; the *Carabidæ*, we know, are amongst the most voracious of insects, feeding upon others in a living state ; hence we find them enabled to pursue their prey by means of their increased agility. On the contrary, all that we know of the habits of *Brachyceri* is, that they abound in the sandy districts of the south of Europe and in Africa, and that they appear early in the spring. But analogy gives us this further insight into their economy ; the similarity in the construction of their oral apparatus with that of the weevils, allowing us to draw the inference that they feed upon vegetable substances, most probably the roots of trees, or smaller plants. Hence no additional agility is required to enable them to obtain their livelihood, neither is it required, as we have taken occasion to observe under the article BLAPSIDÆ, as a means of defence, because the *Brachyceri* are clothed in a coat of mail not less powerful than that of any other coleopterous insect.

The Ethiopian women suspend the body of some of these insects round their necks, by means of a thread, as a kind of amulet.—*Voyage de M. Cailliaud au Fleuve Blanc.*

Schonherr, in his invaluable work upon the Curculionidæ (now in course of publication), has described 112 species of this genus.

BRACHYLOPHUS. A genus of saurian reptiles, bearing considerable resemblance to the iguana lizards, but differing from them in having no teeth on the palate, and small teeth in the jaws. The scales on the body are small ; there is a small crest on the neck and back ; and a row of pores on the inside of each thigh. They are, like all the rest of the tribe, lively and harmless creatures, sporting in the sun in hot climates.

BRACHYPODIUM (Beauvois). A genus of uncultivated grasses, consisting of twenty-two different species, three of which are British, and the rest continental.

BRACHYPTERA (short wings). One of the four families into which Cuvier divides the web-footed birds. (See the article BIRD.) These birds are the divers properly so called. They bear nearly the same relation to the water-rails that the web-footed birds which do not dive bear to common poultry. Their legs are placed much farther backward than those of any other birds, and they walk with difficulty, and carry the body in an upright position. They are in general bad fliers, and some of them are incapable of flight, their proper element being the water, on the surface of which they repose, and in the body of which they seek their food. Their plumage is remarkable for its closeness, the polished lustre of its surface, and its water proof quality. It is never harmed by the longest exposure to the watery element, nor does it appear to need much dressing from the birds themselves. When under the surface they use their wings like fins, and "keep stroke" with them and their feet, swimming very much after the manner of frogs. The principal genera are GREBES, DIVERS, GUILLEMOTS, AUKS, and PENGUINS, under which titles some account of their appearances, characters, and manners, will be found.

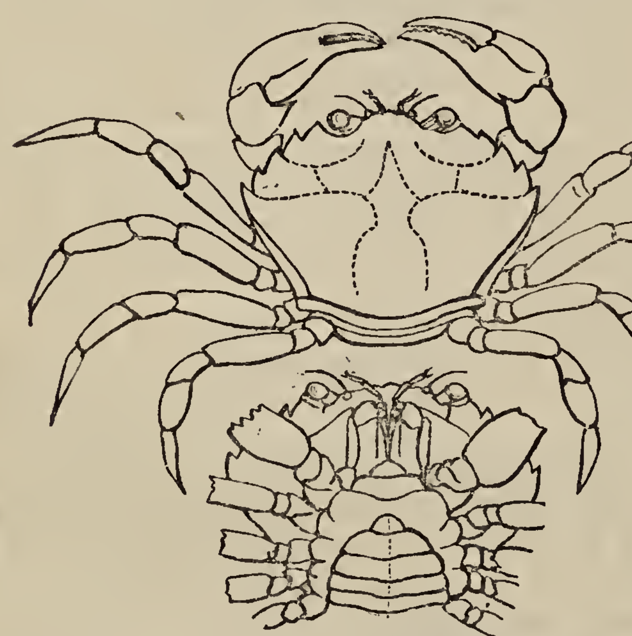
BRACHYSEMA (Robert Brown). A family of two species of evergreen trailing plants from New South Wales. Class and order, *Decandria Monogynia ;* natural order, *Leguminosæ.* Generic character : calyx five-cleft, somewhat unequal, with a swollen tube ; standard shorter than the compressed keel, which latter is as long as the wings ; pod on a stalk, surrounded at the base by a little shield ; style filiform, long, crowning the pod, which is swollen. These plants are met with in botanical collections.

BRACHYSTELMA (Robert Brown). A curious tuberous-rooted plant from the Cape of Good Hope. Natural order, *Asclepiadeæ.*

BRACHYURA (Latreille). One of the chief divisions of the class *Crustacea*, belonging to the section *Malacostraca*, or those with a hard shelly covering; subsection *Podopthalma*, or those with the eyes placed at the extremity of footstalks ; and to the tribe of *Decapoda*, or those which are furnished with ten legs. These characters, body encased in a hard shell, eyes pedunculated, and legs ten in number, are common to the greatest portion (in point of number) of the whole class, the animals which possess them are of large size, being in fact the giants of the class.

The edible crab and the lobster may be cited as the two best known species belonging to the *Decapod* tribe of *Crustacea*; but these two animals differ materially from each other in their structure. In the former the body is broader than long, the abdomen very slightly developed, incapable of being employed in swimming, unfurnished beneath with lamellated false legs, as they are termed, and not terminated by an apparatus for swimming. In the latter the reverse of all this takes place: the abdomen or tail of the lobster, as every epicure can tell, is very much developed, generally longer than the body, which is narrower than long, and furnished beneath with short natatory appendages, and terminated in a fan-shaped swimming apparatus. Now these two animals form the types of two of the chief divisions of the *Crustacea*, the former representing the order *Brachyuri*, or short-tailed crabs, and the latter the order *Macrura*, or long-tailed lobsters. These two orders or divisions, in the arrangements of the majority of authors, comprise all the decapod *Crustacea;* but M. Milne Edwards, one of the most celebrated of modern crustaceologists, in a valuable work published at Paris, in 1834, has proposed the establishment of another or third division, under the name of *Anomoures*, forming a passage between the two other groups, and composed of various species which appear to belong to neither, and which, if introduced amongst them, would violate the spirit of all natural arrangement.

In the various animals which compose the division *Brachyura*, the shell or carapace which covers their bodies, also conceals the greatest portion of the abdomen, and is in general of a square oval or rounded form, its transverse diameter exceeding, or at least equalling its length, its upper surface exhibiting various areas divided by impressions which correspond for the most part with the insertion of the muscles within the shell, and which form so many regions corresponding with the internal organs immediately beneath the different areas. The front of this shell bears a pair of eyes placed on footstalks, and two pairs of antennæ, and beneath these is perceived a pair of large, flat, and articulated pieces, which when raised, are found to conceal a very complex apparatus composing the mouth, and consisting of an upper lip and tongue, a pair of horny mandibles bearing a jointed palpus, a pair of internal* and external maxillæ, and three pairs of foot jaws gradually increasing in size, furnished with palpi, the largest of which is the external pair first mentioned above. Beneath the antennæ is also placed a pair of apertures which have been regarded as organs of hearing. The members, which immediately succeed the external foot-jaws constitute the legs, and are also five pair in number; they vary considerably in size; those of the first pair are always prehensile, and terminated by a didactyle and well-formed claw; in general the four posterior pairs of legs are simply ambulatory or natatory, they are never didactyle. The abdomen is but slightly developed, its length never exceeding three-fourths of that of the entire body, and its thickness not equal to more than one-sixth or one-tenth of the body, being in fact lamellose, and always closely applied to the sternal excavation. It is essentially composed of seven segments, but it often occurs that some of these are so intimately soldered together, that this part of the body appears to be only five, four, or even three-jointed. In general it is much larger in the females than in the males, being oval in the former and somewhat triangular in the latter.



Carcinus Mœnas.

We shall reserve for the article Crab, our observations upon the habits of this division, and shall here simply give the chief subdivisions into which it has been separated. This division comprises a very great number of species, respecting the classification of which crustaceologists are not yet agreed. Dr. Leach, followed by M. Desmarets, arranged the groups according to the number of pieces of which the abdomen is composed, both in the males and females,—a very simple plan, and one of very easy application, but at the same time one which produces the most artificial results, some species belonging to the same natural genus being removed thereby to different families. M. Latreille, on the contrary, founding his earlier classifications upon the general form of the body and the disposition of the feet established seven families, namely, the *Nageurs* (paddle-legged), *Arqués* (arched front), *Quadrilateres* (four-sided), *Orbiculaires* (orbicular formed), *Triangulaires* (triangle formed), *Cryptopodes* (hidden legged), and *Notopodes* (dorsal footed). Subsequently, however, he took into consideration the form of the mouth and some other characters in addition to the preceding, the result whereof was the union of the *Nageurs* and *Arqués* into one family, and the modification of the others. This latter classification has appeared the most natural of any hitherto proposed to M. Edwards, who (from a profound investigation of the structure of the different groups) has been induced further to modify various portions, and to subdivide the *Brachyura* into only four great families, which he terms *Oxyrhynches*, *Cyclométopés*, *Catamétopés*, and *Oxystomes.*

The Oxyrhynchi comprise the various species of crabs known by the name of sea-spiders. The legs are long, the shell more or less narrowed in front into a beak, the epistoma (or part of the head between the antennæ and mouth) very large and nearly square This family comprises three tribes, *Macropodiens*, *Maiens*, and *Parthenopiens.*

The Cyclometopi has the shell very large, regularly curved in front and narrowed behind; the legs are of moderate length; the epistoma is very short, and much wider than long. The abdomen of the male occupies all the space between the hind legs. This family comprises two tribes, the *Canceriens* and the *Portuniens.* The former comprising three subtribes, the *Cryptopodes*, *Arqués*, and *Quadrilateres.* The type is the common edible crab.

* By some accident M. Edwards has described the internal maxillæ as the anterior foot jaws, page 255.

The CATAMETOPÉS have the shell quadrilateral or ovoid, with the front transverse and knotted; the epistoma very short, the abdomen of the male not occupying the space between the hind legs.

The OXYSTOMES have the shell orbicular and arched in front, which is not produced into a point. The epistoma is obsolete.

BRACONIDÆ (Stephens). A family, or rather subfamily, of hymenopterous insects belonging to the section *Pupophaga*, and forming a portion of the Linnæan genus *Ichneumon*. They are distinguished from the true ichneumons by wanting the internal discoidal cell of the upper wings, by having the maxillary palpi five-jointed, and the labial ones either three or four jointed; the recurrent nerve is either unique or entirely wanting. The appearance of these insects bespeaks a certain weakness of structure. They are of small size, their legs are long, the abdomen is attached by its whole breadth to the thorax, or is sometimes pedunculated, the ovipositor is often exserted, the wings are generally obscurely coloured, with bands or spots, the prevailing colours are luteous red and black, the antennæ are never ornamented with a pale band, the maxillary palpi are often very long, and the labial always short. There is considerable difference in the details of the economy of these insects, all however are parasitic in their larva state within the bodies of other insects.

The species of Aphidius prey upon the plant-lice; one of them having been long known to entomologists under the name of *Ichneumon aphidum* of Linnæus and De Geer, but as the specific name has been transformed into a generic one, it has become necessary to substitute another term. Nees von Esenbeck has accordingly given it the name of *Aphidius varius* in his Hymenopterorum Monographiæ (1834), whilst Mr. Haliday, from finding it attached to the plant-lice of the rose trees, has termed it *Aphidius rosæ*, a name scarcely correct since it does not feed upon the rose but upon the insects which swarm upon that plant; moreover, Esenbeck obtained it from the aphides of the pine and buckthorn. As this is a genus of considerable extent and interest, (Mr. Haliday having described upwards of forty British species,) and as it was omitted in its place in the alphabet, we shall here give some account of it. It is distinguished

Aphidius Rosæ.

by the abdomen being pedunculated, the maxillary palpi five-jointed, the labial with three equal joints, and the peduncle smooth. We are indebted to Mr. Haliday for a very interesting account of the habits of the species above named, and which, although we have ourselves repeatedly observed the proceedings of these insects, we prefer giving in the words of that elegant writer. "This is the species most frequently noticed by authors, being a familiar inhabitant of our gardens, where the male may be seen throughout the summer hovering over the rose trees, or creeping under the leaves. His partner is of less roving habits and will generally be found busy in providing for the establishment of her numerous progeny. Placed at her birth amid the myriads of pucerons which encircle the young shoots of the rose, she has no dwelling to construct with artful industry, nor stores of food to collect by distant rovings. With extended antennæ and wings shivering with desire, she paces leisurely among the defenceless herd, and as soon as she has selected one by a light touch of her antennæ, she stops short at about her own length from it, and rising on stiffened legs bends her abdomen under her breast till the end of it projects beyond her mouth, then erecting her thorax by depressing the hinder part she simultaneously makes a plunge forward with the abdomen which is then extraordinarily lengthened, and by a momentary touch deposits an egg on the under side of the puceron near its tail. The victim will sometimes kick and sprawl so as to discompose her, but, being anchored by its sucker plunged in the bark, can make no effectual attempt to elude the deadly weapon. Should it, however, be wandering at large, and free to struggle, she shows great activity in traversing around it in the attitude of attack till she can take it in flank. The delicate sense of the antennæ seems to warn her where a germ has been already deposited, as she will pass by those which have been stung some days before; and I have never found more than a single grub in each individual. When all the interior of the puceron is consumed it will be found separate from its fellows, and motionless usually on the upper side of a leaf, to which it is glued by some viscid exudation. It now appears distended and of an opaque hazel or lighter tint. If opened the full fed grub of the aphidius will be discovered doubled up and filling the cavity, its head being next the tail of the puceron. In a short time the parts of the perfect insect are developed in a quiescent state, and in the same position, the integuments of the grub being shrivelled up below as if in black grains. Like cynips and cullimome, it spins no cocoon for its transformation, being adequately protected by the indurated skin of its victim. A few days are sufficient to give consistence to its parts; and while the new risen sun is yet glistening in the early dews, the winged insect by a push of its head detaches the latter rings of its case, which separate in the form of a circular lid, often springing back to close the orifice after the inhabitant has gone forth, born in the maturity of her energies and instincts, to renew the circle of existence."

The other genera belonging to this family are, *Stephanus*, Jur.; *Cœlinius*, N. ab E.; *Spathius*, N. ab E.; *Perilitus*, N. ab E.; *Hybrizon*, Fallen; *Leiophron*, N. ab. E.; *Bracon*, Fabricius; *Agathis*, Latreille; *Microdus*, N. ab E.; *Hormius*, N. ab E.; *Ichneutes*, N. ab E.; *Microgaster*, Latreille; *Blacus*, N. ab E. Mr. Haliday has added several others, such as *Mirax*, as well as various subgenera.

The genus *Bracon*, forming the type of the family, is distinguished by its sessile abdomen, five-jointed maxillary palpi, three-jointed filiform labial palpi, with the abdomen longer than the thorax, slightly convex or depressed, the segments gradually decreasing in size, the jaws horny and toothed, and the antennæ setaceous. This genus is for the most part composed of elegant exotic species having coloured wings. There are about twenty British species, chiefly of small size. They are generally found amongst plants or upon trees, running about the leaves upon which various larvæ are feeding, whence it may be inferred that they are lurking about with a view to deposit their eggs in the bodies of such insects.

The genus *Agathis* has the lower parts of the mouth produced into a rostrum. Such of the other genera as present any feature of interest will be treated of in their place in the alphabet.

BRADYPUS (Sloth). A genus of mammalia, constituting the *tardigrada*, or "slow-going animals" of Cuvier's order *Edentata*, or "toothless animals," as they have no cutting teeth.

Their grinders are cylindrical, and their canine teeth longer than the grinders, and pointed. They subsist wholly upon vegetable food—the leaves of trees; and they inhabit the trees constantly, living suspended by their claws with the back undermost, and seldom or never coming to the ground. They are very singular animals, and in some respects combine the characters of the apes and other four-handed animals with those of the ruminants; but it does not appear that any of them ruminate, and though their stomachs are divided into four sacs, these have not the same distinct appearance and character as those of the animals which do ruminate, though, like them, they are adapted for digesting green vegetable matter.

The females have two pectoral mammæ, like the apes. The phalanges of the toes are united within the skin, so that there appears no division of the feet except the claws, which are very large and strong, and much hooked. The state of repose of these immense claws, when they are not grasping, is that of being turned flat down upon the palm or sole; and there are stops on the joints that prevent their opening further than to form a hook by which the animal is suspended. Their hind feet are articulated obliquely to the legs, so that the outer edges of them, and not the soles, come to the ground when the animals attempt to walk. The articulation of the toes are perfect hinges, having motion in one plane only, and at a certain age the first phalanges are united to the metacarpal and metatarsal bones; so that altogether the extremities of the feet have much less motion than those of any other animals. The fore and hind legs too, are not so very disproportioned to each other as those of the long-armed apes, but still the arm and fore-arm are both so much longer than the thigh and leg that the animals cannot use them with advantage upon the ground. The whole of the hind legs are articulated more for motion across the mesial plane of the body than for motion in that plane, which is the proper walking motion of animals upon the ground, and supporting the weight of the body. The articulation which gives the cross motion is the proper climbing one, as the legs are adapted for being pressed close together, or of being extended far apart, so that they may take hold of a branch at some distance.

There are only two existing species of these singular animals, the AI and the UNAU, under which names particular descriptions will be found; but it appears that at some former period of the history of South America (probably the same at which those large animals, whose bones are now found in the more northerly parts of both continents, inhabited the swampy marshes there), there were animals of the same or similar structure, of much larger dimensions, as their remains are still to be found. See the articles MEGALTHERIUM and MEGALONYX.

BRADYTUS (Stephens). A genus of coleopterous insects belonging to the section *Pentamera*, family *Carabidæ* and subfamily *Harpalides*, and nearly allied to *Amara* and *Zabrus*. From the former, with which it has been associated by some of the continental authors, it is distinguished by having the mental tooth entire and the body convex, and from the latter by having the thorax transverse and narrowed behind. The species are about a quarter or one-third of an inch in length, and are found in sandy and open situations. They are less agile than the majority of the subfamily. There are four British species in the genus, of which the *Carabus ferrugineus* of Linnæus is the type.

BRAKE is the *Pteris aquilina* of Linnæus: it belongs to an extensive family of ferns, comprising thirty-four species, all foreign except one, which is the brake or bracken of our British wastes.

BRAMA, a genus of acanthopterygeous, or spinous finned fishes, belonging to the family of *Squammipennes*, or those which have the fins, the anal and the dorsal, in great part at least, covered by scales.

There is only one known species, found chiefly in the Mediterranean, though it sometimes ranges into the Atlantic. The dorsal and anal fins are a little elevated at their anterior margins, and have a few spinous rays there; but the principal part of these fins is but little produced, and almost entirely covered with scales. There are seven rays in the gill-flaps; the profile is elevated, the muzzle short; the mouth vertical when closed, and they have teeth in the jaws and the palate. The stomach is short, the intestinal canal simple, and with five small cæca. They are esculent fishes. But they are much annoyed by intestinal worms, which injure their condition as food.

BRAMBLE is the *Rubus fruticosus* of Linnæus. This well-known plant needs no description; but it may be observed, that it belongs to a numerous family, natives of all the tropical parts of the world. There are sixty-three species, and several varieties. The fruit are provincially called "blackberries," and are used for different purposes of the housewife. The dewberry and cloudberry are, like the bramble, wild and eatable; and the excellent cultivated raspberry is an allied species. The long shoots of the common bramble are used by basketmakers and thatchers.

BRAMBLING, BRAMBLE-FINCH, or MOUNTAIN CHAFFINCH (*Spiza montana; Fringilla montifringilla*, Linnæus). This handsomely variegated chaffinch much resembles, in form and size, the common, or white-winged species, but is a trifle larger. The bill is of a lemon yellow, tipped with black, but changes in the summer to dark bluish grey. Irides, dark hazel. The crown of the head, cheeks, and back, a glossy black, inclining to blue; in the winter fringed with yellowish brown edgings, which conceal the black, but which gradually fall off on the approach of the breeding season. The feathers of the back are, at the base, ash-coloured, so that when the bird (in summer plumage) leans forward, the back seems of this colour, spotted with black, but appears, when in an upright position, wholly black. The nape of the neck ash-colour, with two longitudinal black lines. Rump white, bordered with black on each side. The throat, breast, lesser wing coverts (or the small feathers on the angle of the wing), and the termination of the greater wing-coverts, bright reddish orange, the last mentioned forming a band across the wing, as in the chaffinch. The base of the lesser wing-coverts dull white, forming another band, concealed generally by the plumage above; remainder of the wing black, the scapulars having their outer webs bordered with rufous, and the quill-feathers being slightly edged with primrose yellow, and having a white spot at the base; underneath the wing are some bright yellow feathers. The rest of the under parts white, tinged with rufous on the under tail-coverts and flanks, which latter are spotted with black. Tail black, edged with grey, the exterior web of the outer feather partly white. Legs and toes brown.

The female resembles the male in markings, but her colours are far from being as bright. The upper parts are of a blackish brown, margined in the winter with yellowish brown, and over each eye is a streak of black, which is continued down the back of the neck. Throat and breast yellowish orange. The young are similar to the adult female, but have the throat whitish.

This fine species is a native of the northern parts of Europe, and in the more temperate and southern districts is only known as a winter visitant, arriving in the neighbourhood of London generally about Michaelmas, and departing northward early in the month of March—never having, as yet, been satisfactorily ascertained to breed here. Their numbers vary greatly in different seasons, the direction and extent of their migration being, in all probability, regulated by the state of the weather.

In habit, and in their manners, they closely resemble the common chaffinch, with which they frequently associate, and in hard weather may sometimes be seen hopping familiarly about the farm-yard, or in the middle of the road, in the manner of that bird. They are found much about beech trees, and in plantations of larch and fir, where they may be readily distinguished from the chaffinch by the difference of their notes, the most frequent of which is a kind of *chut*, analogous to the *twink* of the chaffinch, and sometimes a harsh jay-like call to their companions. They are never heard to sing during the period of their stay in this country; but in confinement, in the spring and summer, they often utter a few coarse, unmusical notes, which appear to be all the melody they are capable of, and which do not in the least resemble the notes of the common chaffinch, nor those of any other bird with which we are acquainted.

The chaffinches, a group of which the present forms one of the most characteristic species, constitute a small but tolerably well-marked division, the members of which possess in common several little peculiarities at variance with the generality of finches. They subsist much on insect food, which (with the exception sometimes of a few aphides) the goldfinches, linnets, grosbeaks, and others, never touch, and, like the sparrow genus (*passer*), their young are wholly fed upon insects. The crop, or enlargement of the gullet, is very much smaller than in any of the other finches we have examined, and the muscular stomach, or gizzard, proportionably larger. They usually move forward on the ground by hopping, but when feeding, mostly by alternate steps; are in their habits familiar, much resorting to farm-houses, and other human habitations, and, like the other various finches, are in the winter more or less gregarious.

The mountain chaffinch is described to pass the summer in mountainous and wild districts, and to breed in the extensive forests of pine and fir which abound in high latitudes, constructing its nest of wool and moss, and lining it with feathers and hair, and is said to lay four or five white eggs, spotted with yellowish brown. It is, in confinement, tolerably familiar, if taken young, that is, during the winter of the first year; but the older birds remain extremely wild and untameable. In Russia it is very common, and the barbarous peasantry of that country are much in the habit of catching them for the purpose of making them fight with each other, or with other small birds, or mice, often risking greater sums on the issue of such a contest than their slender means can well afford. We were told this by a person long resident in St. Petersburgh, who also informed us of the mode of provoking them to fight: this, of course, we need not here repeat, but may remark, that the species is not naturally irascible; in the aviary we have always found them to live in perfect harmony with their various companions.

BRANCHIFERA. The second family of the second class *Siphonobranchiata*, of De Blainville's System of Malacology. This mollusc has its organs of respiration formed by two large and uniform comb-like branchiæ. The family includes the genera *Fissurella*, *Emarginula*, and *Parmophora*, all of which were blended by Linnæus in his genus *Patella*, from which they are quite distinct, except in general habits and some external resemblance.

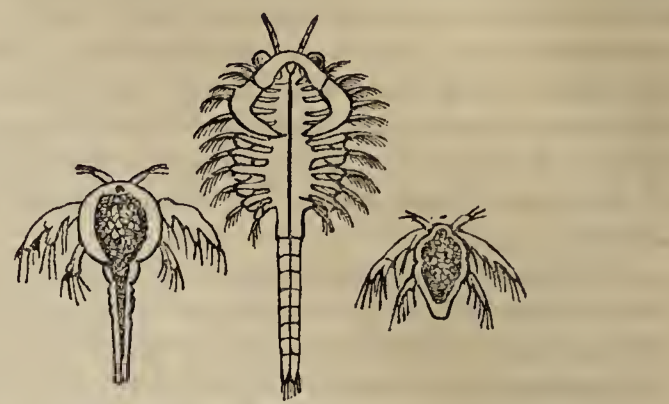
BRANCHIOPODA (Latreille). An order of the class *Crustacea*, and subclass *Entomostraca*, having for its characters, the mouth composed of an upper lip, two mandibles, a tongue, one or two pairs of maxillæ and branchiæ always placed anteriorly. These crustacea are always wandering in their habits, not being parasitic upon other animals, as is the case with the order *Pœcylopoda*. They are generally covered by a shield-like shell, or a case resembling a bivalve; they are furnished with two or four antennæ; their legs are formed for swimming, varying in number, some having only six, others from twenty to forty-two, whilst some have more than a hundred; many have but one eye. They formed in the system of Linnæus the single genus *Monoculus*, but a more precise study of these animals has proved that they present modifications in their structure much more striking than are to be found in the large *Decapod Crustacea*.

This order is divisible into two principal sections, first, the Lophyropoda, in which the number of legs never exceeds ten, with cylindric or conical joints; the branchiæ are few in number. Many have but one eye, and the antennæ, which are generally four in number, are employed as locomotive organs. Latreille divides this first section into three principal and very natural groups. 1. The *Carcinoida* have the shell oval or ovoid, not bivalve, the legs are ten in number, and the eggs are borne by the females in two large external sacks on each side of the base of the abdomen (Cyclops, &c.). 2. The *Ostracoda* (Latreille; *Ostrapoda*, Strauss), having a bivalve shell united by a hinge, and closing during repose; the antennæ are simple and setaceous. They have six legs and only one eye, the mandibles and upper maxillæ are furnished with a branchial plate (Cypris, &c.). 3. The *Cladocera* (Latreille), having also the shell bivalve and a single eye, but without a hinge, and terminating in a point behind, with the head, which is covered by a shield-like plate, exposed; the antennæ are two in number, very large and branched. They have ten legs (Daphnia, &c.).

The second principal section of the branchiopoda is named Phyllopoda, from the legs, which vary in number from twenty to more than a hundred, being flattened, the joints forming ciliated plates. They have a pair of eyes, and the antennæ, of which there is generally only a single pair, are small and not fitted for swimming. This section is divided into two principal groups. 1. The *Ceratopthalma*, having the eyes generally carried upon footstalks, ten or twenty-two pairs of legs, the anterior neither much longer than the remainder nor branched. The eggs are either internal or carried in a sac at the base of the abdomen (*Limnadia. Branchipus*). 2. The *Aspidiphora*, having sixty pairs of legs, all furnished at the base with a vesicle, the anterior very large and ramose, three sessile eyes, with two bivalve capsules enclosing the eggs, and attached to the eleventh pair of legs (Apus, which see). It is to be observed that the subdivisions of this order have been regarded by Messrs. Strauss, Edwards, and some other authors, as separate orders.

BRANCHIPUS (Latreille; Chirocephalus, Jur.). A genus of crustaceous animals belonging to the order *Branchiopoda*, section *Phyllopoda*, and group *Ceratopthalma*. In this remarkable genus the eyes are placed at the extremity of footstalks, the body is narrow, long, and compressed, the head distinct, with two horns between the eyes, eleven pair of legs, the abdomen long and cylindric, with two terminal ciliated plates. The males are distinguished by a pair of very large horns attached to the mouth. The eggs are borne by the females in a pouch attached to the base of the abdomen. Jurine, Prevost, and Dr. Shaw have given very full accounts of the structure and habits of these animals, of which we have met with one of the species, which are few in number, in standing water, near Turnham Green. When full grown they are about an inch and a half long, and are found occasionally in great numbers in small puddles of standing fresh water; indeed, like the species of apus, they are often to be observed in water collected after heavy rain, especially in spring and autumn. They swim well upon their backs, and their legs, which are incapable of assisting locomotion, are kept in constant undulatory movement, which has for its object the forming of a current of water between the base of these organs, and which, following the canal of the breast, conveys to the mouth the small particles upon which the animal feeds. Its movements are caused by repeated jerks of the tail; so that when swimming upon its belly it appears just like a small fish. The eggs are yellowish coloured; they are at first round, but afterwards assume an angular form, which favours their preservation, since it appears that they are enabled to withstand a very considerable degree of drought until a fall of rain sufficient to cause them to hatch takes place. The females deposit their eggs at different times to the number of from one to four hundred at each time. On quitting the egg the body is divided into two globular masses, the anterior of which comprises a single eye, two short antennæ, two large branched organs serving for swimming, and two short and slender legs. After shedding their skin the first time, they have three eyes, the middle one being smooth; the hinder part of the body is elongated, and the tail is terminated by two short filaments. Subsequently the legs begin to appear by degrees, and the branched organs entirely disappear.

Dr. Leach established a genus intimately allied to the preceding under the name of *Artemia*, for the reception of a small but interesting species, of which an account was first given in the eleventh volume of the Linnæan Transactions, by Mr. Racket, and named by him *Cancer salinus*, or the brine shrimp. During



Brine Shrimp.

the past year (1834) Mr. J. V. Thompson has published a very interesting notice of it in his Zoological Researches, accompanied by numerous figures. The body is oval, and flattened, with the head not separated from it; the tail or abdomen is long, terminated by two small points. "The brine shrimp, or *Artemia*" (not *Artemis*, as Mr. Thompson, from whom we quote the following observations, calls it) "*salinus*, is a very small and delicate animal; when full grown about half an inch in length, of considerable transparency, slightly tinged with yellow, and with a highly polished surface; nature having constructed them with members solely adapted to swimming, they seem to be in perpetual pursuit of prey, gliding with an almost even motion through the water, and moving with equal indifference and facility on the back, belly, or sides; the shape of the animal, the undulating movement of its fins, and the glossy appearance of its coat render it an object of a very interesting description, more especially when apprised, that analogous animals appear to have been the first created conspicuous inhabitants of the primitive fluid, of which these may be regarded as a degenerate or pigmy race. Hitherto the only localities in which these little animals have been observed are some salt lakes in Siberia, and the salt-pans at Lymington, Hampshire; in these situations, however, they occur in the greatest abundance; and at the last named place, making their appearance in the early part of the spring, multiplying beyond conception during the summer and autumn, and disappearing during the winter months, a phenomenon common to many of the smaller crustacea. As in all salt-works the pits have different distinctions, it must be observed that they are not found indiscriminately in all, but principally in the tanks, called clearers, in which the brine acquires such strength as to furnish four ounces of salt to the pint measure; by the account with which Mr. Racket has favoured us, it would appear that the workmen attribute to them the property of assisting in the clearing of the brine, and hence transport them to such tanks as seem to be without them. How they came originally to the salterns at Lymington, and what animalcula live in so strong a solution to afford them food, must be left to future investigators placed under more favourable circumstances." Mr. Thompson has traced the gradual development of these curious animals, which nearly resemble those of the branchipus.

BRASSIA (R. Brown). Named in honour of W. Brass, a botanical collector. It belongs to the curious order, *Orchideæ*, and is one of the most beautiful of the tribe. The two species at present known are, *B. maculata*, has large pale yellow flowers; spotted with brown; *B. caudata* has similar flowers, with long tails to their lower segments. This last was called *Epidendrum caudatum* by Linnæus.

BRAZIL NUT is the *Bertholetia* (L. C. Bertholet, a chemist) *excelsa* of Humboldt. It is a lofty-growing tree, common about Para, in South America, and yields those nuts now very common in fruiterers' shops.

BREAD FRUIT is the *Artocarpus* (bread fruit) *incisa* (cut-leaved) of Linnæus. The flowers are monœcious, that is, males and females, separate on the same plant. The former is a cylindrical catkin. Calyx none; petals two; filament as long as the petals. Female flowers have neither calyx nor corolla; ovaries many, collected in a globe; style filiform; drupe compound. This tree, of which so much has been written, is found on the continent of India, and on the islands of the South Seas. The tree grows to a middling size at Malacca, and bears a round rough-skinned fruit, as large as a child's head. The skin is,

Artocarpa.

however, thin, and has a conical-shaped core, surrounded by a white farinaceous pith-like substance, which is the eatable part, after being roasted in thick slices: the taste is similar to that of a frosted potato. In this way it may be certainly used as bread, when nothing better can be had, but is far inferior to the yam (*Dioscorea sativa*), which is capable of being cultivated everywhere in those climates in which the bread-fruit tree appears. The fruit is ripe in December, and is dressed in various ways, according to the taste or convenience of the parties using it. The Dutch cooks improve it, by broiling or frying it in palm oil. Besides the use of the fruit, the natives of the South Sea islands apply different parts of the tree to various purposes. The wood is used in boat-building; a cloth is made of the inner bark. The male catkins serve for tinder; the leaves for wrapping up food, and for wiping hands instead of towels; and the juice for making cement for filling up the cracks of water-vessels. There are, according to Forster, several varieties of the bread-fruit. The principal of these is one without seeds. The natives of Otaheite reckon at least eight, differing in the form of the leaf and fruit.

In 1793, the bread-fruit was introduced to the West Indies by the unfortunate Captain Bligh, and subsequently to other tropical parts of the American continent. It has not, however, answered the expectations of those who advised its introduction to those countries, as an article of negro food.

The *A. integrifolia*, or Jaca-tree, is supposed to be only a variety of the incisa, because its leaves are sometimes divided; but the trees are very different when seen growing together. The incisa is a low spreading tree, very much like a common standard fig-tree; whereas the integrifolia grows more upright, assuming a conical-formed head, though the lower branches rest on the ground. The fruit are produced at the points of the twigs or branches, and, from their weight, are often seen resting on the ground. Sometimes it happens that they fall into the cracks caused by drought, and they ripen, raising up the soil round them, and to greater perfection, it is said, than if ripened in the air. When such fruit are taken, they require to be dug up; hence the report that the tree bears fruit upon the roots! Both kinds of the bread fruit are met with in British collections, and are propagated by "making stout, well-ripened cuttings, placed in pots of sand plunged under a hand-glass in moist heat."—*Sweet.*

BREAD-NUT is the *Brosimum* (good to eat) *alicastrum* of Swartz, a genus of two species of evergreen shrubs, natives of Jamaica. The flowers are polygamous, and belong to the natural order *Urticeæ* The leaves and young branches are full of gum, and are used as food for cattle. The fruit, either boiled or roasted, is sometimes used by the negroes, and the poorer classes of white inhabitants, in times of scarcity, and is said to be highly nutritious, resembling in some degree roasted Spanish chestnuts.

BREAM (*Abramis*, Cuv., *Cyprinus*, Lin.). A genus of soft-finned fishes, belonging to the division which have abdominal fins, and to the carp family CYPRINIDEÆ, which see for the general characters and habits of the family. The general characters are: no spines on the body, and no beards or filamentous appendages. The dorsal fin short, and placed behind the ventral ones. The anal fin long. There are two species known with us, the common bream, and the little bream, the first of considerable value as an esculent fish, the second of comparatively little. There are also two or three species, but generally speaking, of small value or interest, which seasonally ascend the rivers which discharge their waters into the Baltic, and there are also some in India, and in other parts of the world. They are, properly speaking, fresh water fishes, and they prefer deep and still waters, as lakes, and the pools of slow running rivers. The common bream is found in many of the lakes and rivers of England, and in some of the more southerly parts of Scotland, as in the waters of Lochmaben; but it has not been found in the north of that country, where lakes are more numerous and deeper. If there is sufficient depth of water, they breed freely and thrive well as pond fishes.

BREEZE FLY. A term of very indefinite signification, employed to designate such dipterous insects as attack cattle and horses, causing them to exhibit violent signs of alarm, such as running and tossing themselves about. These symptoms are produced by various insects belonging to two different families, for both of which the term has been employed in common with another, equally indefinite, that of Gad-fly. The family *Tabanidæ* produce these effects by sucking the blood of the animals, which they cause to flow by wounding the skin by means of the powerful lancet-like apparatus of their mouths, whilst the *Œstridæ* instil terror into the cattle, not by wounding them, but by the instinctive dread which they cause during the act of depositing the eggs, the grubs from which, when hatched, burrow beneath the skin. As it is impossible to assign these vernacular terms to either one or the other groups with any thing like precision, it will, perhaps, be safer to describe the insects under their scientific names. Some of the *Œstridæ*, however, being sufficiently distinguished by their name of Bot-flies, we have described them under that name; the remainder, with the *Tabanidæ*, will therefore appear in their places.

BREMONTIERA (*Decandolle*), named in honour of M. Bremontier, an eminent agriculturist. It is a leguminous shrubby plant, introduced from the Mauritius. It is also called sand-wood.

BRENTHIDES (Schonherr). A division or sub-family of coleopterous insects, belonging to the great family of the Weevils (of which Schonherr enumerates more than three thousand species) and to the section *Orthoceri*, or those having straight antennæ. The rostrum is long and porrected, especially in the males; the body is very long, cylindric, and narrow, and the neck is distinct. The type of the division is the genus *Brentus* of Fabricius, and the *Curculio anchorago* of Linnæus may be cited as an example.

These insects are peculiar to hot climates, one species only being found in Europe. namely, the *Arrhenodes coronatus*, Germar (*Brentus italicus*, Dej.) It is a remarkable circumstance in the geographical distribution of insects, that this Italian species is the only one belonging to the genus *Arrhenodes* found in the old world, the remaining species of the genus being inhabitants of South America, where they are the only species of the sub-family, *Arrhenodes coronatus*, according to information given to Latreille by M. Savi, and which has been confirmed to us by one of the sons of Mr. Spence, who captured many specimens of these insects in Italy, resides beneath the bark of trees, in the midst of the nests of certain species of ants which establish their abode in such situations. M. Lacordaire also made the same remarks relative to the Brazilian species, and we have been informed by a gentleman, recently returned from an Entomological tour in North America, that the *Brentus maxillosus* burrows beneath the bark of the trees which form the Corduroy roads in the back settlements.

This sub-family comprises eight genera, and about seventy species, in the system of M. Schonherr.

BREVIPENNES (*Short-quills*). The first of the five families into which Cuvier divides his "*échassiers*," or birds which depend for their locomotion, at least when they are seeking their food, more upon the foot than the wing. The genera which are included in the present family are all dry land birds, inhabiting warm, and, generally speaking, dry countries. The *ostrich* of Africa, the *rhea* of South America, the *cassowary* of the south-east of Asia, the *emu* of Australia, and the *apteryx* of New Zealand, are the only known genera. They will be found described under their common generic names; and some general notice of the family will be found in the article BIRD.

It may not, however, be irrelevant here to remark with what accuracy Cuvier chooses the names for his divisions of animals, and that this is nowhere more remarkable than in the two divisions of birds which are characterised by the shortness of their wings, *brachyptera* and *brevipennes*. The former have the wings short, some of them too short for being at all useful in flight; but even in these cases they are still very perfectly formed wings in their bones, their articulations, and their feathers—more firm, compact, and powerful, indeed, than those wings which are used only in the air, and therefore better able to resist the water, in which they act as fins. In the *brevipennes*, again, there is no part of the wing capable of acting powerfully even in the air; there are no quills, and the organs of motion are capable of doing little more than extending the wing from the side, so that it acts as a balance to the body as the birds run along, which most of them do with very considerable swiftness. These birds have motion on land only, and in that motion they carry the axis of the body horizontally, or nearly so; while, when the brachyptera are on land, they must carry the axis nearly vertical.

BREXIA (*Brexis*, rain; leaves protect against), so named by Noronha. A genus of three evergreen trees, from Madagascar and neighbouring islands. They belong to *Pentandria Monogynia* of Linnæus, and form an order of themselves in the natural system. Generic character: calyx short, with five rounded lobes; petals ovate, spreading, rounded; filaments dilated at the base; bristles round the seed-vessel shorter than the stamens. These are fine hot-house plants, with firm, jagged, shining leaves, having flowers produced from the stems. These plants are allied to *Theophrasta*.

BREXIEÆ. A natural order of dicotyledonous plants, containing only a single genus and three or four known species. It is nearly allied to the *Rhamneæ* and *Celastrineæ*, differing from these orders chiefly in its hypogynous stamens and indefinite seeds.

The essential botanical characters of the order are, calyx five-partite, inferior, persistent; petals five, hypogynous; stamens five, hypogynous, alternate with the petals; anthers oval, two-celled, bursting longitudinally; pollen triangular, united by means of fine threads; ovary superior, five-celled; one style; fruit a five-celled, many-seeded drupe.

Brexieæ.

The plants belonging to this order are trees with simple trunks and coriaceous alternate leaves. The flowers are generally of a green colour, and grow in axillary umbels. They are found in Madagascar and Mauritius. Their properties are as yet unknown.

Brexia is the only genus. *Brexia Madagascariensis* is a rare and curious tree-like plant found in Madagascar. Its leaves when in a young state are very long and furnished with prickly teeth, but when full-grown they become ovato-oblong, and the teeth nearly disappear. *Brexia spinosa* is commonly known in gardens by the name of *Theophrasta*.

BROCCOLI. The *Brassica oleracea*, variety *Botrytis* of De Candolle. A highly valued variety of the cabbage family, cultivated for its imperfect flowers as a table vegetable. Broccoli, its Italian name, is supposed to be a sport (as florists call such variations) from the cauliflower, as this last is mentioned in history before the former. When first employed in this country as a table vegetable, it appears to have been used in the state of sprouts rather than in large substantial heads, as it is now brought to table; because it was trimmed and bundled by the cook exactly like asparagus ; hence it was called Italian asparagus, and in botanical books, it is to this day designated *asparagoides*, as a specific distinction. It differs from cauliflower in habit and colour, both of leaves and flowers, when fit for use; and is also more hardy and keeps longer in season.

Cultivation.—The chief objects of the cultivator are to obtain a supply for the table in every possible season, and to grow it to the largest possible size. The first is gained by timely sowing, proper treatment of the seedlings and subsequent management; the second by a due preparation of the soil they are ultimately placed on, by deep digging or trenching, and sufficient manuring. The last particular is indispensable to insure fine broccoli, as the plant is a "gross feeder," and therefore requires abundance of manure, and to be placed on a naturally rich soil. As broccoli is required and may be had from the end of August till nearly the same period in the following summer, sowings must be made consecutively to be transplanted in successional order. The first sowing is made about the 15th of April, and continued weekly till the 1st of July. The seed beds should be in a perfectly open situation, rich, light, and finely broken. Similar beds must be got ready, on which the seedlings are pricked out five or six inches apart, as soon as they have three or four leaves.

The use of transplanting seedlings from the seed to a nursery bed, is for the double purpose of thinning the seed bed, and giving the removed plants a more stocky habit. For the sake of getting very stout plants for final transplanting, some gardeners transplant them twice; others do not prick out into nursery beds at all, but place them out at once from the seed bed; others again sow the seeds where the plants are to remain for good. This last practice requires too long an occupation of the ground, and often much trouble in filling up blanks, or replacing such as turn out any way defective. The Cape varieties grow rapidly, and yield heads sooner than the old sorts; of course they do not require pricking out so much as the latter.

Those portions of the garden usually appropriated to the cultivation of broccoli is that which has borne a spring crop, such as spinach, early peas, or other crop that comes off during June, July, or August. After being cleared of weeds, a coat of good, rich, moist dung is spread thereon and well digged in; it is then ready to receive the plants drawn from the seed or nursery beds. The plants are dibbed in rows at distances according to the growth of the variety, or the time of the year when planted. Late plantations of the dwarf sorts require less space than the large growing kinds. Full and free air is necessary for all; The small varieties should not be put in nearer than two feet between the rows, and twenty inches apart in the rows. The large sorts at three or four feet intervals between the rows, and two feet distances plant from plant in the rows. The plants should be dibbed in as deep as the lower leaves, and water should be immediately given if the soil be dry and the weather warm. The after management consists in keeping the ground well, and frequently hoed among the plants to admit air and destroy weeds; and when the plants advance in height, mould should be drawn to the stems to keep them steady in their places.

Broccoli is liable to be killed in severe winters. To prevent such injury, different expedients are had recourse to for its preservation. When the winters were more severe than they have been lately in this country, a usual practice was to lay it down. This was done about the 1st of November, or earlier if the weather was threatening. Two men do this most expeditiously: an opening is first made at the north end and close to the end plant of the first row, the removed earth is laid on the opposite side of the opening, forming a bank on which the head of the plant is to lie; both spades are then entered behind, deep enough to undermine and move the whole ball of earth containing the roots, and which, plant and all, is whelmed half over till the plant lies on its side, the head facing the north. The firm ground between the first and second plant is digged over upon the stem, which should be well covered to be quite safe from frost; as this part is the first to suffer. An opening being thus left for the second plant, it is laid down as the first, and so on to the end of the row. In this way of laying down broccoli, it is supposed that the rows point south and north; but if they are planted in any other direction, the plants may be laid in the proper position nevertheless. The reason for laying the heads toward the north, is, because in winter sunshine, the heart or bosom is melted, and if followed by a frosty night the thawed parts are sure to suffer; whereas, when laid facing the north, they are less likely to be injuriously affected by a change of temperature. There are other schemes practised for preserving broccoli; instead of laying it down when it grows, the plants are taken up with as large balls of earth as will adhere to them, and removed into vacant pits or frames where they can be plunged closely together, and covered with glass-lights or mats when necessary. Or by plunging them closely together in the open air, and on beds of moderate width and hooped over, they may be preserved from frost by mats, pea-straw, or dry fern. By such means broccoli may be had for the table throughout the severest winters, and well repays every care bestowed upon it. In private gardens, and on a small scale, such precautions should never be omitted; when cultivated extensively, as in market gardens, laying it down where it grows, as above described, is the only plan that can be followed. Indeed, for these five or six winters last past, no precautions whatever have been taken to preserve broccoli, and little loss has occurred, owing to the mildness of the winters.

What are called Cape varieties, introduced about thirty years ago, are a great acquisition. The sorts previously in cultivation, though good in favourable seasons and under proper treatment, all came in too closely together, so that there was either none at all to be had, or for a time too much. But the Cape varieties, particularly that excellent one called "Grainger's," are earlier; good heads being sometimes cut in August from plants raised from seed sowed in April. Indeed it has been proved that, by choosing the proper seasons for sowing, and giving necessary care in the culture, the heads may be had in perfection at any time. The Cape sorts are least valuable from the middle of May to the end of June, because cauliflowers are in season, and generally preferred to any kind of broccoli.

There are nearly twenty varieties in cultivation, and treated so as to succeed each other, with reference to their hardiness, or time of coming into use. Some sorts yield heads in about four months; others require six; and several remain ten or eleven months from the time of sowing before they show flowers, although they may be all sowed at the same time, viz. about the 20th of April.

The market gardeners in the neighbourhood of London, who in the cultivation of every culinary plant excel all others, have determined the characters, value and properties of the various sorts of broccoli, and have arranged them according to the order in which they come into use, viz.

1. Autumnal purple Cape. *
2. Autumnal green Cape. *
3. Grainge's cauliflower, Cape. *
4. Winter green Cape. *
5. Common early purple.
6. Early white.
7. Early brown.
8. Tall purple common. *
9. Cream coloured. *
10. Sulphur coloured. *
11. Spring white.
12. Late dwarf.
13. Siberian, or latest.

N. B. Those marked thus * are tall growers.

Some of these varieties have close compact heads, which, when cut, are not succeeded by sprouts; others have long branched heads, which when, the topmost is cut, send forth numerous shoots bearing smaller heads from the axils of the lower leaves. Of this description is the early purple and some others; proving very useful in those seasons when the uppermost flowers happen to be killed by frost.

BRODIÆA. Named in honour of J. Brodie, a cryptogamist, by Sir J. Smith. A family of small bulbous plant, introduced from various parts of America. They belong to *Hexandria Monogynia* of Linnæus, and to the natural order *Hemerocallideæ*. They are curious little plants, bearing bunches of blue flowers, and usually cultivated in frames, or in the green-house.

BROME GRASS is the *Bromus* (Greek name of wild oats) of Linnæus. A family of grasses chiefly European, containing forty-seven species, of which twenty-seven are annuals. Twelve are natives of Britain, and occur on every hedge bank. The *B. secalinus* is too often met with in wheat crops; and as the seeds are large and heavy, are not easily separated from the wheat, in which, if the *ray*, as it is called by farmers, appear, a lower price is given. The seeds of this species of grass are far from being deleterious in bread, though the reverse is erroneously asserted: on the contrary, both the quantity and quality approach very nearly to the smaller varieties of oat. Indeed, for the purpose of feeding poultry, the *B. secalinus* or ray-grass, is well worth cultivation; for if sowed in October, it yields a bulky crop in the following summer, ripening along with the wheat. As a pasture or forage grass, it is however of no value, as the radical leaves are few in number, and the stems rigidly hard; and being an annual, is too fugitive for grazing purposes. The *B. giganteus*, with its two varieties, the *triflorus* and *longifolius*, being perennials, are admitted among others in laying down meadows. It is said that the panicles, cut before the seeds are ripe, have formerly been used to dye green. The seeds of the *B. mollis* are said to be fatal to poultry: if this really be so, geese are not included, as they will eat nothing else, if the seeds of the soft brome-grass is within reach; hence it is provincially called goose-grass. The *B. asper* is the tallest of British grasses, and often met with on the margins of moist woods.

BROMELIACEÆ. The pine-apple family. A natural order of monocotyledonous plants containing upwards of a dozen genera, and more than a hundred species. The order is allied to the *Commelineæ*, *Xyrideæ*, *Amaryllideæ*, and *Hydrocharideæ*. Its essential characters are, calyx three-parted or tubular, more or less cohering with the ovary, persistent; petals three, coloured, withering or deciduous; stamens six; ovary inferior, three-celled, many-seeded; style straight, terminated by a three-lobed, often twisted stigma; fruit capsular or succulent, three-celled, many-seeded.

The habit of this order is peculiar, and few families are more interesting from their beauty and singularity. The plants belonging to the order are parasitic, perennial, and either stemless, or furnished with very short stems. They have hard, dry channelled leaves, generally with a downy surface, sometimes minutely scaly, and provided with spines. Their rigid calyx is strongly contrasted with their delicate white and blue petals. They are generally acid, and sometimes yield an edible fruit. They are natives of the hotter parts of America, whence they have been spread over Africa and some parts of the East Indies.

The chief genus, and that from which the name of the order is derived, is *Bromelia*, a name given by Linnæus in honour of Olaus Bromel, a Swede, author of several botanical works. *Bromelia ananas* or *Ananassa sativa*, the common pine-apple, is well known to every one on account of the richness and fine aromatic flavour of its fruit, which is esteemed the finest in the world. The plant is originally from Brazil, whence it passed to the West and then to the East Indies. About the middle of the seventeenth century it was brought to Holland, and from that country it was introduced into Britain in the year 1690. It is now cultivated more successfully in this country than in any other part of Europe.

The name pine-apple is derived from the circumstance of the fruit being covered on all sides with small triangular scales, resembling the cone of a pine tree.

Many varieties of pine-apple are known in the West Indies, and upwards of thirty sorts are cultivated in this country. Thus we have the Queen Pine, New Providence, Brown Sugar-loaf, Striped

Sugar-loaf, Montserrat, Antigua, King Pine, Green Pine, &c. Of these the two first are perhaps the most esteemed. The white or queen pine is the most common in Europe, and is the most to be relied on for a certain and good crop.

Pine apples seldom perfect their seeds in this country, and hence they are propagated by suckers, which appear on the fruit stalks or proceed from the base of the plant, and by crowns or tufts, those peculiar productions which grow on the fruit. The suckers, after they have assumed a brownish colour, are removed from the plant, by breaking down the leaf beneath them and then moving them gently backwards and forwards till they fall off. The crowns are generally returned to the gardeners after the fruit has been presented at table.

The culture of the pine apple is very expensive and troublesome. Fruit is seldom produced till after the lapse of two or three years. A *bark-pit* is used for nursing the crowns or suckers, the plants are then transferred to a low stove called a *succession pit*, where they are kept till they are ready for fruiting; they are then removed to the *pine-stove* or *fruiting-house*. In order to secure good pine apples, plenty of room must be allowed to the plants in the nursing and succession pits, so that the lower parts of them may swell out and increase in bulk. Mr. Knight says that a loamy soil, well enriched with rotten dung, and the pots sufficiently drained, with abundance of heat without sudden extremes, will ensure large and well flavoured fruit.

Pines should be watered sparingly in dull weather, more especially in winter, from the beginning of October to the first or middle of March. After that, plentiful waterings may be given every three or four days. Fruiting plants ought to receive plenty of water from the time they go out of flower till they begin to colour. When they approach maturity, water should be applied more sparingly, inasmuch as by this means the flavour of the fruit is increased. The fruit is generally ripened from the month of June to September, and is known to be perfect by its acquiring a fine golden colour and a delightfully fragrant smell. The fruit is eaten in greatest perfection soon after being cut. It may be preserved, however, for several weeks, by putting the stem into a bottle of pure water, renewed every two or three days, and placed in a well dried room at the temperature of 60° Fahrenheit.

In some of the East India islands pine-apples are said to be so abundant at certain seasons of the year, that the inhabitants clean their swords by running them through the fruit.

A juice is obtained from the pine-apple, which by fermentation yields a liquor possessing stimulating and diuretic properties.

Pines are subject to injury from the attacks of brown and white scaly insects of the coccus tribe, as well as from the ant.

Bromelia pinguis which is common in Jamaica, has its fruit separately in clusters, and not in a cone or pine. On account of its prickly leaves it is used for inclosing pasture lands. It also yields a kind of thread used in the manufacture of cloth and in the formation of ropes. The juice of the fruit is said to be diuretic, and when mixed with water forms a cooling drink in fever and dysentery. A vinous liquor is also procured from it.

Bromelia medicaulis is chiefly valued on account of its showy blossoms. Its leaves, like those of the common teasel, retain a considerable quantity of water in their folds, and thus afford a delicious drink to the traveller in the scorching climates in which the plant grows.

Bromelia fastuosa is the most beautiful species of the genus. It has rarely flowered in Britain.

Tillandsia is another genus of this order, which deserves to be noticed on account of the peculiar mode in which many of its species grow. The name is given in honour of Elias Tillands, who was born in 1640, and died in 1692. He was keeper of the botanic garden at Abo, and paid much attention to the botany of Finland.

Tillandsia utriculata, bladder Tillandsia, is a valuable parasite found in the woods of the West Indies. Its seeds are feathery, and being carried along by the wind, adhere to the bark of trees. In this situation they take root, and send forth leaves which grow in such a way as to form at their lower part a deep hollow basin, capable of containing a quart of water. The upper part of the leaves is narrowed, so as in some measure to close the mouth of the basin, and thus prevent the rapid evaporation of the water. Thus even in warm countries a reservoir of water is obtained, whence man and animals draw a welcome supply. The water seems to be destined for the support of the plant during drought. When the stem of this plant is wounded, a clear white gum is said to exude.

Tillandsia usneoides, long-moss Tillandsia, is found in shady woods from Virginia to Florida, as well as in the West Indies and Brazil. It vegetates on the black mould that collects on the bark of the ebony and other trees in hot damp countries, forming dense festoons, which hang from the branches in a most graceful and elegant manner. The slender thread-like hoary stems of this parasite are so twisted together, as to secure for them in Jamaica the name of Old Man's Beard. When the hoary bark of this singular parasite is separated by beating or rubbing, the remains of the stems look like a mass of curled horse-hair, and are used by sadlers and coach-makers for stuffing pannels and cushions. They are also employed in Louisiana for making mattresses. The hanging nest of the Bonana bird is made from the fibres of this plant.

Tillandsia stricta, frosted stiff-leaved Tillandsia, is cultivated in this country, and blossoms freely when suspended by a thread in a warm room. When hung up in a green-house during our winter without the application of any artificial heat, the plant decays, but can be made to revive again in spring. It can thus be made to endure an artificial winter. This is not the case with many of our exotic parasites. *Caraguata ligulata,* is found on old trees in the vast forests of Martinico and of Jamaica. Its leaves, like those of *Tillandsia usneoides,* are said to collect water in the rainy season.

Other species of this genus, with their spiny leaves, form an impenetrable herbage in the pampas of Buenos Ayres and Brazil. Many of the Tillandsias are favourites in the gardens of South America. They are suspended in houses and hung from balconies, throwing out a profusion of flowers, and diffusing a delightful fragrance. From growing in the air without any attachment to the soil, they have sometimes been denominated air plants. See article Air Plants.

The species of *Pitcairnia*, another genus of the order, are readily cultivated in almost any soil in a good stove. They thrive best when plunged in a tan-pit, and allowed to root through their pots into the tan. Tillandsia and Pitcairnia differ from bromelia, in not having the germen completely inferior.

The genus *Agave* belongs also to this order. *Agave Americana*, or American aloe, is a popular succulent plant throughout Europe, which is acclimatised in Sicily, the south of Spain, and Italy. Proper cultivation is required in order to make it flower freely and speedily. It is used for various purposes, as for making ropes, fences, soap, &c. From the *Agave Mexicana* a spirituous liquor is obtained, similar to Scotch whiskey. For a full account of the genus, see article Agave.

Several bromelias are now included under the genus *Billbergia*, *Billbergia iridifolia*, drooping *Billbergia*, is found parasitic on trees at Rio Janeiro. Its seeds take root both on branches of trees, and on stones covered with decomposed vegetable matters.

In general the pine apple tribe are found in situations where the atmosphere is humid, and where at the same time the temperature varies from 70° to 90° Fahrenheit. Hence, in cultivating them in this country we ought particularly to attend to these requisites, if we wish our attempts to be crowned with success.

Among the other genera belonging to this order we may enumerate, *Buonapartea*, *Litlœa*, *Guzmannia*, *Pourretia* and *Caraguata*.

BRONTES (Fabricius, Uleiota, Latreille). A genus of coleopterous insects, placed by Latreille amongst the *Tetramera*, and belonging to the family *Cucujidæ;* the antennæ are long and cylindric, with the third and following joints of equal length; the palpi are slender at the tips. The type of the genus is the *Brontes flavipes*, an European species, of which the male is remarkable for a large pair of horns, with which the back of the mandibles are armed. It is found beneath the bark of trees.

BROOK LIME is the *Veronica beccabunga* of Linnæus. The specific name is derived from the German *bachbunge*, because it is found in brooks. The plant is frequently seen growing along with water-cresses; and, like them, is used as an ingredient in salads.

BROOK WEED is the *Samolus* (pig's meat, Celtic) of Linnæus; a genus of three species of herbaceous perennials, one of which is the brook-weed of Britain. It is a pentandrious plant, and belongs to the natural order *Primulaceæ*. The *S. valereandi* has white flowers in clusters, and found in clear watery places where the soil is gravelly.

BROOM is the *Spartium* (cordage, its use in early ages) of Linnæus, and in his time was a very extensive genus, but is now very much divided by modern botanists, and distributed among the neighbouring genera of *Genista* and *Cytisus*, so that there is only one species of broom left, viz. *Spartium junceum*, the rush-stemmed or Spanish broom. The old common broom of our wastes, one of the most ornamental of British plants, formerly so much used for domestic purposes, as for besoms, thatch binders, and as a substitute for hops as well as medicine, is now no longer a *Spartium*, but the *Cytisus scoparius* of Lamarck.

BROOM RAPE is the *Orobanche* (strange vetch) of Linnæus, a very curious genus of plants, and natives of Britain. They are didynamous, and form a natural order of themselves, viz. *Orobancheæ*. The generic character: calyx of two-lobed lateral leaflets; corolla gaping; capsule one-celled, two-valved, many-seeded; a gland at the base of the ovary. There are six species of this genus, all of which are said to be parasites, that is, living on the roots of other plants, chiefly on those of the order *Leguminosæ*. The *O. major* is met with in great plenty on the roots of the common red clover, in light sandy or gravelly soils, making its appearance along with the second crop. Its roots spread themselves on those of the clover, forming a kind of bulb, and sending up a leafless stem resembling the shoots of asparagus, when they first emerge from the ground. The stem rises to the height of from eight to fourteen inches, having alternate, bracteous scales along its whole length, and also among the flowers, which are borne in a spike at the top. The plant has always a brown withered appearance; the stem and flowers showing only a slight tinge of red or purple. From it so uniformly accompanying the clover, it has long ago occurred to the writer whether it be sown with it. The second crop of clover is usually saved for seed, and with this the broom-rape appears. There is no sign of it attacking the plant during the first twelve months of its existence, nor indeed till it is fifteen or sixteen months old. In other words, the clover is sowed in the month of April; it remains till the month of June in the following year, before it is cut the first time: the second crop is ready about Michaelmas in the second year, and in this the broom-rape appears. Clover seed is always, as already observed, saved from the second crop: the plant which we are noticing is cut and carried to the barn therewith: the whole is thrashed together, and as the seeds are nearly of a size, they may be sacked up, and of course sowed together. This idea is the more reasonable, because the plant is never seen on arable land, but among clover: and there is no accounting for its presence, but by saying that the seeds lie inert in the soil from one clover crop to another, that is, for four or five years, or supposing that they are sowed together. The same plant is met with on commons or on borders of fields, among broom or furze; but is never seen in such quantity as among clover. Other species are found on the roots of other plants, but which will be adverted to under the article *Orobancheæ*.

BROSCUS (Panzer). A genus of coleopterous insects, separated from the Linnæan genus *Carabus*, and comprising a single British species, the *Carabus cephalotes* of Linnæus. The thorax is very much narrowed behind, and remote from the elytra, which are narrow and oblong; the head is large and nearly orbicular, and the anterior tarsi of the males have the three basal joints dilated; the mentum is deeply notched, with an obtuse central tooth. The typical species above mentioned is nearly an inch long, of a black colour, and is found beneath marine rejectamenta on several parts of our coasts.

BROSMIUS (*Tusk*), a genus of soft-finned fishes, with the abdominal fins under the pectorals, and belonging to the exceedingly numerous and valuable family of Cod (*Gadoideæ*). The tusk is a fish of the northern seas, being rare on the coasts of the mainland of Scotland, and more abundant at Shetland than Orkney. Like most of the family which inhabit high latitudes, it is rather hard and harsh in the recent state; but when salted and dried it is a valuable fish to those northern people who depend chiefly on the sea for their food, though it is far inferior to ling both in size and in quality. It grows to the length of about two feet, is dusky on the back, dull yellow on the sides, and white on the belly. The fins have white margins, and the pectorals and tail are rounded off at their extremities. The lateral line is a little curved; the body, from the vent to the caudal fin, compressed; and there is a plait or furrow on the neck. It is found on the same banks which are frequented by cod and ling, and taken by the hook in the same manner. This fish has sometimes been confounded with the *Torsk*, which is a species of cod, but it does not appear to be met with on any part of the British shores. See the name of the family for the characters and differences of the whole.

BROSSÆA. (G. de la Brosse, physician to Louis XIII., and founder of the Jardin des Plantes at Paris), so called in honour of, by Linnæus. There is only one species, a hothouse evergreen shrub, having scarlet flowers, and it is but imperfectly known to British botanists.

BROTULA, a genus of fishes belonging to the cod family, and bearing, in some of its characters, a slight resemblance to the tusk, but having the dorsal and the anal fins united, and forming the caudal, which terminates in a point. There is only one species known; it has six beards or filaments on the head, and is a native of the West Indian seas.

BROUGHTONIA (R. Brown). An orchideous plant, native of Jamaica, having fine scarlet flowers. It is said to be rare in British collections, in consequence of being difficult of cultivation.

BROUSSONETIA (Ventenat), named in honour of the French naturalist Broussonet. A genus of two species, said to be natives of Japan. The flowers are diœcious, and belong to the order *Urticeæ*. This plant was heretofore called *Morus papyrifera*, or Paper Mulberry, and is remarkable for the use made of its bark in the manufacture of paper by the Chinese, and of cloth by the Otaheitans. "The fruit is little larger than peas, surrounded with long purple hairs, when ripe changing to black purple colour, and full of sweet juice. In China and Japan it is cultivated as we do osiers, for the sake of the young shoots, from the bark of which the inhabitants make paper. The bark being separated from the wood, is steeped in water, and the inner bark separated from the outer, the former making the whitest and best paper. The bark is then slowly boiled, then washed, and afterwards put on a wooden table, and beaten into a pulp. This pulp being put in water, separates like grains of meal. An infusion of rice and the root of manihot is next added to it. From the liquor so prepared, the sheets of paper are poured out one by one, and when pressed and dry, the operation is finished. The juice of this tree is sufficiently tenacious to be used in China as a glue in gilding either leather or paper. The finest and whitest cloth worn by the principal people at Otaheite, and in the Sandwich Islands, is made of the bark of this tree. The cloth of the bread-fruit tree is inferior in whiteness and softness, and worn chiefly by the common people."—*Enc. of Plants*

We may here observe, that, notwithstanding the strongest objections made against the natural system have been raised on the apparent desociation of the order *Urticeæ*, yet, that there is a strong affinity cannot be denied, particularly in the instance of so many of the genera possessing the same tenacity of fibre. The common mulberry possesses so fine a web of silky fibres in its leaves, as has induced an experimental philosopher to conceive that the produce of the silk-worm is a vegetable, and not an animal substance.

BROWALLIA (Linnæus). Named in honour of John Browallius, bishop of Abo. A genus containing three species of tender annuals. The flowers are didynamous, and belong to the Jussieuan order *Scrophularinæ*. These plants are treated like other tender annuals, i. e. raised from seeds, sowed in a hot-bed in the spring, and afterwards potted or planted in the open borders, to flower in summer.

BROWNEA (Jacquin), named in compliment to Patrick Brown, M. D., author of a History of Jamaica. A genus of three species of splendid monadelphous plants, natives of the West Indies, and belonging to the natural order *Leguminosæ*. Generic character: calyx double; exterior sheath bifid, the interior funnel-shaped, five-cleft, and coloured; petals five, inserted in the calyx, longly clawed; stamens attached to the base of the tube; style filiform; pod flat and cimeter-shaped; seeds covered with fungous fibres. These plants are not yet very common in botanical collections; but, for the beauty of their flowers, they are well worth cultivation.

BRUCEA (Le Heretier). A genus of plants named to commemorate James Bruce, the Abyssinian traveller. They are ornamental evergreen shrubs, belonging to the class and order *Diœcia Pentandria*, and to the order *Terebinthaceæ*. There are three species; one a native of Abyssinia, where it was discovered by Bruce, the others natives of India.

BRUCHIDÆ (Leach). A family of coleopterous insects, belonging to the section *Tetramera*, and division *Rhyncophora*, nearly corresponding with the Linnæan genus *Bruchus*. The upper lip is distinct, the head is produced in front into a broad large and flattened snout; the palpi are very evident and filiform; the antennæ not clavate, but filiform or serrated, and the eyes notched; the elytra likewise do not conceal the extremity of the body. The larvæ of these insects are fleshy grubs, resembling those of the nut-weevil; they are produced from eggs deposited by the females in the tender germs of various leguminous or other plants, such as the palm, &c. These eggs are not hatched until the grains have acquired some size, so as to afford a sufficient supply of food to the inhabitant, until it is ready to assume its pupa state, which it does within the now hollow seed, out of which, when it arrives at the perfect state, it makes its escape by eating a small hole, the lid of which it detaches in the shape of a cap. It is an insect of the family *Bruchus granarius*, which destroys our peas, an egg being often deposited in every seed in a pod. Sometimes this vegetable is damaged to so great an extent, as to become unwholesome, as was the case in 1780, when the public authorities in France prohibited the sale of peas in the markets, being attacked by this or some similar insect. The *Bruchus Pisi* of Linnæus, in like manner, commits very great ravages in certain seasons in North America, so that the growing of pulse has even been occasionally abandoned as useless. Schonherr describes three genera, and upwards of one hundred and sixty species belonging to this family; of these seven only are inhabitants of our country.

BRUGMANSIA (Persoon). Named in honour of Professor Brugmans, a botanical author. It is a Pentandrious genus, and belongs to the natural order *Solaneæ*. Generic character: capsule spineless; calyx bursting at the side, persistent; corolla funnel-shaped, large; anthers glued together; stigma is a line running down each side of the style.

B. arborea.

B. arborea is one of the most ornamental hot-house plants, and withal one of the most fragrant. The flowers issue from the divisions of the branches, and burst from a loose tubular calyx, nearly four inches long. The corolla is large and trumpet-shaped; the lower part of the tube narrow, but spreading widely out at the mouth, where it is divided into five angles, terminating in long points. The flower is yellowish without, and pure white within; and its fragrance so powerful as to scent a whole conservatory. Being natives of Peru, the plants require stove treatment in this country, and in moist heat flower readily.

BRUNIA (Linnæus). A genus of twenty-four species of ornamental shrubs from the Cape of Good Hope, named in memory of C. Brun, a celebrated traveller. They belong to *Pentandria Monogynia*, of the sexual system, and give a title to the sixty-first order of Jussieu, viz. *Bruniaceæ*. The foliage of these plants being remarkably soft and attenuated, resembling some of the heaths, have always an elegant look, and are a fine contrast to plants of more ample and coarser foliage. Generic character: flowers

B. lanuginosa.

aggregate; calyx superior, five-parted; filaments inserted into the claws of the petals; stigma cloven; capsule small, and two-celled There is nothing reported relative to the virtues or uses of this tribe of plants: the previous cut represents a small twig of the *Brunia lanuginosa*.

BRUNIACEÆ. A natural order of dicotyledonous plants, containing nine or ten genera, and upwards of thirty species. Decandolle considers this order as nearly allied to the *Rhamneæ*, while other botanists think it approaches the *Hammaelideæ*.

The essential characters of the bruniaceæ are, calyx adherent with the ovary five-cleft, the segments often callous at the point; petals five, arising from the throat of the calyx, and alternate with its segments; stamens five, alternate with the petals; anthers turned outwards, two-celled, bursting longitudinally; ovary half adnate, one to three-celled; cells one to two-seeded; style simple or bifid; stigma simple; fruit dicoccous or indehiscent; seeds solitary, or in pairs, suspended, with a small embryo at the apex of a fleshy albumen.

The plants belonging to this order are branched shrubs, resembling the heaths and proteas in habit. Their foliage and flowers are very ornamental. They are furnished with small linear stiff leaves, generally in whorls. The flowers are small, and grow in heads, panicles, or spikes.

They are natives of the southern parts of Africa, and are found at the Cape of Good Hope and in the island of Madagascar. They are propagated chiefly by cuttings. Their properties are as yet quite unknown.

The genera are: *Brunia*, whence the order derives its name, *Staavia*, *Linconia*, *Raspalia*, *Berzelia*, *Berardia*, *Audounia*, and *Brunia*, so called in honour of Cornelius Brun, a traveller in the Levant and Russia towards the end of last century, is a pretty Cape genus, which thrives well in sandy peaty soil with a moderate supply of water. *Raspalia* is remarkable as being an instance in which the stamens arise from the top of a superior germen.

BRUNSFELSIA (Linnæus). A genus containing four species of hot-house evergreen shrubs, named after Otho Brunsfels, a Carthusian monk. The flowers are didynamous, and the plants belong to the natural order *Solaneæ*. They have showy white or purple flowers, and are easily cultivated.

BRUNSVIGIA (Heister). A beautiful family of bulbous plants, introduced from the Cape of Good Hope, and named in honour of the royal family of Brunswick. Like other liliaceous plants, they are hexandrious, and belong to the order *Amaryllideæ*. They are a magnificent genus, with ample foliage and flowers. Their bulbs grow to a large size, and consequently require large pots. When in a growing state they should be well supplied with water; but when dormant, like all the Cape *Amaryllideæ*, they must be kept perfectly dry.

BRUSSELS SPROUTS. A useful sub-variety of the Savoy cabbage, called *Brassica oleraceæ gemmifera*. The principal head is inconsiderable, and inferior. The plant rises to the height of three feet or more. The leaves are quickly deciduous; but from the axils of each, little compact heads are produced from the top to the bottom of the stem. These little heads continue long in season, and are always admired at table for their tenderness and flavour. Although Brussels sprouts may be had all the summer by timely sowing and culture, yet as they are not equal to other delicacies of summer, and as they are esteemed a winter vegetable, one sowing about the middle of April on a bed of dry rich soil, sowed with an ounce of seed, will furnish plants enough for winter and spring consumption for any moderate family establishment. Brussels sprouts should be planted in rows, two feet asunder every way, on rich well digged ground, and afterwards kept free from weeds and fallen leaves. To have true seed, it is recommended to save it from the side branches, it being found that seeds from the crown do not give the true character for which this vegetable is so much esteemed.

BRYA (Patrick Brown). Bryo, to sprout; seeds germinate before falling. This is a genus of two species; one, a native of Jamaica, and there, from the colour and hardness of its wood, is called ebony; the other has been, according to Loddiges' catalogue, received from Sierra Leone. They have Monadelphous flowers, and belong to the natural order *Leguminosæ*.

BRYAXIS (Knoch). A genus of coleopterous insects, belonging to the minute but very singular family *Pselaphidæ*. The tarsi are furnished with a single claw; the maxillary palpi are rather short, and the body is broad or ovate, with the extremity of the antennæ thickened. These insects are of small size, and are usually found in damp places amongst moss, during the winter and spring. We have met with several species in Battersea fields. Nine species are recorded as British in the works of Messrs. Curtis and Stephens, but of these the *Pselaphus insignis* of Reichenbach is an *Euplectus*, according to M. Aubé, whose memoir we have already alluded to in the article BRACHELYTRA; and the *Pselaphus nigriventris* of Denny belongs to the genus *Batrisus* of Aubé. We take this opportunity of introducing the article upon an allied genus, which was accidentally omitted in its place.

ARCOPAGUS (Leach). A genus of coleopterous insects, belonging to the family *Pselaphidæ*. The body is short and convex; the maxillary palpi terminated by a large hatchet-shape point, and the antennæ eleven-jointed, with the basal joint larger than the second. They reside in moss, &c., growing in damp situations and in marshes, throughout the year. There are four British species. There are some sexual peculiarities in this genus deserving of notice: the tibiæ of the fore legs in the males is notched, which character Mr. Curtis considers as characteristic of the genus; but Mr. Denny, in his beautiful work on this family, has also noticed it in another genus, *Bryaxis*. Moreover, as he observes, that the notch varies in size in the same species (*B. longicornis*), we may perhaps conclude that this is a specific instead of a sexual character, and consequently that two species of the present genus have been regarded as the opposite sexes of the same species.

In one sex (respecting which a difference also exists) the first joint of the antennæ is produced into a fine point on the inside.

BRYONY is the *Bryonia dioica* of Linnæus, a genus of herbaceous climbing plants, consisting of twenty-three species found in every quarter of the world. They bear unisexual flowers, and belong to the order *Cucurbitaceæ*. The red-berried bryony is frequent in hedges every where in England, and is easily known by its long rambling shoots climbing among the thorns of the hedge, dearing bunches of red nauseous berries in the autumn, and particularly by its immense tuberous root, sometimes weighing several stones. "These roots have been formerly, by impostors, brought into the human shape, carried about the country, and exhibited as *mandrakes* to the common people. The method which these impostors practised, was to open the earth round a young thriving bryony plant, being careful not to disturb the lower fibres of the root; to fix a mould, such as is used by those who make plaster figures, close to the root, fastening it with wire to keep it in its place, and then to fill in the earth about the root, leaving it to grow to the shape of the mould, which is effected in one summer."—*Lind.* The root has been long used medicinally, it being highly purgative and acrid.

BRYOPHILA (Ochsenheimer). A genus of lepidopterous insects, belonging to the section *Nocturna*, and family *Noctuidæ*. The body is very slender, thus differing from the majority of the family (which are termed simple-horned full bodies); the wings are slightly deflexed during repose. These insects, of which there are two British species, are amongst the smallest and most elegant species of the family; they are found upon old walls, &c., the larvæ feeding upon the lichens which grow there; the moths are about an inch in expanse, of a white or greenish hue, prettily variegated with black markings. The type of the genus is the marbled beauty, *Noctua perla*, of Haworth, common in the neighbourhood of London.

BRYOPHYLLUM (Salisbury). Bryo, to grow, and phyllon a leaf; young plants produced from the crenatures of the leaves. This curious plant belongs to *Octandria Tetragynia* of Linnæus, and to the natural order *Crassulaceæ*. The generic character consists in the flower having four sepals, four petals united into a cylinder, and many-seeded. This plant differs from the generality of others, by bearing young progeny on the edges of its leaves. In ordinary cases the young of plants are produced from seeds, or from buds attached to, and springing from, the stem or roots. These vital gems are either visible or hidden, and come forth under favouring circumstances of time, place, and temperature. Such plants are clothed with leaves also; but they are simple appendages, and possess in themselves no reproductive principle, nor are they constituted like the stems and roots in having a vital membrane. But the leaves of the plant we are noticing are actually foliaceous parts of the stem, and possess similar powers of reproduction; inasmuch that buds are not only present in the notches of the leaves, but are actually developed there, and fall to the ground perfect plants.

Viviparous progeny are produced by many different descriptions of plants, and in various ways. Bulbs put forth offsets, as the tulip; tubers increase their numbers by a similar process, as the potatoe; the strawberry, and many kinds of grass, send out runners, spreading far and wide. Of these powers of plants, it is evident that that of the bryophyllum is only a modification; but certainly very curious; being so unlike the ordinary modes of the reproductive processes of the vegetable kingdom. To propagate this plant, and there are a few others propagated in the same way, it is only necessary to take a leaf and lay it on the damp surface of a pot of earth; roots are quickly exserted, and several young plants obtained. It is a stove plant, requiring a dry porous soil, and very little water.

BUBO, Cuvier's generic name for the great horned, eared, or tufted owl. See the article Owl.

BUBON (Wildenow). The meaning of the name is uncertain, being employed by Pliny. A family of plants chiefly herbaceous, natives of Europe, Asia, and Southern Africa. They are pentandrious, and belong to the order *Umbelliferæ*. From the *B. galbanum*, the drug of that name is obtained. It is collected from the spontaneous exudation of the stem, or from an incision made in the stalk a little above the root, from which it immediately flows, and soon becomes sufficiently concreted for gathering. Medicinally considered, this gum-resin is said to hold a middle place between asafœtida and ammoniacum; but is less fetid than the former. The *B. Macedonicum*, cut and dried, is put among clothes to give a pleasant scent. They are plants of no beauty.

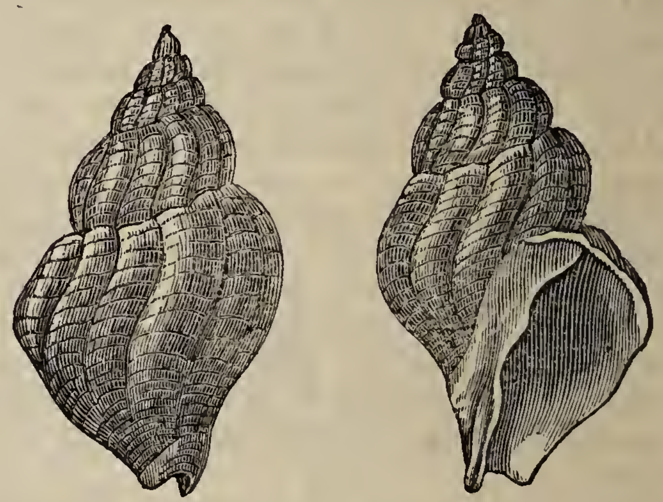
BUCCINUM (Linnæus, Lamarck). The extremely confused and widely extended genus *Buccinum*, as constituted by Linnæus, like many others of that great naturalist, required reformation; and Bragniere appears to have been the first to separate from it his genera *Cassis* and *Terebra*. There yet remained a great number of distinct species intermingled, rendering the generic characters of the buccinum still very vague and inconsistent. Lamarck, therefore, farther classified the enormous number of molluscs called buccina, and established the additional genera of *Harpa*, *Dolium*, *Monoceros*, *Concholepas*, and *Eburna*, each presenting distinctive and peculiar anatomical structures, very different from the Linnæan genus *Buccinum*. As it now stands, there are still a great variety and diversity of species, allied to each other nevertheless by characteristic assimilation.

The animal is well known, and will be described under *Entomostomata*, the second family of the order *Siphonobranchiata*. First class *Cephalophora*, of De Blainville's system of malacology, in which they are now subdivided as follows:—First, those that are smooth, the spire rather elevated, with the aperture enlarged in front, as in the *Buccinum achatinum*. Secondly, such as are more or less tuberculated, with the edges of the aperture separated by a notch or sinus backward, rather deep, the right side dentated in front, as in the *B. papillosum*. Thirdly, the oval species, which are rather globular and subcoronated on the whorls of the spire, as in the *B. glaciale*, and *B. undatum*. Fourthly, those species that are short, rotund and subglobular, as the *B. reticulatum*. Fifthly, such as are nearly similar in form, with a large callosity on the internal edge, as the *B. arcularia*, constituting Lamarck's genus *Nassa*, in which the thickened lip, and great callosity of the columella, with

Buccinum tuberculatum.

the irregular lump or tuberculations on the back of some species, are remarkably characteristic. Lastly, all the anomalous species, such as the *B. neriteum*, &c.; they all possess an operculum, which is oval, horny, and formed of subconcentric circles, its summit marginal and slightly marked.

The general characters of this mollusc are its being slightly covered with an epidermis, oval shaped, lengthened, and the spire moderately elevated; an oblong-oval aperture, notched, and sometimes anteriorly subcanaliculated, the right lip thickened, not turned over, the columella plain, and nearly all seen. They are found in every part of the globe, and many of them constitute a nutritious food, particularly in the northern countries. These molluscs are not very remarkable for the brilliant lustre of their colours, being for the most part of sombre tints, and inhabitants of cold climates; but their great diversity of form, delicacy of sculpture, and pencilled markings, render them highly interesting to the mere collector of natural history, without a reference to their more scientific examination. They nevertheless possess many useful purposes, which the rapidly increasing study of natural history may reasonably be expected to develope, some of which will be enumerated under the leading article Conchology. De France mentions thirty-six fossil species, but there is not so great a number as the genus is now constituted, and it is yet capable of



Buccinum undatum.

further alteration to great advantage. The name is derived from a trumpet (*buccinum*), and in the South Seas a large species—*B. giganteum*, of Linnæus; *Triton variegatum*, Lamarck—is used for that instrument.

BUCCO (Barbet, or bearded bird). A very numerous, but not very interesting genus of *Zygodactylic*, or yoke-toed climbing birds, combining some of the characters and appearances of the magpies and jays, with some of those of the more showy and elegant climbers. They are heavy birds for their size, and not swift either on the wing or in climbing. They are found only in the woods, and there upon the lower branches of the trees, and they move with some difficulty. Their bills, heads, and necks, are disproportionably large for the rest of their bodies. The base of the bill is surrounded by hairs or bristle-shaped feathers, from which they get their common English name of "barbet," and the generic name of *bucco* (puffy-cheek) is given them on account of an enlargement or tumefaction at the base of the bill, which consists partly in the cheek itself, and partly in the retroflexure of the hairs at the bottom of the gape. The beards or bristles form five tufts, one directed over each nostril, one at each side of the base of the lower jaw, and one under the chin. The

The bill is large, strong, conical, and sharp at the tip, which is a little bent. Like many others of the climbers, and indeed all birds which have the bases of their bills beset with bristles, they are omnivorous, eating insects, eggs, small birds, and fruits, and other succulent vegetable substances. They build their nests in the holes of trees, generally at but a small height above the surface of the ground.

They are usually divided into three sub-genera:—

1. *Barbicans* of Buffon. This sub-genus is found in the warmer parts of the eastern continent only, but in both parts of it, that is, in India and in Africa. They have the culmen of the upper mandible arched, but without any ridge, and blunt; and they have two strong teeth on each side of the same, on the cutting edges. They are said to feed more upon vegetable substances than the other two sub-genera. There are many species, some of which are found in Africa, some in the south-eastern parts of continental Asia, and some in the eastern islands, but they are all retiring, and what may be called dull birds of the deep forests, and thus their manners are very imperfectly known.

2. *Barbets,* properly so called (*Bucco*). These have the bill simply conical, without any ridge on the culmen, though that is a little raised in the middle. They are found in the two continents, but the greater number of the species belong to the eastern one. They are more gay in their plumage, and a little more lively in their manners, than the former sub-genus. The birds belonging to that are seldom seen in pairs, even in the breeding season; but those of this sub-genus are always found in pairs at that time, and generally in parties of about half a dozen or so at other times of the year.

3. *Tamatias* (*Tamatia*). This is said to be the native Brazilian name of a bird, but whether of all, or of any of those of this sub-genus, is not very well known. These have the bill a little larger and more compressed than the former sub-genera, and the upper mandible more hooked downward at the point. Their tails are also very short, and their heads disproportionately large and thick. This form gives them a very dull appearance, which is in no degree relieved by their manners, which are solitary, and to appearance melancholy. They are found only in South America, and there only in the depth of the forests, to the gloom of which they rather add, by the heaviness of their air, and the sluggishness of their motions. They are understood to be wholly or chiefly insectivorous. Their chief colours are black, white, and reddish brown, very delicately mottled in some of the species, but never gay. They are, in fact, among the least interesting of the birds of those head-quarters of the climbing birds of which they are natives, and there is nothing in their manners to redeem the homeliness of their appearance.

BUCEPHALUS. A species of Distoma approaching to the Infusoria, and even in some respects to the lower forms of vegetable organisation; it is a parasite of the fresh water muscle recently discovered, and deriving its name from the disproportionate size of the head.

BUCEROS (horn-bill), a very singular genus of birds, combining the characters of several other families, but having abundant peculiarities of their own, by which they are distinguished from all the other genera of birds. Their air and their habits have no inconsiderable resemblance to those of the crow tribe. They are quite miscellaneous in their feeding; fruits, small mammalia, reptiles, insects, carrion—all come alike to them; and they eat voraciously, casting up their food into the air, in order to swallow it, as their tongue is too short for being used in the ordinary way in assisting deglutition. The feet of these curious birds bear no inconsiderable resemblance to those of the king-fishers and bee-eaters—that is, they are in so far syndactylic, or have the three front toes, which are all of nearly the same length, united together at their bases, so as to form a kind of solid palm or flat to the foot. This is not a walking foot, neither is it one adapted for perching—that is, for holding on upon a branch or twig while the bird performs any action with the other parts of its body, but simply a foot by means of which the bird can stand firmly either on the ground or on a branch. To assist the birds in maintaining their standing posture firmly, the toes, both the three front ones and the hind one, are very much elongated, so that, instead of the toes all grasping toward a point, as they do in the anisodactylic feet, or toward a line passing across the middle of the foot, as in the zygodactylic, the two extremities grasp toward the palm or flat portion of the foot; and it will be easily seen that, for mere rest, or firmness of position, this description of foot is much better adapted than any other. But birds with such feet cannot walk, but are obliged to hop, and assist their balance in hopping by raising the wings. The hopping motion is, however, the one best suited for capturing the prey upon which these birds chiefly subsist.

The most remarkable character of these birds, however, is the bill, which is wholly unlike that of any other species. It is not only of very large size and peculiar shape in itself, that is, in the mandibles, which perform nearly the same function as those of other birds, but in certain additional parts to which there is not any thing corresponding in any other species. There are other birds which have enlargements at the base of the bill, as in some of the varieties of pigeons; and there are others, as, for instance, the coots, that have the horn of the upper mandible extended in a plate upon the point. But the horn-bills have a singular enlargement, which, in some of the species, is almost as large as the bill itself, of which it is not easy even to guess at an use. This part of the bill is cellular, and very light in its substance; and the whole of the bill, large and formidable as it appears, is weak and brittle. The tomia are naturally jagged, and they are often chipped into notches in the using.

All the species have not this singular protuberance, and none of them have much or any of it when they first come out of the shell; but it enlarges with age, and also changes its form, so that some of the birds might, at different ages, be taken for different species. In using this bill they do not peck, or strike, but seize their food, keep grinding it for some time between the jagged tomia, and then swallow it entire. They are all natives of the warmer parts of the eastern continent—that is, of Africa, of the south-east of Asia, and of the eastern islands, and perhaps they are most numerous in the last of these localities. There are many species, and they are usually divided into two sections—those which have a protuberance on the bill, and those which have not. We can find room for only one or two of the species in each division.

I. WITH A PROTUBERANCE.

RHINOCEROS HORNBILL (*Buceras rhinoceros*). This is a native chiefly of the eastern Archipelago, and it is the largest bird of the genus. Its length is nearly four feet, of which the bill takes up at least one foot, and the extent of the wings is about three feet. The true bill is slightly crooked, and the mandibles are rough and jagged in the edges. The protuberance is, in old birds, of nearly the same size as the bill itself. It advances for some distance upon the culmen of the upper mandible, with which it is connected as one substance, and then it turns upward something in the same manner, but not in the same form, as the horn of a rhinoceros, and terminates in a variously shaped point in different individuals. The true bill is black at the base of the upper mandible, passing through a dull reddish colour to pale straw yellow at the point. The protuberance is yellowish on the under side, and reddish on the upper; and there is a black line proceeding along the junction with the upper mandible on each side, and continued to the point of the protuberance, separating the yellow from the red. This line very much resembles the meeting of a pair of mandibles, and makes the bird appear as if it had two bills, the under one slightly curved, and tapering to a sharp point, and the upper turning upwards, and even backwards. The upper one, however, has no opening of any kind, but consists of a very thin horny case, covering and being connected with a number of horny cells, the walls of which are very thin, so that the whole protuberance is not heavier than a crest of loose feathers of the same size. The colours of this curious bill are much brighter when the bird is alive, and in good health, than in the preserved specimens.

The colour of the bird is black, but the tail, which is slightly wedge-shaped at the end, indicating a bird which has to make its way among bushes, or other tall vegetation, is tipped with dull white. The eyes are large, and shaded from the upward light by superciliary bristly feathers. The feet and tarsi are strong, and covered with large scales of a brownish colour, and the nails on the toes are flat and blunt. There is nothing about this large, and, at first appearance, formidable bird, that can in any way be considered as a weapon capable of doing injury to any but very small animals; and in countries where the waste of life is great as well as the production, it is understood that the chief office of the hornbill is that of scavenger. Its general manners are dull and sluggish.

THE UNICORN HORNBILL (*B. monoceros*) has the protuberance of the bill continued nearly parallel to the curve of the mandibles, and a portion toward the point, which is sharp, detached from the upper mandible. The general colour, as in the last-mentioned species, is black, but glossed with reflections of green and purple. The first three quills of the wings and the tail-feathers are white.

THE GREAT-BILLED HORNBILL (*B. cassidix*) is nearly of the same size as the rhinoceros, but it is more showy in its plumage. The body, wings, and thighs, are of a rich deep bronze, or rather nearly black green, of very splendent lustre, and brilliant reflections; the tail is white, the neck and breast rich golden yellow; and the top of the head, on which the feathers are produced and silky, forming a loose crest, is rich maroon red. The bill is about ten inches in length, very large at the base, but tapering toward the tip, and for the greater part of its length of an uniform yellow colour, but toward the base, each of the mandibles is sheathed with three ridges of transparent horny matter, which advance by curves upon the culmen and mesial line of the lower mandible. These ridges are of a reddish orange colour, and separated from each other and divide the yellow part of the bill by lines and furrows of deep black. The protuberance of the bill rises from the culmen, in front of the basal ridges, forming there a trenchant edge, standing naturally and rounded. It rises to nearly the same measure as the depth of the bill, and proceeds backwards in a curve descending on the head opposite to the posterior part of the eyes. The sides are formed into ridges convex to the front, and the whole is of a purple red colour.

This species is an inhabitant of the Eastern Archipelago, and it is said to be much more of a mountaineer than those formerly mentioned; but to be an inhabitant of the wooded mountains only, and to live chiefly upon fruits, which are very abundant in that part of the world. From the structure of this species, and the character of the vegetation where it is native, we might perhaps be led to conjecture, if not to conclude, that the protuberance on the bills of these birds, serves to divide the flexible vegetation for them so that they may see and reach those substances on which they feed.

Ten or twelve more species of hornbills with more or less of a protuberance on the upper mandible, are mentioned by systematic writers on ornithology; but too little is known respecting them for making the details of any use, or any interest to the general reader, as the greater part of them are only descriptions of single specimens which have not been seen by the describers till they were dead, and in part, at least, altered.

II. HORNBILLS WITHOUT PROTUBERANCE.

In all respects, except that of not having the enlargement from the base of the upper mandible, these appear to agree very much with the former division. The bill is of the same enlarged form, and nearly of the same shape; and there is not enough known respecting either the one or the other, for enabling us to know with any certainty, to what it is that the very singular formation of their mandibles adapts them. But as those with the protuberance are most plentiful in the Eastern islands, and those without in India and Africa, and as the former is the place where the most exuberant vegetation is met with, some colour at least is given to the conjecture which we have ventured to hazard; but we do not give that conjecture as an established truth; and, indeed, before we can consider anything as established respecting the habits of those most singular of all the feathered tribes (at least in the form of their bills), there must be much and careful observation in those places which they inhabit.

BUCHANANIA (Roxburgh). Named in compliment to Francis Buchanan, M.D. A genus of two East Indian trees, regarded for their fruit, being allied in some way or other to the mango. The trees were called *Mangifera* by Lamarck, and *Spondias* in the *Hortus Bengalensis*.

BUCIDA (Linnæus). So named from *bos*, an ox; the fruit being in shape like an ox's horn. It is a tree common in Jamaica, belongs to *Decandria Digynia*, and to the natural order *Combretaceæ*. The tree affects low swampy lands near the sea coast; it is remarkable for its slender crooked branches, and the tufted disposition of the leaves; growing to a considerable size, it is reckoned an excellent timber tree, and the bark is used by tanners.

BUCKBEAN is the *Menyanthes* of Linnæus. It receives its generic name from *men*, a month, and *anthos*, flower, because it remains that time in blossom. The flower is pentandrious, and belongs to the natural order *Gentianeæ*. There are two species, both aquatic plants: *M. trifoliata* is a common British plant, and one of the most beautiful of the British Flora. It is said that it is used in Sweden as a substitute for hops, two ounces of the leaves being considered equal to a pound of hops. It is also used medicinally, and recommended in cases of dropsy and rheumatism.

BUCKLER MUSTARD is the *Biscutella* of botanists, so called from *bis scutella*, a double shield, the form of its seed-vessel when bursting. There are several species, all inferior plants.

BUCKTHORN is the *Rhamnus* of Linnæus, a genus comprising thirty species of ornamental shrubs, chiefly evergreen, They are Pentandrious, and give name to a natural order, namely, *Rhamneæ*. The *R. alaternus* has already been noticed as a common and favourite shrubbery plant, of which there are nine varieties. Many of the others are found wild on the continent, and two are indigenous to England, viz. *R. catharticus*, and *R. frangula*. The berries of the first are sold as French berries, used to stain paper and maps; the juice mixed with alum makes sap-green; but if the berries be gathered late in the autumn the juice is purple; the bark dyes a fine yellow. The *R. lycioides* furnishes the wood of which the Moguls make their images, on account of its hardness and orange-red colour. *R. saxatilis* resembles *catharticus*. The berries are used to dye the morocco leather yellow. The leaves of the *Rhamnus Teezans* are used as tea by the poor in China. *R frangula*, found in British woods, have dark purple berries, which are purgative. Gathered before they are ripe, they dye wool green and yellow; when ripe, blue-grey, blue, and green. The bark dyes yellow, and with preparations of iron, black. The berries of this sort, and also those of the *cornus*, are sometimes sold for those of the buckthorn; but they are easily distinguished, the true buckthorn having four seeds, the *frangula* two, and the *cornus* one.

BUCK WHEAT is the *Polygonum fagopyrum* of Linnæus. The generic name signifies many-jointed, being the true character of the stems. The specific name should be Beech-wheat, because the seeds resemble beech-mast in shape. This plant is supposed to be a native of the warmer parts of Asia, though it is found apparently wild in many parts of Europe. It is impatient of frost, and therefore can only succeed in those months when no frost occurs. Its growth is rapid, and it is very prolific, sometimes yielding five or six quarters per acre. As an agricultural plant, it is of considerable value as food for all sorts of poultry, wild and tame. For cattle of every kind it should be given with other food in moderation, because it is of so hot a quality, that it will poison sooner than fatten even a hog. Swine fed with buck-wheat alone become restless, and almost raving mad; and if near water, are in great danger of drowning themselves, so much are they tormented with the inflammatory effects of the grain. To the distiller it yields a stronger spirit, bulk for bulk, than any other kind of corn. Much of the demoralising spirit gin is compounded of this grain; a worse ingredient could not be thought of. How the peasantry on the continent manage to use it in bread is unaccountable, unless it be that the spirit is dissipated by the oven. The health of horses are very often hurt by being allowed too much buck-wheat. One bushel mixed with five of oats is quite enough; and one bushel ground with two of barley is as much as even pigs should be fatted with.

It is only the farmer who employs light sandy or gravelly land that can grow buck-wheat, who, by sowing it, gains an advantage quite independent of its value. In fallowing such land for the purpose of sowing common wheat, it often happens that he gets his field perfectly clean before the beginning of June. If, at that time, he sows the land with buck-wheat, it will rise quickly, and shade the ground all the summer; and when dissevered, about the beginning of October, the ground will be left in better heart for the ensuing crop of common wheat, than if no intermediate crop had been taken. This is a consequence of shading the land during the summer drought, keeping down weeds, and having a rich succulent stubble to plough on. This plant is also sowed about the beginning of August, for the purpose of being wholly ploughed in as a dress; but for a crop of the grain it should be sowed any time between the twentieth of May and fifth of June. One bushel sows an acre.

BUDDLEA (Linnæus). Named in honour of a Mr. Buddle, an amateur of botany. There are ten species of this family, all more or less ornamental, and all tender, except one, the *B. globosa*, which stands our winters pretty well, if it receives the least shelter. The flowers are small and yellow, but, being united in globular heads above an inch in diameter, pretty fully distributed over the branches, make a showy appearance. The *B. neemda* is said to be one of the handsomest plants in Nepal, of which it is a native. The buddleas belong to the order *Scrophulareæ*.

BUFFONIA (Willdenow). Named after the celebrated French naturalist, Count Buffon. It belongs to *Tetrandria Digynia*, and to the natural order *Caryophylleæ*. Its generic character is: calyx of four sepals, having membranous edges; petals four, shorter than the calyx; stamens shorter than the corolla; capsule oval, one-celled, two-valved; seeds two, compressed. There are only two species; one is, though rarely, found in England; the other in France. The specific name of the English one, *Tenuifolia*, slender-leaved, was given by Linnæus, as expressive both of the leaf and of the *slender* pretensions to botanical distinction of the Count after whom it was named. It is said by another author, that Linnæus, to show his disrespect for the Count, slily dropped an *f* in the name!

BUG. The name of a disgusting insect belonging to the Linnæan order *Hemiptera*, section *Heteroptera*, Latreille, and distinguished systematically by the name of *Cimex lectularius*. It may seem almost superfluous to give a description of this insect, the very name of which produces a nauseous sensation, yet its peculiar characters as well as several points in its economy are not destitute of interest, and we trust that we shall not be charged with want of delicacy in dwelling upon them. In the first place therefore it is to be noticed as a curious circumstance, that, although belonging to an order of winged insects, the *Cimex lectularius* is destitute of organs of flight, a deprivation which appears attributable to the peculiar habits of the insect, which would in a great measure render the possession of wings almost useless; there is, however, to be perceived a pair of flat, rounded, and moveable appendages, occupying about one-sixth part of the abdomen, and which are evidently the rudiments of a pair of wing-covers. The abdomen itself is flat and nearly of a rounded form. The rostrum or sucker is attached to the under side of the head, and when unemployed is extended towards the breast; but this organ, instead of being four-jointed, as in the majority of the great Linnæan group *Cimex*, is composed of only three short joints, enclosing several fine setæ or bristles, which serve not only to wound but also to act, by way of capillary attraction, in raising the blood of the objects attacked. This numerical deficiency induced Latreille in his 'Familles Naturelles' to unite this insect with several other groups into a separate tribe which he termed *Membranaceæ*, but the *Cimex lectularus* is distinguished from all the insects with which it was thus associated, by the slender thread-like terminal joints of the antennæ, a character of some importance in the classification of the Linnæan *Cimices*. Fabricius states that the mouth is unfurnished with any lip, but we have distinctly perceived this organ at the external base of the rostrum, in the form of a small and flattened nearly oval plate. The tarsi of the cimex are three-jointed, in which respect it likewise differs from the other membranaceæ. In respect, therefore, to the structure of this insect, we find numerous characters which throw considerable difficulties in the way of its classification amongst the other species of the Linnæan geuns. Fabricius has introduced much confusion into the nomenclature of these insects, by applying the term *Cimex* to other species, and by placing the *Lectularius* in his genus *Acanthia;* this improper application of names, although not adopted in France and England, is still pursued in Germany, where the Fabrician system was most deeply rooted. The original English name, as we learn from Mouffet, was likewise different from that now universally given to this insect, which in his time (1634) was termed wall-louse, and Messrs. Kirby and Spence suggest that the term bug, which is a Celtic word signifying a ghost or goblin, was applied to them after Ray's time, most probably because they were considered as "terrors by night;" hence, our English word bug-bear: and in like manner the passage in the Psalms, "Thou shalt not be afraid for *the terror* by night," (xci. 5,) is rendered in Matthew's Bible "Thou shalt not nede be afraid of any *bugs* by night."

Southall in his treatise upon the Cimex Lectularius, published at Ipswich in 1793, and which reached a second edition, states that the first appearance of bugs in London, occurred after the great fire in 1666, "which learned men," says he, "united in thinking were imported with the new deal timber, as the bugs were naturally fond of turpentine woods." That the latter circumstance took place is perhaps perfectly correct*; indeed, Linnæus was of opinion, that this insect is not originally a native of Europe, and that it was imported from America; but there is abundance of evidence to show that they were known in England before the great fire, since Mouffet records the circumstance which occurred in 1503, of a Dr. Pennius being called in great haste to visit two noble ladies, residing at a little village called Mortlake, on the banks of the Thames, who were greatly alarmed by the appearance of bug bites, which were considered as symptoms of the plague or some such contagious disease, and whose fears were only dispelled by the capture of the insects and the statement of their physician, who happened also to be a naturalist. As a native of Europe it has been known for centuries, being noticed by Aristotle (Hist. liv. 5. chap. xxxi.) under the name of Coris, by Galen, Dioscorides, Pliny, &c., who state the medical virtues which it was supposed to possess, especially as a remedy against the bite of serpents. It was also applied in numerous other diseases, as we learn from Mouffet, who has collected the learning of the ancients and of the middle ages upon this and other similar subjects. The medical student of the present day will smile at learning that twelve live bugs taken fasting (four per diem) was an approved remedy against the colic. Whether the apparent rarity of these insects in England was the result of the superior cleanliness of its inhabitants over those of France, Germany and Italy, as Mouffet states, may, perhaps, indeed be doubted; certain it is that it now thrives in our climate as well as elsewhere, sometimes, especially when unmolested, swarming to a most intolerable degree, not only in inhabited but also in empty houses, getting under the wainscotting, &c., where it appears strange that it should be able to obtain nourishment. A precisely analogous case, however, occurs in the musquito and some other bloodthirsty insects, which, although they are exceedingly tormenting, must, from their place of residence being in damp, marshy, and unfrequented situations, for the most part be totally unacquainted with what appears their natural food. So, in like manner, we are informed by Oedmann, in the New Transactions of the Academy of Sciences of Stockholm, that it is a prejudice amongst the country people in Sweden, that the house bug resides in the common yellow wall lichen which grows on juniper bushes, &c., but that no entomologist ever yet found the real house bug in standing trees; and he proceeds to detail some circumstances which appear to prove that these insects are occasionally resident in trees, stating that some workmen in the month of August, whilst engaged in cutting wood in Namdo Sound, aroused a bat which flew out of a hole in a hollow elder tree: searching for more, the workmen hit the tree violently, and a mass was heard to drop, which on being pulled out consisted merely of bugs; it was impossible that they could be deceived with such well known vermin; moreover, they found beneath the wings of the bats real bugs in addition to the usual insects which infest those animals. The whole quantity of bugs amounted to about three quarts. M. Blix, examining this phenomenon, found in the bottom of the hollow tree two nests of bats, formed of straw and soft earth; and

* "A sort of prejudice exists in England, and particularly in London that while all old houses swarm with bugs, the newly built ones are exempt from this execrable annoyance; in no part of the metropolis, however, are those noxious insects to be met with in such abundance, as in the new houses erected in the Regent's Park, into which they have been introduced in the American timber employed in their construction. On examining the timber as it comes from the ship, it will be found that the bugs absolutely fill up the crevices."—*Monthly Mag.*

afterwards, on examining the roof of another hollow tree, from which he had driven thirty-seven bats with a stick, its extremity was covered with bugs. At Christmas neither bats nor bugs were to be found in this tree, which had been also inhabited by woodpeckers and squirrels, the bugs having probably been carried from some habitation by the bats, and having been found in company with them in the former instance on an uninhabited island. It may be asked, how so many bugs could have been nourished upon so few bats, even supposing that they were really parasitic upon them; but stone-buildings are occasionally infested with bugs although uninhabited for a year, and yet the numbers have not been lessened; hence Oedmann supposes that they eat one another when they have no other nourishment, their loss being supplied by their great multiplication. In confirmation of which, M. Carlson adds, that, in 1777, he found an old rotten stake, which had been used as a hedge-stake, and not in or near either house or building, so covered with bugs, that it resembled an ant-hill; it was not hollow, and therefore could not be inhabited by bats; he therefore concludes that they live and propagate even in timber; they also bear the winter cold, as he placed a piece of furniture in the open air for three winters, and every summer bugs were observed upon it in great numbers.

It would appear that there are several species of these insects. Fabricius, after describing the common European species as never occurring with wings, adds another species, under the name of *C. hemiptera*, having rudiments of wing-covers, and inhabiting the houses of South America.

Southall, who tells a marvellous story of his journeying to the West Indies, where he was tormented with bugs, and of his meeting with "an ancient black negro, very clean," who informed him that his cleanliness was owing to his being free from bugs, describes and figures the American bug, which is somewhat larger than our common species. Latreille also states that the latter has been asserted occasionally to acquire wings. It also infests young pigeons, swallows' nests, &c.; but those which live upon the latter bird appeared to him to form a distinct species. More recently, at the meeting of German naturalists at Breslaw, a winged species was described under the name of *Cimex domesticus*. According to Southall, these insects are eleven weeks in attaining their full growth, and they spawn four times in a year.

Numerous remedies have been from time to time proposed by various writers for the purpose either of driving away or killing these insects, which are almost as notorious for their disagreeable scent as for their annoying propensities. Of these remedies, Mouffet gives a long list; Mr. Brande has given another in the index to the Materia Medica. We have known that an uninhabited house which swarmed with these insects has been completely cleared by a powerful fumigation of brimstone. And Southall, who obtained from his "ancient black negro" the secret of making a fluid for the prevention of bug bites, states it to have been made by boiling several strong herbs, as herb Robert, cormint, &c. in water, and adding corrosive sublimate and sal ammonia; this liquid being applied with a sponge to furniture, &c. Our readers will, perhaps, smile at this statement, and inquire how the negro had gained a knowledge of English herbs, and the other substances employed, and will probably be inclined to think the whole story to savour rather of quackery. We will only add, that these remedies are, for the most part, either insufficient or dangerous, and that by carefully examining furniture infested at the commencement of the spring, and by strict cleanliness, they will either be entirely destroyed, or their numbers considerably reduced.

But if our common species, which does not exceed a sixth of an inch in length, be able to produce such annoyance, how much greater must be the torment caused to the inhabitants of Chili by a winged insect called benchuca, in shape and form like our common species, but of the size of a cockchafer. This species conceals itself by day in the thatch and cane roofing of the houses, and sallies forth at night in quest of food. They annoy people much after the manner of our bug, but from their great size are terrific enemies. They are thin and flat like the common bug, but after satiating themselves with blood, of which they take as much as the medicinal leech, they become quite round. St. Pierre likewise, in his Voyage to the Isle of France, mentions a species of bug found in that island, the bite of which is more venomous than the sting of a scorpion, and is succeeded by a swelling as large as a pigeon's egg, and which continues for four or five days.

In speaking of the paucity of the species belonging to the genus *Cimex*, the student will understand that we refer to the restricted group adopted by modern entomologists. The Linnæan genus comprises several hundred species, which together compose the section *Hemiptera geocorisa*, or the families of land bugs, the majority of which are furnished with ample-sized wings and wing-covers; the latter, however, instead of being of the same substance throughout, as is the case in the beetles and grasshoppers, are opaque and coriaceous, or leathery, at the base, and membranous at the extremity, the two parts being separated by a strong nerve. They also differ from the beetles in the nature of their transformations; for, whilst the latter pass the intermediate state between the grub and beetle—namely, that of the pupa—in a quiescent state, the bugs are active throughout the whole period of their existence. It is true, however, that they undergo a series of changes perfectly analogous to those of the beetles. Thus, during the early portion of their lives, they shed their skins several times, by which means they are enabled to increase in size; they then again shed their skin, when a pair of short rudimental wing-covers are seen upon the back, which, at the next moulting, are developed into a large pair of wing-covers, concealing a pair of delicate wings. The *Cimex lectularius* undergoes these changes as well as the winged species, but in it the development of the wing-cases is not perfected. This insect is devoured by another Linnæan species of *Cimex*, viz., *Reduvius personatus*, so named from the covering of dust, &c., beneath which the larvæ is masked.

BUGLE is the *Ajuga* (a yoke) of Linnæas. A family of herbaceous annuals and perennials, containing eleven species, four of which, and two varieties, are inhabitants of Britain. They belong to the natural order *Labiatæ*, and though all wild, are rather handsome flowering plants.

BUGLOSS is the *Anchusa* (paint for the skin) of Linnæus. A genus of annual, biennial, and perennial herbs, chiefly natives of Europe. They belong to *Pentandria Monogynia*, and to the natural order *Boragineæ*. The common bugloss, *A. officinalis*, or ox-tongue, and the evergreen, *A. sempervirens*, are natives of Britain; the former resembles, and possesses nearly the same qualities as Borage. Its root was formerly used for giving colour to the lips and cheeks of those who were told they were sick or too pale. The flowers secrete honey, which is eagerly gathered by bees. *A. tinctoria* is cultivated in the south of France for the roots, which give a fine deep red to oils, wax, and all unctuous substances, as well as spirits of wine. This is called Rhatany Root in commerce, and is much used by apothecaries for colouring plaisters, lip-salves, &c., and by vintners for staining the corks of their port-wine bottles, or for colouring the compound sometimes sold as port-wine.

BUGWORT is the *Cimifuga* (bug-driver) of botanists. A genus of four species (formerly called *Actæ*) of perennial herbs. The flowers are polyandrious, and the plants rank in the order *Ranunculaceæ*. Whether any of the species possess the virtue attributed by the name is uncertain; but the root of *C. serpentaria*, called Black-snake Root, is used, it is said successfully, by the native practitioners of physic in North America, for curing the bite of the rattlesnake.

BULBINE (Willdenow). A genus partly of bulbs, whence the name is derived. They have hexandrious flowers, and belong to the order *Asphodeleæ*. They are natives of the Cape and New Holland, and, like most of the bulbous plants from the same localities, are desirable ornaments for the green-house and conservatory, the flowers being both showy and fragrant. Their propagation is also easy, as they produce abundance of suckers. Linnæus, R. Brown, and Thunberg, ranked several of the bulbines with the anthericums.

BULBOCASTANUM is the specific name of the Earth-nut, given in English botany by Smith and Sowerby: noticed under its proper name.

BULBOCODIUM (a woolly bulb), so called by Linnæus. Of this genus there are two species; one Spanish, the other from the Crimea. They are hexandrious, and belong to the order *Melanthaceæ*. They flower only in the spring, and have much the appearance of a crocus.

BULIMULUS (Leach). A genus separated from Bulimus, which see.

BULIMUS (Lamarck; Helix, Linnæus), or more properly Bulinus, Mr. Broderip having pointed out the propriety of correcting the orthography, it being evidently a typographical error in Scopoli's work, which has been copied by subsequent writers. Of this beautiful genus of molluscs, all of which are terrestrial, some were blended by Linnæus in the genus *Bulla*, and others with the genus *Helix*, from which they essentially differ in several points, and particularly in never being of an orbicular shape. The animal, it is true, in every part of its organisation, resembles that of the common helix; but the structure of the shell being altogether different, it must necessarily be separated from either the genus *Helix* or *Bulla*. This mollusc is ovate, oblong, or spiral, more or less ventricose; sometimes subturriculated; the summit of the spire obtuse; the last whorl larger than all the others united; the aperture entire, longer than wide; margin very unequal; the columella straight, smooth, not truncated, or widened at the base; and when the shell has attained maturity, a reflected lip is formed, thickened round its circumference on the right side, and frequently nearly covering the umbilicus on the other. In the *B. ovata*, the type of this genus, the outer lip has a thickened callosity at the junction of the columella, not noticed by Lamarck. These molluscs have no operculum; their substance in some species is extremely fragile; and in a young state the margin of the aperture is smooth and sharp; all of them are oviparous; and the eggs of some species are nearly as large as sparrows' eggs. Many of the species are sinister, or with the whorls turning towards the left hand, of which such as have the aperture pointed at the two extremities have been formed by Gray into his genus *Balea;* and of the species which are slightly umbilicated, Leach has formed his genus *Bulimulus.* De Blainville does not, however, admit of sufficient reason to separate them, and consequently merely forms a subdivision of them; his arrangement now stands in a well defined and simple order as follows:—the first, oval and of the ordinary form, as in the *B. hæmastomus;* secondly, the ventricose or bellied species, *B. ventricosus;* thirdly, such as are turriculated, as in the *B. calcareus;* fourthly, *B. citrinus* (*Balea* of Gray), nearly all the species of which are heterostrophe or left-handed; and lastly, such as are slightly umbilicated, forming Leach's *Bulimulus*, the type of which is *B. trifasciatus*.

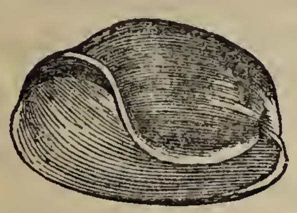
These molluscs constitute a genus very generally found in almost every part of the world, from the torrid zone to the frigid regions; in the former, as with every other species of molluscs, they are larger and more beautifully coloured, and among them will be found the lemon, amber, and sea-green colours, so rarely found as a pigment in other testaceous shells, if we except some species of the helix, their immediate congenors. They are more commonly found in islands, or on the margins of the sea, than in the interior of the land; and as far as their habits are known, the animal perfectly resembles the common snail.

Lamarck enumerated fifty-four recent species, but from the present arrangement the number is more limited; of the fossil species about forty have been described. De Blainville places this genus in his second class *Paracephalophora*, first order *Siphonobranchiata*, and the family *Limacinea*, or *Helix* of Linnæus.

The derivation, given by a modern writer, of bulimus from *voracious*, for the reason above given, now falls to the ground, and none has been offered for bulinus.

BULLA (Lamarck, Cuvier). This genus of molluscs, as constituted by Linnæus, included a great variety of the most opposite genera, which by Lamarck and other modern naturalists have been removed from it, and separately classed in natural groups, under the names of *Bullæa*, *Ovula*, *Achatina*, *Physa*, *Terebellum*, and some are comprised in the genera *Pyrula* and *Bulinus*. The great confusion that formerly existed in consequence of the manifest incongruity of blending together marine, freshwater, and land shells is now obviated, and a clearly defined and natural association of species formed, each possessing characters easily distinguishable, and Bulla may now be described with one consistent family character, perfectly unlike all other shells with which it was intermingled by Linnæus. This mollusc is an univalve, of an oval form, more or less globose, as it were rolled up loosely, having no columella, and being without a visible spire in most of the species; the large external whorl elevated above the others, giving an umbilicated appearance to the upper part of the shell; the aperture is open the whole length of the shell, and usually wider at the base; the outer edge sharp and smooth; it sometimes attains a considerable size, and is very prettily clouded with red or ash-coloured markings, broad pink, and black bands or fine lines. The type of the genus *B. lignosa* is of a straw colour, and elegantly marked with hair-like lines running spirally; and the animal possesses a very singularly formed testaceous substance within its body, not noticed by Lamarck, and familiarly called by English collectors the gizzard. The animal inhabiting the bulla has an oblong oval body, thick and obtuse at the extremities, which are formed of two parts, the posterior entirely covered by the shell. with the edges of the mantle thickened in front, but particularly so, backward on the left side, where it forms a lobe bordering the aperture; the anterior more considerable, provided on the right and left with a swimming enlargement of the foot; the head indistinct, with two inconsiderable labial appendages, two sessile eyes very distinct, and behind these a pair of tentacules prolonged on the lateral parts of the neck.

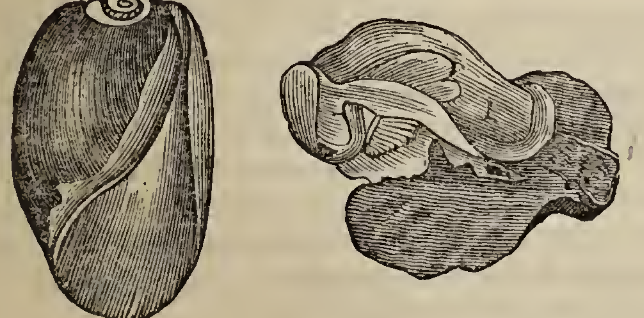
De Blainville places the bulla in his second class *Paracephalophora*, third order *Monopleurobranchiata*, fourth family *Acera*, and he arranges the species in the following order:—first, such species as are closely convoluted, with the spire visible and projecting externally, the aperture very narrow backward, as in the *B. jonkaria*, here figured, and forming the genus



B. jonkaria.

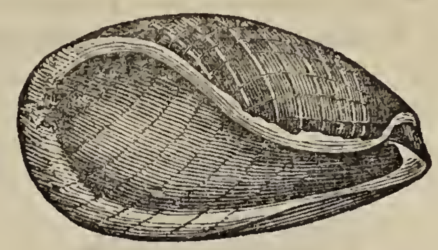
B. aplustre.

Aplustre of some autnors; secondly, the species that are completely convoluted, rotund, the spire very distinct, but not projecting, with a sort of thickened band at the anterior part of the columella edge, as in the *B. aplustre*, here figured; thirdly, such species as are of a thicker substance, very completely convolved, the turns of the spire scarcely visible in an umbilicus more or less deep, projecting inwardly, as *B. hydatis*, in the figure; fourthly, the species that are thin, ventricose, the turns of the spire externally visible, but not projecting, with a suture, as if channelled, and without any thickened band on the columella side, as in the *Bulla naucum*; fifthly, the species extremely thin, much involved, the turns of the spire distinct within and without, the suture deep, angular,



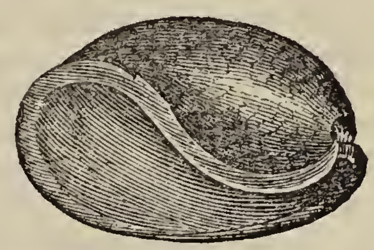
B. fragilis.

and channelled the whole or part of its length as in the *B. fragilis*, here figured; sixthly, the species in which are much more involved than the others, and without the spire being visible internally or externally, as in the *B. lignaria*, figured below; and lastly, the internal species, which are very thin, convoluted, with a



B. lignaria.

nal species, which are very thin, convoluted, with a slight commencement of becoming rolled at the origin of the left lip, as in the *B. aperta*, here figured, constiuting Lamarck's genus *Bullœa*.



B. aperta.

De Blainville has thus united Lamarck's genus bullœa to the bullæ, the propriety of which we do not admit, as the reasons which led to their separation remain unshaken. In the first place, the genus bulla is never an internal mollusc, and can altogether recede within its covering. The animal is also attached to its shell by a muscle, while, on the contrary, the bullœa is totally enveloped in the mantle of the animal, not visible externally, nor attached to the shell by any muscle; to which may be added, that the thickness, colouring matter, and more regular convolutions of the bulla, seem to mark it most distinctly as a separate genus. It is true they are both said to be carnivorous, and to swallow bivalve molluscs, but the evidence of that circumstance appears to want confirmation.

These shells are found in all climates, but the most beautifully coloured are from the warmer latitudes. Lamarck enumerates eleven recent species, and about ten fossil have been described by different authors.

The derivation of the name of this genus is obviously from a bubble, which their inflated appearance and slight texture greatly resembles.

BULLACE TREE is the *Prunus insititia* of Linnæus. This is a useful fruit-tree, and often found wild in the hedges about old farm houses. Why it should be called *insititia* (grafted) is not explained, as it propagates itself by suckers as easily as its congener, the sloe. Indeed, the bullace seems to be only an intermediate variety between the sloe and the damson plum, being much better and larger than the first, though not so large nor so good as the last. A bullace pie is a standing dish at the harvest-home supper in the south of England; only, it requires rather more sugar than the housewife is always willing to allow.

BULLFINCH. See PYRRHULA.

BULLŒA (Lamarck). This mollusc has been separated from the genus *Bulla*, for reasons which are stated in the description given under that name. The type of the genus and the only species known to us, as being exclusively *an internal shell*, without spire or columella, and involved or turned so loosely round from its origin, is the *B. aperta*, figured p. 643. De Blainville indeed has added to the genus thus characterised by Lamarck, two other species, the *B. ampulla* and de Ferussac's *Bullæa*,

B. ampulla.

distinguishing the inhabitant of these species either with an external or internal shell, by having the foot thicker, not dilated into swimming appendages, and possessing in fact distinct habits from the bullæ, which swim with great freedom, while the bulloea climb well and swim badly. We are not, therefore, disposed to adopt his classification in this instance, and consider the *B. aperta* as a well defined species, quite distinct from those added by de Blainville, though upon reasonable grounds. We shall endeavour to point out in the proper places of this work, that a peculiar character attaches to internal shells, which may be traced in a connected series, from such as are quite or nearly flat, as in the genus *Umbrella*, to such as are like the present genus and the bulla, and we think to prove satisfactorily that in most cases climate and the force of habit, or the necessities of nature, have led to the peculiar configuration of each, never presuming, however, to arrogate to ourselves the power of accounting for the wisdom of the Great Creator of all, beyond reasoning by the light of analogy and our own finite understandings.

BUMELIA (Swartz). A genus of West Indian shrubs and trees, consisting of fourteen species, belonging to the natural order *Sapoteæ*. Some of them are timber trees, and they mostly have fine foliage, but their flowers are inconspicuous.

BUNIUM (Linnæus) is the earth-nut of the provinces; a very common tuberous-rooted plant in some places, eagerly sought and eaten by hogs. The flowers are pentandrious, and are produced in umbels; of course the plant belongs to the order *Umbelliferæ*. The foliage is attenuated, much divided, and lies close to the ground. The tubers are about the size of hazel nuts, and may be eaten raw. They have a sweetish nutty flavour, and are said to be very nutritious. They are also used either boiled or roasted; and in Italy are called ground chestnuts.

BUNTING. See EMBERIZA.

BUPALUS (Leach). A genus of moths belonging to the great family *Geometridæ*, or Loopers. This genus was proposed by Dr. Leach in the Edinburgh Encyclopædia, and was characterised by the antennæ of the males being pectinated, the body slender, the palpi slightly hirsute, and the wings horizontally extended, and neither angulated nor indented. The type of the genus is the *Phalæna Geometra Piniaria* of Linnæus, or the bordered white of English collectors, a pretty species, about an inch and a half in expanse, with dark brown wings, having a large basal whitish spot, and another towards the anal angle of the upper wings of the same colour; the lower wings (except the outer portion) are whitish, with two irregular brown bands. This species frequents fir plantations, but it is by no means a common species, especially in the metropolitan district. We have taken it on Porstsdown Hill, near Portsmouth, the ridge of which is ornamented with rows of firs, which form so conspicuous an object from the opposite coast of the Isle of Wight. It is indeed fortunate that it is thus rare amongst us, since it will be seen, from the following account, that it is capable of committing considerable ravages. This communication is extracted from a report addressed by the inspector of forests at Strasbourg to the bureau of the administration of woods and forests at Paris, and is published in a recent number of Silbermann's Révue Entomologique. —"At the end of 1832, a malady occurred amongst the fir trees in the forest of Hagenau, one of very considerable extent, near Strasburg, extending over 7000 hectares. The firs, covering a space of about forty hectares, were observed to have their leaves of a yellow colour, and of a dried appearance. The cause of this malady was at first sought for in vain; but during the following year, it was so much increased, that more minute researches were made, and it was at length discovered that it was owing to the attacks of the larvæ of the bupalus, which commenced its ravages at the commencement of the month of May, passing from tree to tree until the month of October, when it descends to the ground to undergo its chrysalis state. The hundred hectares attacked in 1832 are now entirely destroyed without hope of future vegetation." In conclusion, the inspector calls upon entomologists to suggest plans for preventing the extension of so serious a damage.

BUPHAGA (*pique-bœufs* — cattle-pecker). A genus of birds, belonging to the *conirostral* division of Cuvier's great and miscellaneous order *papeus*. The name of this bird has been sometimes given in English as the *beef-eater*, but that is a mistake. It does not eat "beef" in our sense of the word, that is the flesh of dead cattle, and a bird not the size of a thrush can hardly be expected to eat live oxen in the field. The fact is, that it eats the eaters of the live flesh of the ox tribe and the other large ruminant mammalia. In the central parts of Africa, of which this bird (for there is only one species) is a native, these animals are terribly infested by insects which deposit their eggs in the skin, and leave them to be hatched by the heat of the animals; and these birds diligently resort to the animals which have their backs filled with the larvæ of these insects, dig them out and eat them. The only species is *B. Africana*, about the length of a song-thrush, but more slender in the body. It has the bill well formed for the particular office which it performs. The basal part is cylindrical, there it enlarges toward the tip, which terminates in a blunt point. Thus they are calculated to make an opening into the tumour occasioned by the larva, sufficient to draw it out, and also to lay hold of it and extract it with much more certainty than if they were of smaller dimensions and sharper at the points. The opening also prevents that inflammation and suppuration which are said to attend the presence of the larva in that warm climate.

BUPRESTIDÆ (Leach). A splendid family of coleopterous insects belonging to the section *Pentamera*, and sub-section *Serricornes*, or those which have the antennæ serrated, and not terminated by a club, and corresponding with the Linnæan genus *Buprestis*, of which upwards of a thousand species are known in collections.

The two Linnæan genera, *Buprestis* and *Elater*, are nearly related to each other, and compose a division termed *Sternoxi*, from having the prosternum terminated in an acute spine, and the body is of a firm consistence, with the head immersed to the eyes in the prothoracic cavity. In the latter of these two groups, this prosternal spine becomes of essential service to the insect, being employed, in conjunction with a corresponding cavity in the front of the mesosternum, to effect those singular leaps which have given to the Elateridæ the common name of Spring Jacks. The Buprestidæ, on the contrary, are destitute of this power, being unable to leap; since, although the prosternum is produced behind into a spine, there is no corresponding cavity for its reception as in the former. The latter family is further distinguished from the Elateridæ by having the jaws short, strong, and entire at the tip, and the terminal joint of the maxillary palpi either nearly cylindric or oval. The body of these insects is generally oblong, or oblong oval, and narrowed behind; and the penultimate joint of the tarsi is bilobed.

These insects are, for the most part, inhabitants of tropical climates, where the splendour of their metallic colouring corresponds with the richness of the flowers and the brilliancy of the butterflies. Very few species are found even in the central portion of Europe, and in England scarcely more than half a dozen can be considered as really indigenous. They are found upon trees, creeping but slowly, although they fly well in the hottest sunshine, taking flight with great facility; when in danger they have no other means of escaping from their adversaries, than to fold their antennæ and legs along the body, and drop from the branches upon which they ordinarily rest, into the grass. We believe no authentic account has hitherto been published of the economy of these insects in the larva state, considering that the statement of Madame Merian relative to the transformations of *B. grandis*, an inhabitant of Surinam, to be very unsatisfactory. It is probable, however, that they reside in timber in their early states, since the perfect insects are often found in timber yards and other places where quantities of wood have been placed. Another circumstance which corroborates the opinion that the larvæ feed in timber, is the great length of time which some of them are recorded to have passed previous to assuming the perfect state, and which is known to be the case with other xylophagous insects, as the *Prionidæ*, &c.; thus one of the most remarkable instances of insect longevity is recorded in the tenth volume of the Linnæan Transactions, in which it is stated by Mr. Marsham, that a Mr. Montague, on going to his desk in the Office of Works at Guildhall, London, observed an insect which had been seen by his brother in the early part of the day, endeavouring to extricate itself from the wood which formed part of the desk; he carefully released it from the cell, and it proved to be the beautiful *B. splendens* of Fabricius, full of strength and vigour. The desk had been fixed in the office twenty-two years before, and was made of fir wood imported from the Baltic. That the insect existed in the wood before the desk was made, was proved by the fact, that the channel formed by the insect had been then transversely cut.

These insects have been designated *Richards* by Geoffroy, a name originally given to the Jay, in consequence of the facility with which that bird was taught to pronounce the word; and the French Entomologist, from a fanciful analogy between this group of birds and insects, gave to the latter the same name as the former, because, says he, "les pays étrangers en fournissent de très-grandes et tres-brillantes espèces; c'est ce qui nous a porté à donner le nom de Richard à cet insecte." In fact, nothing can exceed the brilliancy of colour of some of the species, some of which have a general coppery tint, whilst others present the beautiful contrast of fine yellow or flame-coloured spots or lines, on a polished blue, green, or bronzed surface, and others exhibit the appearance of burnished gold, inlaid on emerald or ebony. In fine, all that is rich and brilliant in colours may be observed in the decoration of these insects. The females have a coriaceous appendage at the posterior part of the abdomen, composed of three pieces; this is probably the oviduct with which they deposit their eggs in crevices of old wood and trees. Their existence in their perfect state appears to be short, and is devoted almost exclusively to the great object of continuing the race.

The systematic name of these insects has likewise been involved in some confusion. By Linnæus, whose nomenclature has been adopted by all entomologists, they were inappropriately termed buprestis. This name, as well as the synonymous one of *Vulprestis*, was employed by the Roman naturalists, and that of *Voupristi* by the Greeks, to designate a noxious insect, which possessed such irritating powers when taken internally, that cattle, which accidentally swallowed them when feeding upon grass, died of inflammation in a short time, the insect acting as poison to them. Indeed so powerful were the effects of the application of this animal, that we find that legislative enactments were passed respecting it; the Cornelian law punishing with death those who should with malice prepense administer either it or the insect called *Pithyocampa*, having similar powers:—"Qui buprestem vel pityocampem, tanti facinoris conscii, aut mortiferi quid veneni ad necem accelerandam dederit, judicio capitali et pœna legis Corneliæ afficiator." According to Pliny, this insect was rare in Italy, and resembled a scarabæus with long legs. Now this insect, it would seem, was regarded by Linnæus as one of those to which he gave the name of buprestis; but these, as Messrs. Kirby and Spence observe, being timber insects, are not very likely to be swallowed by cattle with their food. Mouffet, on the other hand, followed by Geoffroy, regarded the ancient buprestis as a species of ground beetles, *Carabus*, giving to the Linnæan buprestis the name of *Cucujus;* the former insects, however, seldom or never frequent pastures. The larger species of carabi are rare in the south of Europe, and even did they exist there, they are found upon the ground under stones, and are sufficiently agile to escape from the murderous jaws of the cattle. Moreover, from several passages in the old writers, it is evident that these buprestis were vesicatory beetles; and M. Latreille, in an extended memoir which he has published on this subject, in the "Mémoires du Museum," has endeavoured to prove that they are referrible to the modern genus *Meloe*. The same author has more recently stated that Dr. Boisduval has employed the meloes as vesicants, and has ascertained that they possess greater energy than the common cantharides of the shops. Belon, nevertheless, in his

Voyage to Greece and the other Countries of the Levant, states that the insect named voupristi by the inhabitants of Mount Athos is able to fly, that it emits a strong and fetid odour, that it resembles a cantharis, but that it is larger, of a yellow or buff colour, and that it is often found upon chicoraceous plants. Now these characters indicate a species of mylabris rather than a meloe, whence Latreille is induced to regard the ancient buprestis and voupristi is two distinct species of insect. Messrs. Kirby and Spence, on the contrary, consider the insect of Mount Athos (which is so noxious that when horses or other cattle even feed upon the herbs which the insects have touched, they die from inflammation, and which is an immediate poison to oxen) to be the buprestis of the Greek writers, and as Pliny usually compiled from them it may be regarded as his also.

In the second edition of the Règne Animal, Latreille divided this family into five sections.—First those with dilated tarsi and antennæ simply serrated. Of this section, which comprises the majority of the family having simple antennæ, some of the species are furnished with an evident scutellum, as *B. fasciculata* from the Cape of Good Hope. *B. vittata* and *scutellata* from India, &c.,—others are destitute of a scutellum, as *B. grandis* from South America. Some species of a linear shape, including several British insects, compose the genus *Agrilus* of Megerle; whilst others, of a short and nearly triangular form (some of which are likewise British) form the genus *Trachys* of Fabricius. Another genus, *Aphanisticus*, also British, is distinguished by its clavate antennæ. The second section, having the antennæ comb-shaped, and the tarsi nearly cylindric, comprised only the genus *Melasis* of Olivier, the type of which is likewise found in England. Since the publication of this work, however, the family has undergone revision by several authors, who have divided the species into numerous generic groups. The memoir of M. Eschscholtz, in his "Zoologischer Atlas" of M. Solier, in the "Annales de la Sociéte Entomologique de France," and the new catalogue of the Baron Dejean, may be especially noticed; but as all these new groups rest merely upon structural distinctions, without any facts relative to their economy having been added in support of their establishment, we shall not further notice them, especially as they are for the most part composed of rare and exotic species in the possession of very few entomologists.

BURCHELLIA (R. Brown). A genus named after W. Burchell, a traveller in Africa. There are two species, *Bubulina* and *Capensis*. The flowers are pentandrious, and belong to the natural order *Rubiaceæ*. The *B. capensis* is a beautiful shrub, with scarlet flowers in terminal clusters.

BURDOCK. That is, bear-dock; the *Arctium* of Wildenow. A large coarse looking plant, common on hedge banks, and sides of high-ways. The hooked scales of the calyx fix the burs on the fleeces of sheep, or on garments made of wool. The seeds are food for birds, but no domestic animal except the ass will eat the leaves. The peeled stem, while tender, may be eaten as salad, and the green plant by calcination yields a fine alkaline salt.

BURMANNIÆ. A natural order of monocotyledonous plants, containing three or four genera. It is not very closely allied to any known monocotyledonous order, but seems to approach nearest to the *Hæmodoraceæ*, or blood-root tribe.

Its characters are: flowers hermaphrodite; perianth adnate with the ovary, coloured; membranaceous, with six teeth, of which the three outer have a wing or keel at their back, while the three inner are minute; stamens three, inserted into the tube opposite the inner teeth; anthers sessile, two-celled, opening transversely; ovary inferior, three-celled, many seeded; style single; stigma three-lobed; capsule covered with the withered perianth; seeds minute and streaked.

The plants of this order are herbs with tufted radical acute leaves, and terminal sessile flowers. They are mostly tropical, and are natives of the main regions of Asia, Africa, and America. Their proparties have not as yet been investigated.

The principal genera are: *Burmannia, Tripterella,* and *Maburnia*. *Burmannia biflora* is a delicate little plant, with pale pimple flowers, found in the swamps of Virginia. *Tripterella capitata,* with its slender threadlike stem and capitate white flowers, grows in wet places, and on the borders of ponds, in Lower Carolina.

BURNET is the *Poterium* (infused in drink called cool-tankard) *sanguisorba* of Willdenow. This is a British plant, and there are two other species found in Spain and Hungary. The flowers are unisexual, and the genus is placed in the natural order *Rosaceæ*. The generic character is, barren flowers—calyx of four leaves; corolla in four divisions; stamens thirty to forty; fertile flowers—calyx of four leaves; corolla four-clefted; seed-vessels two; fruit two-celled, invested with the calyx. Burnet occurs frequently in the south of England, and has long been employed as an agricultural plant, to mix with permanent grasses in laying down pastures. It continues to grow during winter, with more vigour than any other pasture plant, and hence it gained a character which it really does not deserve. The fact is, it is not relished by either horses, cattle, or sheep; and therefore when other plants are closely grazed off, this remains in tufts untouched. It is said to be particularly palatable to deer, and if so, should be introduced into deer-parks. It is a favourite salad plant on the continent; and as we have already stated, is sometimes used in this country like borage for adding flavour to the beverage called "cool-tankard." The leaves when bruised smell like cucumbers, and taste somewhat like the parings of that fruit.

BURNET SAXIFRAGE is the *Pimpinella* of Linnæus. A family of European weeds, only noticed by botanists. The flowers are pentandrious, and the plants belong to the natural order *Umbelliferæ*.

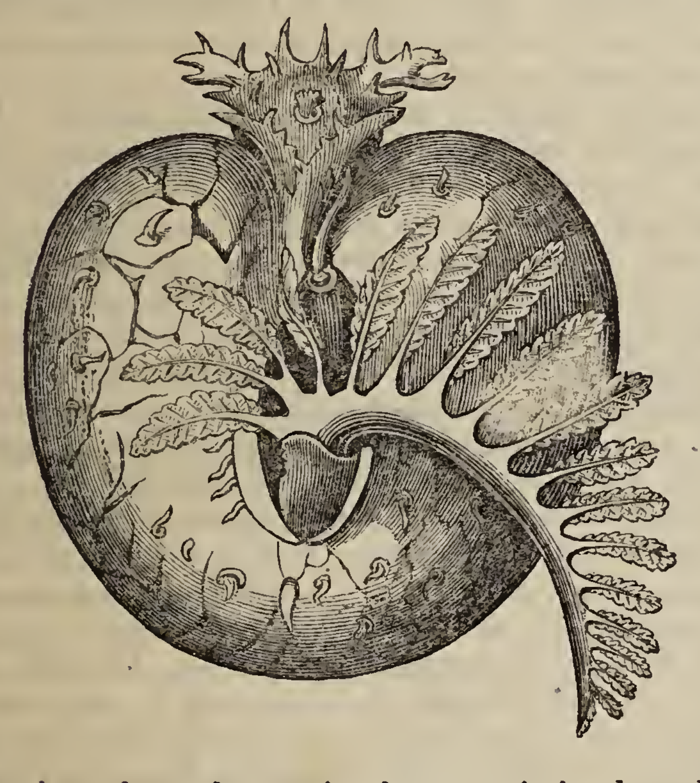
BUR REED is the *Sparganium simplex* of Willdenow. It receives its generic name from the riband-like shape of the leaves. The flowers are unisexual, both males and females sticking like burs upon the reed-like stems. All the species are found in England, and in many other countries, both in warmer and colder latitudes. The *S. ramosum* is a luxuriant growing plant, and troublesome in pools or water courses required to be kept clean.

BURS (Cammerson). A genus of spinous finned fishes, belonging to the lancet-fish family, or those which have their bodies armed with spines capable of inflicting severe wounds. They are all inhabitants of the warm seas, and feed chiefly if not entirely upon vegetables. The ventral fins of this genus have the external and internal ray in each spinous, and the three intermediate ones articulated. They have five rays in the gill-flaps, and a strong spine placed in front of the dorsal fin. The etyloid bones of the shoulders are produced and reversed, till they are attached by their extremities to the interspicuous rays of the anal fin. The species are very numerous, and they have been differently varied by different authors. They are the genus *Ampharanthus* of Black, the *Antrogastri* of Houthryn, and in part the *Sheutis* of Linnæus.

BURSARIA. A genus of the Linnæan class *Infusoria.* It is found in wet places, where stagnant water has for some time imbibed the infusion of animal or vegetable matter. It is not visible to the naked eye; but when examined under a powerful microscope, it appears a transparent membrane, excavated in the centre, with four laciniæ on the margins, of which the two lateral ones are equal and short, the anterior and posterior unequal and longer. They are mostly found in the months of July and August, in damp woody situations, near the Limnea. The *Bursaria hirundinella* is the only species described.

Under the article INFUSORIA, these wonderful proofs of Almighty wisdom will be more fully described.

BURSATELLA (Leach). A genus of molluscous animals established by Dr. Leach. It is very large, and inhabits the Indian seas. There is no trace of shell, and the animal is thus described:—the body sub-globular, the lower part offering an oval-formed space, circumscribed by thick lips, indicating the foot, the upper part with a thick edged oval slit, symmetrical and formed by a complete union of the swimming appendages of the mantle, communicating with a cavity in which are found a very large free branchia and anus, four divided and branched tentacules, besides two buccal appendages. The *B. Leachii,* here



figured, is the only species known; it is classed by de Blainville, in the *Paracephalophora,* third order *Monopleurobranchiata,* second family *Aplysiacea.*

BURSERA (Jacquin). Called after J. Burser, a botanist. There are two species, both lofty trees; one is common in the West Indies, which is called *B. gummifera,* from the great quantity of balsamic gum exuded by it; the other species is found in the East Indies. They belong to the natural order *Terebinthaceæ.*

BURSERACEÆ. Balm of Gilead tribe. A natural order of dicotyledonous plants, containing eleven known genera, and upwards of forty species. The *Burseraceæ* are closely allied to the *Anacardiaceæ,* or cashew tribe, but differ from them in their compound ovary and pinnated leaves. By many authors they are considered as a section of the *Terebinthaceæ.*

The essential characters of the order are: flowers hermaphrodite, sometimes unisexual; calyx, having from two to five divisions, persistent; petals varying from three to five, inserted below the calycine disk; stamens twice, rarely four times, the number of the petals; ovary two to five-celled, superior sessile; fruit, a drupe; seeds without albumen.

The plants included in the order are trees or shrubs, with alternate unequally pinnated leaves, and axillary or terminal flowers growing in racemes or panicles. They are natives solely of the tropical regions of Asia, Africa, and America, and are propagated by cuttings, layers, and seeds.

Most of the genera of this important order furnish fragrant balsamic resin, possessing more or less stimulating properties.

The genera are: *Bursera, Boswellia, Balsamodendron, Icica, Canarium, Colophŏnia, Protium, Hedwigia, Sorindeia, Garuga,* and *Marignia.*

Bursera, named after Joachim Burser, formerly Professor of Botany at Sara, in Naples, is the genus whence the order has been designated. *Bursera paniculata,* or *Colophonia Mauritiana,* called *Bois de Colophane,* in the Isle of France, yields, by incision, a copious limpid oily fluid, having an odour of turpentine, which, by drying, acquires a butyraceous consistence, and has somewhat the appearance of camphor. Like camphor, it burns with a vivid flame, and leaves no residuum. *Bursera gummifera* is a large lofty West Indian tree, with a fine leafy head, and a smooth trunk, covered with a thin brown or greyish epidermis, which peels off in shreds like the European birch; hence the tree is sometimes called *Jamaica Birch-tree.* It yields a resin called *chibou,* having an odour like turpentine. The balsamic fluid produced from this tree is used in America as an external application to wounds in the same way as the balsams of the East. The root, which is said to be bitter and tonic, and to resemble the *Quassia simaruba* in its properties, has been prescribed with success in various fluxes. Hedges are made of this plant by the Spanish residents in South America. *Bursera acuminata* yields a yellow concrete essential oil, which is not put to any particular use.

Boswellia, another genus of this order, has been named in honour of Dr. John Boswell, of Edinburgh. *Boswellia serrata,* of Roxburgh, *Libanus thurifera,* of Colebrooke, yields the gum resin called *olibanum.* This substance was formerly supposed to be the product of the *Juniperus Lycia.* It is said to ooze spontaneously from the bark, and is collected in Arabia, and brought from Mecca to Cairo, whence it is imported into Europe. It is also procured from the East Indies. In commerce it occurs in the form of grains of different sizes, of a red or yellow colour, having a peculiar aromatic odour, and a bitterish pungent taste. With spirit it forms a transparent solution; but when triturated with water, it forms a milky fluid. It is inflammable, and is said to be the true frankincense of the ancients. It is still used as incense in Roman Catholic churches. It possesses stimulant, astringent, and diaphoretic properties, and was formerly prescribed in affections of the head and chest, in coughs, spitting of blood, and various fluxes. It was also employed in fumigations, as a perfume in sick-rooms, and externally as an application to wounds. It was formerly an ingredient of the famous Friar's balsam. It is now chiefly used in forming the frankincense plaister which is applied in cases of weakness of the large muscles, as of the loins. The resin of *Boswellia glabra* is used in India as frankincense, and is administered by the native practitioners in various diseases. When mixed with coarse oil, it is used for pitching ships. The wood of the tree is heavy, hard, and durable, and has been employed in ship-building.

Another genus of the order is *Balsamodendron*, which furnishes several important resinous substances. *Balsamodendron Giliadense* yields the liquid resin called Balm of Gilead. This tree grows in Arabia, on the Asiatic side of the Red Sea, near Mecca. It appears to have been cultivated in very early times, and frequent allusion is made to it in Scripture. Thus it is stated in Genesis, that the Ishmaelites who purchased Joseph "came from Gilead, with their camels bearing spicery, and balm and myrrh;" and balm is noticed among the substances which Jacob ordered his sons to take as a present to Joseph. The prophets, Jeremiah and Ezekiel, also mention the balm of Gilead as being held in high repute. Pliny states that this resin was brought to Rome by the generals of Vespasian. According to Josephus, the balm-tree was first carried from Arabia to Judea by the queen of Sheba, as a present to Solomon, where, being afterwards cultivated for the sake of its fragrant medicinal juice, particularly on Mount Gilead, it acquired the name of Balm of Gilead, or *Balsamum Judaicum*.

The balm is procured from the tree by incisions in the bark and branches, and also by the decoction of the leaves and young branches in water. It is furnished in very small quantities, and hence generally commands a high price when pure. It is very liable to adulteration. It has a strong pungent odour, an aromatic bitter and astringent taste, and, when fresh, is of a bright yellow colour. The balm was formerly highly esteemed on account of the many miraculous cures which it was said to effect. In Egypt it was looked upon as a panacea, and was prescribed in wounds, ulcers, poisonous bites, nervous and pulmonic diseases, as well as in affections of the stomach. It is still looked upon by the Egyptians as an antidote to the plague. Mahomet affirmed, that a grove of balm trees sprung up from the blood of his own tribe killed in battle, the juice of which cured the wounds of the faithful, however deadly. The wonderful properties ascribed to this resin are not entitled to much credit, and it is now nearly discarded from European practice, as being in no way superior to the balsams of Canada and Copaiba. By eastern nations, however, it still continues to be valued as a medicinal agent, and as an odoriferous unguent. In Turkey it is prized as a cosmetic. The Turkish ladies, after having been in a hot bath, anoint the face and breast with it, and repeat the process every third day for a month. Oil of almonds, and other cosmetics, are then rubbed over the parts, and thus the complexion is said to be greatly improved. Lady Mary Wortley Montagu tried this cosmetic, but suffered severely from the swelling, redness, and pain which it occasioned.

The dried fruit of this tree was formerly sold under the name of *Carpobalsamum*; it entered into the composition of the celebrated Mithridate. The dried twigs, called *xylobalsamum*, are burned in temples, and in the palaces of Sultans.

The balsam of Mecca is the product of another species of *Balsamodendron*, which has received the name of *Opobalsamum*. This resin is similar to the balm of Gilead, but is said to be purer and much more valuable. All the properties ascribed to the latter are said to reside in a still greater degree in the balsam of Mecca. The value of this balsam may be judged from the fact, that it is considered a great privilege of the Governor of Cairo to receive one pound of it yearly.

Balsamodendron Kataf, formerly *Amjus Kataf*, a native of Arabia Felix, appears to be the tree which yields the gum-resin commonly known by the name of myrrh, and which is imported into this country from the East Indies. Though this substance was well known to the ancients, and is frequently mentioned in Scripture, still great obscurity lies over the tree which produces it, as well as the mode in which it is procured. Myrrh is met with in commerce in the form of irregular, fragile, and semi-transparent grains of a reddish-yellow colour, having an agreeable odour, and a bitter aromatic taste. It consists of resin, essential oil, and gum. Alcohol extracts that part in which its bitterness, virtues, and flavour reside.

Myrrh was used for various purposes by the ancients. The native practitioners in India order it in cases requiring cordials. It is much more used in Britain than in France. In doses of six or ten grains it is tonic, promotes digestion, and increases the appetite. In larger doses it is stimulant, and is prescribed in asthma and chronic catarrh. It is often combined with other tonics, and with purgatives, such as aloes. In the form of tincture it is used as a gargle, as an application to foul ulcers, and as a wash for the teeth and gums.

Icica is another genus deserving notice. *Icica heptaphylla* furnishes the resin called *Elemi*. This resin formerly came from Egypt and Ethiopia, in masses of two or three pounds, wrapped up in palm leaves. It is now imported in tin cases from Brazil, New Spain, and the warm regions of America. The resin is got by incision into the bark, and occurs in semi-transparent masses of a yellowish colour, having a strong odour, somewhat like fennel, and a hot bitter taste. It consists of resin, a bitter extractive matter, and an essential oil, to which its odour is owing. It is a stimulant, and is chiefly used externally in the form of plasters and ointments. It is an ingredient in the balsam of *Fioraventi* and the liniment of *Arcæus*, or the compound ointment of *Elemi*. The resin got from two other species of icica, viz., *Icicariba* and *Carana*, is very similar to elemi, and is often mixed with it. *Icica heterophylla*, or *Acuchini*, furnishes the balsam of *Acouchi*. The exudation from *Icica Guianensis* is made into a varnish. This tree is called in Cayenne *Bois d'encens*. The stimulant tonic resin called *Tacamahac*, which is generally procured from the *Fagara octandra* and *Populus balsamifera*, is also obtained from one of the species of *Icica*.

Canarium commune, another of the *Burseraceæ*, is a resinous tree found in the Molucca Islands and New Guinea. It yields a balsamic substance similar to *Copaiva*. The nuts of this tree are eaten by the inhabitants of Java and Celebes, either raw, or made into a kind of bread, and an oil is expressed from them which is used as an article of diet, and also as a means of giving light. The nuts, when eaten raw, are said to be apt to produce dysentery. The fruit of the *Canarium oleifolium* is also eaten, and an oil is expressed from it. The bark of this plant, when wounded, yields a resin similar to copal, which is used as a varnish. The substance called *Damar*, in the East Indies, and employed for caulking ships, is made from this resin, mixed with powdered bark of bamboo and chalk.

The wood and juice of various species of icica and canarium are used for perfuming apartments, and burning in temples.

BUSTARD (*Otis*). A very interesting genus of birds, arranged by Cuvier as the first of his *Pressirostral* family of the order of *Echassiers*, "stilt," or long-legged birds; for a general account of which see the article Bird in this work.

The characters of the genus are these: they have the massive body of the gallinaceous birds, only their legs and necks are much longer in proportion. Like the gallinidæ, they have the bill of a mean length, slightly compressed, slightly arched in the culmen of the upper mandible, a little incurvated at the tip and projecting over the under one. They have also short membranes between the toes in the same manner as the gallinidæ. In other respects they, however, differ, and resemble more the other long-legged birds which frequent dry pastures. They have the naked legs of these; and their whole anatomical structure agrees more with them than with the gallinaceous birds, and even their flesh has the same flavour. Like them also they are without hind toes, and the smaller species have a very considerable degree of resemblance to the plovers. Their tarsi are reticulated, their wings are short for the size of the birds, and they do not fly much unless when they are alarmed. Their ordinary march is on foot, and when they run swiftly they use their wings partially raised for balancing themselves. They are very miscellaneous in their feeding, eating indiscriminately, seeds, green vegetables if they are succulent, insects, and worms.

There are several species, most of them inhabiting countries which are warm and temperate, and where they can range undisturbed. Though there is a very great difference in the sizes of the species, there is a very remarkable correspondence in their manners, —enough to characterise them as a well marked genus, and perhaps even family; for there are no other birds which resemble them very closely. There is one species still a resident though a very local resident in some parts of England, and there is another which occasionally makes its appearance as a visitant; and from some notice of them, a general idea of the manners of the genus may be obtained.

I. The Great Bustard (*Otis tarda*). The name *tarda*, or slow, is very incorrectly given to those birds, for they are far from slow on foot, and though they are reluctant to take the wing, they are not bad fliers when they have once taken it, neither have they that difficulty in getting on the wing, which has sometimes been alleged. That they take long migratory flights is certain, because we have well authenticated accounts of straggling bustards being found at the distance of four or five hundred miles from any place where they are known to be resident,—as for instance, there was one shot in the lowlands of the county of Moray, in Scotland, in the year 1823, though it is pretty clearly made out that there could not be any resident ones in the island at that time, nearer than the county of Norfolk; and it is very probable that the straggler found in Moray came not from Norfolk, but from the continent, and that it must have crossed the German ocean upon one stretch of flight.

The great bustard is truly a magnificent bird, the largest of all the native birds, not only of the British islands but of Europe. The male bird, when full grown, is at least four feet in length, and not less than nine in the extent of the wings,—so that it is really a well-winged bird for its size and weight. Not equal to many of the air birds certainly, but still well-winged as compared with the majority of low-flighted birds, whose natural place of abode is on the level surface of the earth, and which use the wing only when they are raised by terrestrial enemies, or compelled to shift their quarters by want of food, or any other cause.

The bill is of a sort of ashen grey colour; but the legs, which are covered with reticulated scales, and not feathered down to the tarsal joints have a garter or naked space above, are black. The tarsi is about half a foot in length; the tibia is also long and comparatively free, and well supplied with muscles. There are only three toes, all turned to the front; and there is an elastic pad on the lower part of the tarsus which answers as a heel,—the structure of the toes being well adapted for giving a spring to the foot when raised in walking, and also for receiving the weight of the bird when the foot is planted, without any concussion to the body. The march is thus firm and stately, and performed with the alternate foot without any hopping.

The colours are not gaudy, but the plumage is warm and rich, and the markings very beautiful, and even elaborate. The head is silver grey, with a very well defined streak of black along the middle. In the male bird, there descends from near the angles of the gape, or rather from the ear coverts, two pendent tufts of black silky feathers, which hang for eight or nine inches down the sides of the neck. These pendent tufts of feathers play backwards and forwards on the sides of the neck, as the position of the head is shifted, and alternately display and conceal two patches of naked skin on the sides of the neck which are of a violet colour, more intense in the pairing time of the birds. The lower part of the neck passes into a reddish orange, of a rich but rather subdued tint. The ground colour on the back is nearly the same; but it passes into greyish on the scapulars; and there is a greyish tuft of downy feathers at the setting on of the neck. The whole of the orange feathers are very elaborately streaked, barred and mottled with black. The greater coverts of the wings and some of the secondary quills are of a dull black colour; but the primary quills are brownish black with white shafts. The feathers of the tail have some white at their bases, and generally also at the tips; but the principal part of them is rich brown with black lines, which form a regular band. The black markings on the feathers are in general regular crescents, with their convexity toward the point of the feather, and a small line of the same colour running parallel to it. On the fore part of the neck, in the male, there is a membranous sac or pouch, having its opening under the tongue, and capable, when distended to its full stretch, of containing at least two quarts. This pouch is not covered with feathers, but with a naked elastic skin of a bluish black colour. There have been many conjectures as to the use of this pouch in the economy of the birds, but they are far from satisfactory, and the point remains undecided,—it is not understood ever to contain any liquid. It has been considered as a reservoir for water; but bustards drink very little, if they drink at all; and the usual stories of animals carrying water in any reservoirs within their bodies, either for their own supply or for that of their young or any one else, have no better foundation than the now exploded error, that water for the supply of travellers in the desert can be had from the reticulated portion of the compound stomach of the camel.

The female bustard wants this pouch, as also the pendent feathers and the violet-coloured naked skin on the sides of the neck. She is not half the size of the male, or exceeding it, and her colours are rather different. The grey upon the head and scapulars is darker; the mottlings with black are smaller and more uniform, and they are continued on the feathers of the tail in place of the definite black hue which is drawn upon that of her mate. She lays her eggs upon the ground with little or no formal nest, as is the case with the gallinidæ, and also with those long-legged birds which the bustards most resemble in other respects. The female bustard is a very close sitter during her incubation, and can with great difficulty be raised from her eggs. There are in general only two for a brood, produced early in the season, and the time of sitting on them extends to about four weeks. The young are, at first, wholly covered with down of a pale yellowish brown colour, mottled with darker brown and black: and they follow the birds which have the chief resemblances to the bustard in other respects, in being able to follow their mother, and to pick up their own food as soon as they break the shell. Until they are fledged and able to take to the wing, they seek their safety from enemies by squatting closely among the clods, which they resemble in colour. When bustards are fledged, they always seek to escape from ground enemies by flight; and therefore the old stories which are told of the sport obtained by coursing them with greyhounds cannot be true.

The small remnant of those birds which is left in England is found chiefly, if not exclusively, in the county of Norfolk, but they summer and winter there, and are not migrant birds. The extensive corn fields, where there are few trees or enclosures, are their favourite haunts in the breeding season, and generally till the harvest comes on; and after that they retire to the fields of turnip. They are much more abundant, and also more migrant, on the continent of Europe than they are in England; but they always prefer dry flats to marshy ones, and in those places which are subject to heavy periodical rains they shift their quarters.

The Little Bustard (*Otis tetrax*) is much smaller than that species of which a very short account has been given. It is not much more than one-third of the length, and its wings are shorter in proportion, but it is a stouter and weightier bird in proportion to its lineal dimensions. The upper part is brown, mottled with innumerable small spots of black, and the general tint of the under part is white, with spots of black. The male has a tinge of rose colour on the breast, and, when full grown, a black collar round the neck, with white margins. This collar is wanting in the female and immature birds and in the adult male, both it and the rosy tint on the breast are most conspicuous during the breeding season. Though rare in Britain, this species is met with plentifully in the dry and warm parts of southern and eastern Europe.

Ruffed Bustard (*Otis houbara*). This species is a native of Arabia and the north of Africa. It is about the size of the common fowl, but the body is larger in proportion, and better fitted for running. The prevailing colour is pale yellowish brown, with black; there is a pendent crest of white feathers on the head, and a ruff of produced and erectible feathers on the side of the neck, which are of a dull white colour, marked with black lines.

There are various other species in Africa and India, but they have nothing peculiar in their manners as differing from those already mentioned, and many of them partake so much of the characters of some of the plover family, that it is not easy to draw a line of distinction between them.

BUTCHER'S BROOM is the *Ruscus* (box-holly) of Linnæus. The English name is derived from the custom of butchers frequently making besoms of it to sweep their blocks. It belongs to the Linnæan class and order *Diœcia Monadelphia*, and to the natural order *Smilaceæ*. The generic character is: calyx of the males in six sepals; corolla none. Females,—rudiment of the ovary oval, perforated at the end; style one; berry three-celled: seeds two. This is, though a humble, a very curious plant: it has thick, white roots, and sends up a plurality of stems, which are half shrubby. It has numerous leaves armed with sharp prickles at the points. The flowers of some species are borne on the upper surface of the leaf; on others on the under side: the *R. androgynus* bears the flowers on the edges. The female flowers are followed by fruit resembling small cherries, each containing two seeds. All the species are readily increased by suckers.

BUTEA (Roxburgh). Named in honour of John, Earl of Bute, a great patron of botanists. It is a genus of three species of East Indian trees. They are decandrious, and belong to *Leguminosæ*. Generic character: calyx bell-shaped, with five teeth; vexillum lance-shaped, and somewhat reflexed; pod on a footstalk, smoothly compressed, membranaceous, not bursting, having one seed at the point; seed large and flat. These trees, like almost all the order to which they belong, bear splendid flowers, and are also useful to man. From *B. frondosa* is obtained the *gum lac* of commerce. Infusions of the flowers, impregnated with a solution of alum, or of alum and tartar, dye cotton cloth of a beautiful yellow colour.

BUTIRINUS. A genus of malacopterygeous, or soft-finned fishes, with abdominal fins, belonging to the herring family. They are very abundant in the warmer seas, and there are a good many species, as well as abundance of individuals, of each. They have the silvery appearance of the scales, which is characteristic of the family, and, like all the rest, they are esculent and wholesome. Their jaws are formed like those of the herring, but their bodies are longer and rounder. They have the snout projecting something in the manner of the anchovies, and the opening of the mouth not very deep. Their most distinguishing character is having teeth arranged in raised spots and lines both on the tongue and the palate. So far as their manners are known, they do not appear to differ materially from those of the common herring. Indeed, all the family have a great resemblance to each other in this respect, though they differ a good deal in geographical position, in the size of the individuals, and in the flavour of their flesh.

BUTOMEÆ. The flowering-rush tribe. A natural order of monocotyledonous plants, containing two genera and five or six known species. The genera included under this order are by many authors referred to the Alismaceæ, to which they are closely allied, but differ in the mode in which their seeds are attached.

The characters of the order are, calyx having three divisions, which are usually herbaceous ; petals three, coloured ; stamens, definite or indefinite, hypogynous ; ovaries varying from three to six or more, more or less free or united ; follicles many seeded, distinct and beaked, or united into one mass ; seeds very minute, attached to the whole inner surface of the pericarp by a sort of vascular network ; no albumen.

The plants belonging to this order are aquatic, having cellular leaves furnished with parallel veins and handsome umbellate flowers of a yellow or, purple colour. They are natives of the marshes of Europe, South America and the East Indies.

The genera of the order are *Butomus*, *Limnocharis*, and *Hydrocleys*.

Butomus umbellatus, common flowering rush, is frequent in the ditches and ponds of England and Ireland, and grows in Duddingstone Loch, near Edinburgh, and the Loch of Clunie in Scotland. It is highly ornamental, and is interesting as being the only British plant in the ninth class *Enneandria*, of the Linnæan system. Another species, *Butomus latifolius* is found in Nepal. These plants are said to possess acrid properties.

Limnocharis plumieri is found in the marshes of Brazil. Its flowers are yellow, and its leaves have a singular hole at their apex, which seems to be intended as an outlet for the moisture which constantly distils from the plant. A milky juice is yielded in great abundance by this plant.

BUTOMUS (Linnæus). So called from *bous* and *temno*, cropped or cut by oxen. A genus of two

species, one British, the other from Nepal. Class and order *Enneandria Hexagynia*, and natural order *Butomeæ*. Generic character: calyx none; corolla six-petalled, three outmost smaller, withering; stigma abrupt; capsules six, oblong, taper, each one-celled; seeds many. This is the flowering rush of our rivers, and is an elegant plant, having its flowers in an umbel four or more inches in diameter; each flower is about an inch broad, of a fine rose or purplish white colour. Professor Lindley thinks it the most beautiful of all our native plants; adding—that the number three is evidently predominant in the fructification: the corolla being doubly tripetalous, the stamens thrice three, the seed-vessels six, in a hexagonal form, and the involucre three-leaved. The quaint description of old Gerard, in his Herbal, deserves to be for the hundredth time reiterated. "The water-gladiole, or grassie-rush," says he, "is of all others the fairest and most pleasant to behold, and serveth very well for the decking and trimming up of houses, because of the beautie and braverie thereof." The annexed cut gives an idea of the umbel of flowers.

BUTTER BUR is the *Tussilago* (good for a cough) *petasites* of English botany. It is called petasites, specifically, because of its very broad leaves affording a shelter from rain to poultry and other small animals. It is called butter bur in allusion to a former application, and pestilent wort, from its supposed efficacy in the plague. The plant is syngenesious, and belongs to the order *Compositæ*.

BUTTER CUP is the *Ranunculus* (frog-wort) *bulbosus* of Willdenow. It is the plant which gilds our meadows with its glossy yellow flowers in the months of May and June. Like most of its congeners it possesses the property of inflaming and blistering the skin; hence the roots have been applied for that purpose, particularly to the joints, in cases of gout. Besides the name butter-cup, it is also called butter-flower, king's-cups and crow-foot; and it is "the cuckoo-buds of yellow hue" of Shakspeare.

BUTTERFLY. The ordinary English name of a very extensive * group of insects belonging to the order *Lepidoptera*, and corresponding with the great division *Diurna* of Latreille, or the Linnæan genus *Papilio*.

Who has not been struck with the elegance and beauty of these delicate insects,

> "Which flutter round the jasmine stems
> Like winged flowers or flying gems"?
> MOORE'S LALLA ROOKH.

Who has not watched them hovering and fluttering over the flowers which they more than rivalled in splendour of colour, or seen them at length resting with a touch so light as not to appear to be there?

> "Proles arbusti, papilio ut forem,
> Violas et lilia et rosas halens,
> Erraticus usque de flore ad florem
> Quæ pulchra, quæ suavia sunt, osculans."
> *Archdeacon Wrangham's elegant Translation of the Song "I'd be a Butterfly."*

Who has not observed them, when at last reposing on the bosom of a flower, opening and shutting their beautiful wings to the summer's sun, alternately erecting and depressing their long and slender antennæ, which, by a fanciful idea, have been generally termed horns.

* The number of species of butterflies is far greater than would be supposed. Latreille has described not less than 1804 species in the Encyclopédie Méthodique; of this number about 237 are natives of Europe, the rest are extra European. If, however, it is considered that out of Europe the entomological treasures of the globe are but very incompletely known, and supposing that even one-third of the diurnal lepidoptera were unknown to Latreille, the number is raised to about 2500, of which number 260, or one ninth part, are inhabitants of Europe.

"Two deadly weapons first he bore,
Strongly outlanced towards either side,
Like two sharp spears his enemies to gore—
So did this fly outstretch his fearful horns,
Yet so as him their terror more adorns."—SPENSER.

Or, lastly, who has not perceived the beautiful spiral apparatus which they employ in extracting the nectar of flowers?

We do trust that there are many amongst our readers who have been sufficiently imbued with the spirit of observation to have noticed these things, since they will thereby have attained a knowledge of the chief characters by which this beautiful group of insects is distinguished from the other lepidopterous tribes.

"The velvet nap which on his wings doth lie,
The silken down with which his back is dight,
His broad outstretched horns, his airy thighs,
His glorious colours and his glistening eye."—SPENSER.

We have hitherto, however, seen the butterfly only in its final and glorious state; let us now look at it in the earlier stages of its life. "Were a naturalist to announce to the world the discovery of an animal, which for the first five years of its life existed in the form of a serpent, which then penetrating into the earth, and weaving a shroud of pure silk of the finest texture, contracted itself within this covering into a body without external mouth or limbs, and resembling more than any anything else an Egyptian mummy; and which, lastly, after remaining in this state without food and without motion for three years longer, should, at the end of that period, burst its silken cerements, struggle through its earthy covering and start into day a winged bird, what, think you, would be the sensation excited by this piece of intelligence?" In this striking manner do the authors of the Introduction to Entomology introduce the interesting subject of the metamorphoses of insects, a subject which, from the numberless variations in which it is to be observed, merits the most fixed attention.

The butterflies, indeed, rarely enshroud themselves in a cocoon, but the measures which they take to supply its want are far more remarkable, even than the formation of a silken case spun from the mouth.

The female butterfly deposits her eggs upon such plants as are proper to nourish the caterpillars which proceed from them; thus the common white butterflies place them upon cabbages, the tortoise shell and peacock butterflies upon nettles, &c. These eggs are simply attached by some glutinous secretion to the leaves or stems, without any of that curious precaution of inclosing them in down, which takes place in some species of moths.

The caterpillars which are disclosed from these eggs are for the most part, at first, of a dark colour, previous to their first moulting, which takes place at the end of several days after their birth; after this event, however, they appear with their respective colours. They are of a long and cylindric form, composed of twelve segments, exclusive of the head, and with nine spiracles on each side. Some are slightly hairy, others quite smooth, and many have simple or branching spines upon the different segments of the body. The majority are furnished with sixteen feet, of which six are scaly and attached, in pairs, to the three first segments, and the remaining ten are membranous. In the three anterior pairs of legs are inclosed the rudimental legs of the future butterfly. During their growth, and before arriving at their full size, they shed their skin several times, an operation which, although perfectly natural, and which only lasts in general three or four minutes, is often exceedingly painful, and causes the death of some caterpillars, which, owing to some circumstance or other, do not possess sufficient strength to accomplish it. At this period of its existence, its head is furnished with a pair of very powerful horny jaws almost of a triangular form; a pair of lower fleshy jaws, and a fleshy lower lip united to the latter, and furnished with a curious apparatus for spinning silk. The sides of the head are likewise furnished with twelve simple and globular eyes, exceedingly minute, scarcely perceptible, and totally unlike the eyes of the future butterfly. It now feeds voraciously upon leaves, gnawing them to pieces with its powerful jaws. Having, however, arrived at its full size, and being in this state incapable of reproducing its species, it now prepares for those singular changes of form and functions, which are destined to end in the production of a creature perfect in its kind. It now ceases to eat, voids whatever portion of its food remains unassimilated, quits the leaves, and seeks a secure situation in which to undergo its inactive and helpless state. We have said that the majority of the chrysalides of butterflies are not inclosed in a cocoon, few of them likewise descend to the ground to undergo their transformations. How then can an animal, having completely cast off its outer covering, furnished with legs, and appearing in a state in which the rudiments of legs are completely soldered to the body and incapable of rendering the least assistance, support itself from falling to the ground? This is a problem which it would be most difficult to solve, and yet the difficulty is overcome by the caterpillars in several different manners, and which depend in a great measure upon the position in which the future chrysalides are destined to be placed; some being suspended in the air vertically, head downwards, the tip of the tail being the only point of attachment to a twig or leaf; others, on the contrary, are attached against walls, &c., having the head higher than the tail, and many are placed horizontally, these being attached not only by the tail, but by a skein of silk passing across the middle of the body. It is to Reaumur that we are indebted for a precise account of the manner in which the different manœuvres employed by these caterpillars are effected. We will notice first the manner in which the suspension of chrysalides is performed, a process which may be observed by every one in the common tortoise-shell butterfly, which is found upon every bed of nettles. Reaumur asks how is the circumstance to be accounted for, that the chrysalis is found hanging precisely in the same place as we had observed the larva suspended,—seeing that when the latter is attached, every portion of the chrysalis is covered by the skin of the larva; it is therefore the tail of the caterpillar which we had seen attached in the very same spot where we now perceive the tail of the chrysalis. It might be imagined that the skin of the caterpillar was slit from the head to the tail, or that the tail of the chrysalis had, in some manner, been protruded through the skin of the caterpillar; but neither of these circumstances takes place: the skin of the latter only bursts a short distance down the back, and the tail of the chrysalis is entirely concealed within the envelope of the caterpillar. Moreover the difficulty is increased by the threads to which the tail of the chrysalis is suspended, being spun by the mouth of the caterpillar.

The proceedings of the caterpillar are, however, of the most simple kind. It first proceeds to form a small conical mass of silken threads, which it spins from the mouth; this mass, however, instead of being smooth and entire, is loose, and but slightly woven together. It now proceeds to seize hold of this button of silk with its hind pair of legs, which instead of terminating in a single claw like the six fore legs, are, as well as all the four other posterior pairs, armed with a vast number of very minute curved hooks, which therefore are well fitted to seize the loose threads of the silk button previously formed. When this is effected and the legs firmly fixed, the fore legs of the insect quit their hold, its body falls in a vertical direction, and the larva appears to be suspended by the tail, the hind legs being placed at the extremity of the body.

Shortly afterwards, however, it raises its head a little, which gives a curve to its back, and this motion is repeated until a slit is made behind the head, and which is increased by degrees along the back, until the insect is enabled to extricate by muscular contraction the anterior part of its chrysalis form from within the skin of the latter. Now this lower part is broader than the upper, which gradually decreases in size, so that the exuvia easily slides upwards towards the tail, the chrysalis alternately extending and contracting its body. This alone would be sufficient to cause the exuvia to mount towards the attached legs, but its movement is favoured by the angular projections of the body of the pupa, which, as they point towards the tail, prevent the skin from slipping down again; they are, in fact, cogs acting like the cog-wheels of our machinery. By degrees, therefore, the old skin of the larva is pushed upwards, until its folds are pressed together into a very small space, and it appears like a small bristly mass surrounding the tail of the chrysalis. The situation of the insect has now become critical, since, notwithstanding its tender state, it has three steps still to take, each of which seems pregnant with danger. First, the chysalis is compelled to suspend itself for a time to the insecure, yet still attached, shrivelled skin of the larva: secondly, it is necessary for it to withdraw itself even from this support, and to attach itself to the silken mass; and thirdly, it has to rid itself of the mass of exuvia, which would not only embarrass, but also hurt it, from its spiny state. The first step is effected by the pliability of the terminal rings of the body, by which, being attached together by membrane, the insect is enabled to form a kind of pliers, so as to seize a part of the exuviæ, whereby a resting place is obtained, which enables it to withdraw the extremity of its body from within the skin. Still the most difficult part of the process remains to be performed; retaining hold, therefore, of the shrivelled skin, it is enabled, by the elongation of the same membranous connexion of the segments, to extend its tail upwards, and, by the assistance of various minute hooks at the extremity of the body, to attach itself to the little mass of silk. This is indeed so delicate and perilous a step, that the insect, even after redoubled efforts, has sometimes been unable to hook itself in this manner, and has consequently fallen to the ground. This, however, only takes place with those which having been stirred during the first part of the process, have not spun a sufficiently large button of silk. In a natural state, this of course does not occur; and we can scarcely avoid wondering how an animal, which performs this intricate manœuvre but once in the course of its life, should do it so perfectly. "On en conclut," adds Reaumur, "necessairement qu'il a été instruit par un grand Maitre." Having, however, attached itself by the tail, it proceeds to get rid of the shrivelled skin of the larva, by first bending the terminal portion of body into the form of the letter S, and then giving the whole a sudden jerk, causes both its body and the slough to spin round eighteen or twenty times; as, however, the latter is further removed from the centre of gyration than the extremity of the body, it is evident that the attaching threads of the slough must suffer a greater strain than those of the chrysalis; consequently, the former, or more probably, the hooks of the legs, give way first. This is no sooner perceived by the chrysalis than it resumes its vertical position, and the skin drops. If, however, the first series of pirouettes does not prove successful, another in the opposite direction is tried; but if, after repeated efforts, it is unable to tear off the slough, it quietly submits to an evil which it cannot remove.

Such are the steps pursued by the caterpillars of a great number of butterflies, including, amongst the English species, the tortoise-shell, red and white admiral, the frittillaries, Camberwell beauty, purple emperor, &c., all of which are pre-eminently distinguished by their powerful flight and splendour of colouring, and which form the family of *Nymphalidæ;* but most of the other butterflies forming the families *Papilionidæ*, or true-tailed butterflies, white butterflies, &c., *Lycænidæ*, or the blues and copper butterflies, not only attach themselves by the tail to the stems of plants, &c., but the caterpillar fastens a skein of silk across the middle of the body previous to assuming the chrysalis state. The mode in which this is spun from one side of the body to the other (being attached on each side to a small mound of silk), differs in different species; some having a flexible body, merely throwing the head of the caterpillar over the back, and passing it repeatedly from side to side until the skein is sufficiently strong; whilst others, having a body less pliable than the preceding, adopt a method somewhat similar to that by which a skein of silk is wound upon the hand—the caterpillar first attaching a thread on one side of the body, and then carrying it over to the opposite side, forming a loop about twice the size of the body by holding the threads open with the assistance of its fore legs. Sometimes, however, notwithstanding all the care of the caterpillar, the threads will slip off its legs, whereupon it endeavours, with surprising patience, to replace them; but, notwithstanding every contortion, sometimes in vain.

Unlike the caterpillars of some species of moths, those of very few butterflies have been ascertained to be social; examples of the spirit of sociability, however, occur in the peacock and tortoise-shell upon nettles, and also in one of the frittillaries upon the plantain, but their nests are of very slight texture. The most perfect instance of sociality amongst butterflies is recorded in the first number of the Transactions of the Entomological Society just published, in the case of a gregarious nest-making butterfly found in Mexico. Mr. Hardy, who also appears to have noticed this species, describes the nests as being inclosed apparently in white paper bags, in the manner of grapes in England, to preserve them from birds and flies. He had the curiosity to examine one of these, which he found to contain numberless caterpillars.—(Travels in Mexico, p. 32.)

The caterpillars of the Hesperiidæ, or skipper butterflies, differ from those of the other butterflies by spinning a web-like covering of silk; whilst that of Doritis Apollo is still more different, since it encloses itself in a kind of cocoon formed of numerous leaves woven together with silken threads; but the chrysalides of the majority of butterflies are naked, of angular form, some having the head terminated by two short and conical horns, whilst others have this part prolonged into a point. Different parts of the body likewise present various eminences, of which the number, form, size, and arrangement, differ materially. Many species of butterflies are in this state remarkable for the brilliancy of the golden or silvery spots with which they are adorned, whence, in fact, the names chrysalis and aurelia, by which they have been distinguished, are derived. See the article Aurelia.

The newly-formed chrysalis of a butterfly, when opened, is found to contain only a mass of pap or soft substance, in which no trace of the limbs of the future butterfly can be observed; yet we are able to perceive, in the external covering of the chrysalis, all the external organs of the future butterfly, in a very short period after the skin of the caterpillar has been cast off. Indeed Swammerdam (whose incomparable dissections of various insects in their different states, induced our celebrated English naturalist Ray, in his "Wisdom of God in the Works of the Creation," to place him at the head of those observers who had, by their exquisite investigations, completely overthrown the doctrine of spontaneous generation) very plainly demonstrated, that even before the period when the caterpillar is ready to become a chrysalis, all the organs of the butterfly might be discovered within the body of the former, thus satisfactorily showing that the chrysalis is no other than "a beautiful and orderly external representation of such limbs of the caterpillar as have grown under its skin; for though the limbs now mentioned may be seen under the insect's skin at the time it crawls and eats, in the form of a caterpillar, nevertheless it is in this state, on account of their extreme tenderness and delicacy, a very difficult matter to have a satisfactory view of them. They are, in fact, as fluid as water, and they lie folded up in many very tender membranes, interwoven with pulmonary tubes."

Hence, too, the incorrectness of the application of the terms metamorphosis or transformation (implying, as they certainly do, supernatural changes, similar to those described in the fables of the old classic poets) to the various stages of development exhibited by an insect in its passage to the perfect state, will be at once perceived. Swammerdam was indeed so well aware of the impropriety of this, that we find him, so long ago as the close of the seventeenth century, observing, "The particulars here named being rightly understood, the change, or, to express it more properly, the growth of the creature from the caterpillar state into an aurelia, cannot but appear plain and intelligible; for the whole operation consists in this, that the caterpillar casts its skin and shows the parts which hitherto lay concealed, unfolds its limbs, and arranges each in its right place with great regularity and order. This is the whole operation to which so many authors have substituted a monstrous metamorphosis, or absolute change of one creature into another, not to be found any where but in their own misguided imaginations. What wonder then, if, in their vain and idle attempts for some hundred years past, to explain this metamorphosis, they should have met with no success? Thus it is that we are apt to err, when, depending too much on our own reason and imaginations, we sit down contentedly in our studies, and feed ourselves with our own weak fancies, instead of looking for truth into the magnificent works of the Creator, though such inspection alone can give us just notions of what we desire to know."

On examining a chrysalis we are enabled to discover, encased in separate parts, the eyes of the future butterfly, as well as its wings, of a small size, folded upon the sides; whilst arising from the head, and laying along the breast, are to be observed several slender divisions, which on being carefully examined, are easily discovered to be the two filaments of the proboscis or tongue, the coverings of the legs and of the antennæ, which are the outermost pair, and are distinctly articulated along their whole length, and are thickened towards the tip; the joints of the abdomen are all plainly marked by various indentations, but the lower legs and wings are not very plainly visible, being concealed beneath the preceding pairs of those organs.

When the insect has remained under the form of a pupa for a sufficient length of time to bring all the various enclosed organs to a proper state of consistence, the period of bursting the walls of its prison may often be easily ascertained; the golden colour with which it had been adorned becomes indistinct, and in those chrysalides which have the skin of a sufficient thinness, the colours of the wings of the enclosed butterfly may be distinctly perceived. The extremities of the legs are now observed to move very plainly, and at length this motion is so much increased, and the wings are so enlarged, that it is no longer possible for the dry and brittle skin which covers the whole to withstand the movements and dilatations of the enveloped butterfly; it accordingly gives way in a longitudinal slit down the middle of the back, where there is usually a suture for this purpose. This slit rapidly extends along the head, and then down the breast on each side of the cases of the antennæ, so that the skin of the chrysalis is burst into four distinct and regular formed pieces, one of which had previously enclosed the antennæ, legs, &c., another the abdomen, and the remaining two the two pairs of wings. The butterfly now makes its escape out of this rupture—its wings soon assume their full size, the insect emits a quantity of reddish coloured liquid, which has been regarded by the superstitious as bloody rain, and in a short time it is enabled to join its companions in the air.

> "Where he arriving round about doth fly
> From bed to bed, from one to other border;
> And takes survey, with curious busy eye,
> Of every flower and herb there set in order.
> Now this, now that, he tasteth tenderly,
> Yet none of them he rudely doth disorder;
> Ne with his feet their silken leaves deface,
> But pastures on the pleasures of each place."
>
> Spenser.

Some groups of butterflies are remarkable in their perfect state for the very small and undeveloped state of their fore legs, and it is a curious circumstance that this should occur in those species which we have already seen to be distinguished by their powerful flight and splendour of colouring, namely, in the family *Nymphalidæ*. There is another circumstance of considerable singularity connected with this subject, and which appears not easily reconcilable with our ideas of the instincts of animals, viz. that those butterflies, which in the perfect state are furnished with six perfect legs, attach themselves, on assuming the pupa state, in such a position that, on arriving at the perfect state, they will have occasion only to burst their fetters and creep at once along the surface upon which they have been affixed, whilst those butterflies which have the fore legs rudimental and apparently incapable of rendering any assistance, suspend themselves vertically in the manner above described, so that they must necessarily come into the perfect state head downwards, and have to ascend the outside of the fragile pupa case with the assistance only of their four hind legs, before they can obtain a sure footing on the twig or leaf from which they have been suspended.

It has been well said that the life of the perfect butterfly affords but few materials for the historian; however pleasant to contemplate, it is barren of facts. The historian, both of butterflies and men, must not look to peace and pleasure for the most abundant interest in his subject.

The mode of flight in these diurnal lepidoptera varies as considerably as in birds, and affords to the experienced entomologist a surprising number of shades in which the distinction of species may even be traced. The collector knows at a distance the flight of the different genera, and even occasionally that of the different species. But unfortunately the knowledge of these differences in the modes of flight is the fruit of long experience, and can scarcely be imparted by simple descriptions; in fact, it is necessary to employ comparative terms for the purpose, which, except to the experienced collector, can scarcely be considered as intelligible.

M. Lacordaire has published the most complete memoir upon this subject in the Annales of the French Entomological Society; but his paper is exclusively confined to the butterflies of South America.

We must reserve for a future occasion various peculiarities relative to the physiology of these insects in their different states, as well as their systematic distribution.

In like manner we have reserved our pictorial illustrations of these insects for our two plates of butterflies. In the first we have represented several splendid exotic species, as *Papilio Turnus* from North America, *Papilio Ægeus*, and *Sarpedon* from New Holland, *Cynthia Orythia*, var. from China, and *Thecla Sugriva*, (Horsf.) from Java. Our second plate consists of rare British butterflies, as *Papilio Machaon* and *Podalirius*, the purple edged copper (*Lycæna Chryseis*), and the *Polyommatus Arion* and *Artaxerxes*—together also with the caterpillars of the swallow-tail and nettle butterflies in the act of commencing their transformations, and the chrysalis of the latter, at the moment before attaching itself to the silken button.

BUTTERFLY-PLANT is the *Oncidium* (tubercles on lip) *papilio* of Lindley. It is one of the *Orchis* tribe, and a native of Trinidad. Like many of the same family, it is of very curious structure, and in shape quite grotesque.

BUTTER-NUT is the fruit of the *Caryocar nuciferum* of Linnæus. A large tree indigenous to Brazil. The flowers are polyandrious, and the tree belongs to the order *Rhizoboleæ.*

BUTTON-FLOWER is the *Gomphia* (a club) of Schreber. A genus of evergreen shrubs, natives of Jamaica. They are decandrious, and belong to the order *Ochnaceæ.* They bear long spikes of brilliant yellow flowers, and neat serrated shining leaves.

BUTTON-TREE is the *Conocarpus* (cone fruit) of Jacquin. It is a pentandrious plant, and belongs to the natural order *Combretaceæ.* They are natives of the West Indies, and said to be highly ornamental.

BUZZARD (*Bute*). One of the genera, or perhaps rather sub-genera, into which the great genus *Falco*, or diurnal birds of prey, are sometimes divided, and

Buzzard.

which includes a number of species, some of which differ considerably in the minutiæ of their characters. In general they have the wings long, but there are differences in that respect, and some are known par-

Moor Buzzard.

ticularly by the name of long-winged hawks, and others by that of short-winged hawks. Their feet are sometimes feathered down to the toes, and sometimes not; indeed, the only character in which they all agree is that of having the beak hooked from the base. We shall be better able to show the manners of the leading species, as well as their differences from each other, in one general article, HAWK, than

Honey Buzzard.

in detached notices of the genera, the arrangement of which is far from being satisfactory. To that article we shall therefore refer for notices of all the diurnal birds of prey, with the exception of the *Vultures*, *Eagles*, and *Kites*.

BYRRHIDÆ (Leach). A family of coleopterous insects belonging to the section *Pentamera* and to the division *Clavicornes* of Latreille, or those beetles which have the antennæ terminated by a club-shaped mass. The legs are more or less compressed, and capable of being so closely applied to the body that they are not all perceivable when the insect is alarmed; hence, and from the rounded form of these insects, they have obtained the name of pill beetles. This group appears to be intermediate between the families *Dermestidæ* (bacon beetles, &c.), and that of the mimic beetles, *Histeridæ;* from the preceding it differs in having the legs perfectly contractile, the tarsi folding upon the tibiæ, the latter upon the femora, and the whole being then lodged in grooves formed for their reception on the under side of the body; whilst it is distinguished from the mimic beetles by the antennæ not being elbowed at the extremity of the first joint, and by the jaws not being exposed.

These insects are of small size and of obscure colours; their numbers are likewise not very extensive, but there is considerable difference in their economy, some, in the perfect state, being found in sand-pits and under stones, in fields, roads, &c.; whilst others frequent flowers, as the perfect anthreni, or are observed beneath the bark of trees, or upon the coast.

The genera are *Byrrhus*, Linnæus; *Simplocaria, Oomorphus, Syncalypta, Nosodendron, Aspidiphorus, Trinodes* and *Anthrenus*, all of which are natives of England.

The first of these genera, *Byrrhus*, is distinguished by the club of the antennæ being distinctly five-jointed, by the palpi being terminated by a somewhat hatchet-shaped joint, and by the prosternum being dilated in front, covering the under side of the mouth. These insects possess in the highest degree the power of counterfeiting death by the contraction of their legs. They are likewise the largest individuals in the family, although their length seldom exceeds one third of an inch. There are nine or ten British species, of which the *Byrrhus pilula* of Linnæus is the type, as well as one of the most common species.

The genus *Nosodendron* (Latreille) is distinguished by its oval shape, large exposed mentum, and antennæ terminated by a large three-jointed club; the elytra are moreover adorned with little bundles of hair. The only British species, *Nosodendron fasciculare* (Fabricius), is found in elm trees, having been taken by the Rev. F. W. Hope, at Southend, under the bark of some of these trees which were placed in the sand to arrest the incursions of the tide.

With the exception of *Anthrenus* (Geoffroy), the other genera do not present any material characters worthy of notice in a work like the present. The genus last mentioned is, however, more deserving of attention, both from the ravages which its larvæ commit upon preserved animal substances, objects of natural history, &c., and from the curious formation of the larvæ themselves. Perhaps there is nothing more curious amongst insects than that, during the preparatory states of an animal, its habits should be totally distinct from those of its adult state. The perfect Anthreni are generally found on flowers, preferring, as we have often observed, those of umbelliferous plants. They employ their wings, seeking after impregnation, to penetrate every spot where dried and preserved animal remains are to be found, in order to deposit their eggs in such situations. They counterfeit death, also, like the Byrrhi, and, from their small size and banded colouring, look like small seeds. In the larvæ state they are exceedingly destructive, especially in museums, whence they have obtained the name of museum beetles, devouring the internal parts of bird skins, preserved insects, &c., and attacking feathers and hairs, reducing all to powder. They must not, however, be confounded with the *Tineæ*, or small fleshy grubs found in similar situations, which form for themselves cases of hair, woollen, &c. The larvæ of the anthreni, on the contrary, are uncovered except by their own coating of hairs, which are disposed in bundles, the posterior part of the body being furnished with two large patches, which are longer than the first, and each of which is thickened in a singular manner at the tip, These crests, as they may be termed, are so arranged that the insect has the power of spreading them out, in which position it affords a very beautiful object when magnified.

The perfect insects are of a rounded and depressed form, the surface of the body being adorned with undulated bands of coloured scales, which are easily rubbed off; the antennæ are terminated by a three-jointed club, and are capable of being retracted and concealed in grooves on the under side of the thorax, which is produced behind, on its upper side, into three lobes. There are five or six British species, of which the *Anthrenus* (Byrrh.) *Musæorum* of Linnæus is the type, and which seldom exceeds one-eighth of an inch in length.

BYRSONIMA (Richard). So named from byrsa, a hide; for tanning which the bark is useful. There are thirteen species, all tropical trees and shrubs. They belong to *Decandria Trigynia*, and to the natural order *Malpighiaceæ*. The greater number of the species were heretofore ranked in the genus *Malpighia*.

BYSSOMIA (Cuvier; Saxicava, Lamarck). This genus, which Cuvier considered perfectly distinct from the genus *Saxicava* with regard to the animal, differs but little as respects the shell, which closely approximates to the genus *Saxicava*, of which Lamarck makes it a species: it inhabits rocky fissures, with the muscles and other shells attached by a byssus; but it is sometimes found buried in the sand, small stones, and the roots of fuci, and even in the polymorphous *Millepora*, in which cases according to the observations of Fabricius, it is divested of byssus. The animal has its body more or less elongated, subcylindrical, and prolonged backward by a tube bifurcated only at its extremity, there being an opening at the lower and anterior part of the mantle, for the passage of a small channelled foot, and for the byssus, situated at the posterior base, and it has two powerful adductor muscles.

The shell is bivalve, often irregular, with a strong epidermis, oblong, coarsely striated lengthwise, equivalve very inequilateral, obtuse, larger in front, and as if rostrated at the back part; the summits but slightly marked, hinge without a tooth, or with only the rudiment of one; beneath the corslet a rather long exterior ligament, and two distant rounded muscular impressions. Only one species is known, the *Byssomya pholadis*, mentioned by Muller in his Danish Zoology.

BYSSUS. Several species of acephalous, or headless molluscs, produce an extremely fine kind of silky filament, commonly called the beard; it is similar to that of insects, and employed by the animal to attach itself to rocks or other objects, in such places as it inhabits. It is formed by a conglomerate gland placed near the foot, which latter part draws out the silk from the excretory duct, and moulds it in a groove on its surface. The muscle, perna, pinna, and some other genera of molluscs, produce a byssus; the latter in such abundance that it is found in tufts several inches long: in texture it closely resembles raw spun silk, it is of a pale brown colour, and capable of being manufactured into articles of dress, such as stockings and gloves, more however as objects of curiosity than articles of commerce: of these, specimens are to be seen in the British, and other museums. The configuration of many molluscs not known to spin a byssus, appears to indicate its existence, and their local dwelling tends to confirm that opinion; but the impossibility of becoming intimate with creatures we cannot study in their native element, while they are in the full exercise of their functions, renders it difficult in many cases for naturalists to reason beyond analogy; the best guide perhaps that can be taken, though not always a safe one to build a system upon, as the sports and freaks of nature are so extraordinary, that they baffle the best endeavours to reconcile them to our understanding.

That colossus of bivalves, the *Tridacna gigas* of Lamarck, *Chama gigas* of Linnæus, is said to affix itself to rocks by a bundle of tendinous fibres, or byssus, by which it remains suspended, notwithstanding the magnitude of these shells, which sometimes attain the weight of 600 pounds, and measure several feet in length: this assertion, and that of the force with which the valves are closed, being able to snap a ship's cable asunder, like many of the strange sights travellers see, want additional confirmation to be here given as established facts, though, reasoning by analogy, no doubt might exist of the one or the other.

A modern author, speaking of the byssus spun by the common muscle, *Mytilus edulis*, asserts that the animal, when it has commenced "spinning its cable, will make a trial of its strength by drawing it strongly towards her, before she proceeds to stretch out a second, and these cords, which she spins with so much art, are in reality as serviceable to them as cables are to a ship." He adds, that there are "frequently 150 of those little cables employed in mooring a muscle, each cable scarcely two inches long."

The writer of this article has patiently observed the habits of muscles for days together, in situations favourable to their growth, and never could witness the animal in the act of spinning its miniature cables, much less observe that spider-like kind of wisdom, of trying their strength when produced. He made numberless experiments to enable him to do so, all ending in the fact, that these animals *do* moor themselves to various submarine bodies by their silken threads, under peculiar circumstances of situation, often in groups suspended to each other, generally in beds or strata, and sometimes, but very rarely, single individuals were seen attached to stones or other matter, not moveable by the action of the tide; but when or how this operation was effected, the writer never could ascertain, from the most minute ocular examination. With regard to the length of the threads, they varied from one-tenth to two inches and a half, but they never appear disposed with any appearance of regularity or order, as to *purpose*, beyond that of meeting with any object in its vicinity. The numbers of these threads frequently exceeded one hundred, and when all but a few were separated or removed from the mollusk, no attempt was made to renew them in the same or any other direction; but when a number of individuals were carefully wiped, and freed entirely from every appearance of byssus, they all shortly spun threads attached to the nearest object, whether each other or not, indicating a consciousness of their utility, without exhibiting any other of those instinctive habits, more peculiarly observable in some of the spinning animals, and another proof, were it requisite, of the difficulty of ascertaining where instinct ends, or reason commences.

The fine linen called, in Greek, byssus, mentioned in sacred writing, of which the costly sacerdotal garments were made, is supposed by some commentators to have been fabricated from the silken produce of the pinna; but as its brilliant white hue is so highly praised, it was more probably made from asbestos, the art of weaving which was well known to the ancients, and cloth of it was used to preserve the ashes of princes and heroes from becoming mingled with the more ignoble dust of the woods and rare spices whose aromatic flames consumed their mortal remains.

BYSTROPOGON (Le Heritier). The name signifies close throated, as applied to the tube of the flower. It is a genus comprising four species of green-house under-shrubs, natives of the Canary Islands. They belong to the natural order *Labiatæ*, and are plants of no great beauty.

BYTTNERIA (Loeffling). A genus of shrubs, under-shrubs, and herbs, natives of many of the warmer parts of the world. They bear pentandrious flowers, and give name to an order of the natural system, viz. *Byttneriaceæ*. The generic character, according to Loeffling, is—calyx five-parted; petals clawed, cupped at top, or eared, ligulated at the back; tube pitcher-shaped, bearing the stamens, having from five to ten teeth; anthers twinned, seated on the top of the tube; styles short; stigma five-cleft; capsule five-berried, somewhat prickly, in each berry one seed.

BYTTNERIACEÆ, or BÜTTNERIACEÆ. A natural order of dicotyledonous plants containing thirty-five genera, and upwards of two hundred species. It sometimes receives the name of *Sterculiaceæ*, or *Hermanniaceæ*. It is nearly allied to the *Malvaceæ*, *Tiliaceæ*, and *Elæocarpeæ*. From the first of these orders it is distinguished by its two-celled anthers, and from the two last by its stamens being united into one bundle by their filaments.

Its essential characters are, calyx consisting of five divisions or sepals, more or less united at the base with a valvate æstivation, sometimes furnished with bracteæ; petals five, alternate with the sepals; stamens five or indefinite, monadelphous; anthers two-celled, opening behind; pistil consisting of five, rarely three carpels, distinct or combined into one ovary; styles equal in number to the capsules; seeds often winged.

The plants included in this order are exotic trees or shrubs with alternate leaves, and a starlike pubescence, and are propagated by cuttings and seeds.

The order is divided into several sections.

I. The true *Byttneriaceæ*, including the genera *Byttneria*, *Theobroma*, *Abroma*, *Guazuma*, *Commersonia*, *Glossostemon*, *Ayenia*, and *Kleinhovia*, natives of South America the East and West Indies, and New Holland.

II. The *Sterculiaceæ*, comprehending the genera *Sterculia*, *Heritiera*, *Triphaca*, and *Reevesia*, found chiefly in Africa and India.

III. *Lasiopetaleæ*, including *Lasiopetalum*, *Leringia*, *Guichenotia*, *Thomasia*, and *Keraudrenia*, which are solely New Holland genera.

IV. *Hermanniaceæ*, comprehending *Hermannia*, *Melochia*, *Mahernia*, *Waltheria*, *Altheria*, and *Riedleia*, genera chiefly found native at the Cape of Good Hope.

V. *Dombeyaceæ*, to which belong the genera *Dombeya*, *Pentapetes*, *Astrapæa*, *Ruizia*, *Assonia*, *Melhania*, *Trochetia*, *Pterospermum*, *Kydia*, and *Gluta*, natives of Africa and the East Indies.

VI. *Wallichieæ*, including the genera *Wallichia*, *Eriolæna*, and *Gœthea*, which are found native in India and South America.

The general properties of the order are mucilaginous and emollient, and it contains some plants which are highly important in an economical point of view.

One of the most important genera is *Theobroma*, a name derived from two Greek words signifying "the food of the gods." *Theobroma cacao*, smooth-leaved chocolate tree, is found native in South America, and grows in abundance on the banks of rivers in that country. It is also cultivated extensively in the West Indies. It is a tree about the size of a middling apple-tree, attaining a height of fifteen or sixteen feet, with bright green leaves, and small reddish inodorous flowers. Its fruit is about three inches in diameter, and has some resemblance to a cucumber. It is smooth, of a yellow or red colour, and is furnished with a fleshy rind nearly half an inch thick, which encloses a whitish pulp of a buttery consistence. The pulp separates from the rind when ripe, adhering to it only by a few filaments. Hence the seeds are ascertained to be ripe by the rattling of the seed-vessel. The pulp has a sweetish, slightly acid taste, and is eaten by the natives of America. The tree has a very beautiful appearance when laden with ripe fruit. The seeds, after being separated from the pulp and dried in the air, are sold under the name of cacao beans or nuts. They must not be confounded with cocoa-nuts, which are the produce of a totally different tree. Cacao-beans resemble almonds in shape, and, when fresh, have a flesh-colour and a sharp bitter taste. They were formerly used as money in America. Each capsule contains about twenty-five seeds, and a cacao-tree yields three or four pounds of beans annually. The unripe seeds are sometimes eaten when preserved in sugar.

From the kernel of the cacao-tree the well known paste called chocolate is prepared. This has been used from time immemorial by the Indians, and was first introduced into Europe by the Spaniards from their American colonies. The French did not cultivate the tree in their colonies till the middle of the seventeenth century. Large cacao plantations now exist in America and the West Indies, whence the beans are exported in considerable quantities. These plantations are generally formed near the banks of rivers, in order that a copious supply of water may be procured in dry seasons. The trees are generally planted in straight lines, about fifteen or sixteen feet asunder, and they are screened as much as possible from the direct rays of the sun by plantains and other large trees. They thrive best in a moist atmosphere and cloudy sky, and under a mean temperature not below 73° of Fahrenheit. The trees do not acquire their full vigour for seven or eight years, and they are very apt to be attacked by insects and parasitic plants. Two crops are gathered from them in the year, one in June and another in December. The kernels, after being freed from the shells and well dried, so as to prevent them from becoming mouldy, form the basis of chocolate, which is prepared in the following way. The kernels are first roasted at the fire in an iron pan full of holes, they are then pounded in a mortar and freed from any impurities, afterwards they are ground on a warm marble slab and made into a sort of oily paste, sugar being at the same time added in greater or less quantity. This paste is then mixed with vanilla and various spices, such as canella and cinnamon, in order to make it easy of digestion, and some colouring matter, as arnotto, is added. It is then put into polished iron moulds and made into cakes or rolls, which must be kept in a box perfectly dry. In France, chocolate is manufactured in various forms, and a stranger is not a little astonished at the curious figures made of chocolate, which are exhibited in the shops in Paris. When chocolate is prepared plain, without any spices, it is called, in France, *Chocolat de Santé*. Chocolate as manufactured by Spaniards, besides cacao, sugar, and vanilla, sometimes contains pepper, cloves, cinnamon, anise, achiotte, and even musk and ambergris. The Italians and Spaniards roast the cacao-beans much more than the French, so as to give them a darker colour and a more bitter taste. Chocolate is not imported into this country, and hence what is consumed in Britain is manufactured in the country from the cacao-beans, which are imported from the West Indies and the Caraccas. It is said that Castile soap is often added to British chocolate in order to make it froth when dissolved in hot water. The chocolate made in this country pays a fixed duty. Families are allowed to make their own chocolate provided three days' notice is given, and a quantity of the nuts, not less than half a hundred weight, is used at once. Spanish chocolate has more oil in it than that which is manufactured in Britain. Chocolate is a favourite beverage with the Spaniards, and is also much used in Jamaica. It is used either in a crude state, or boiled in water or milk. When good it ought to be entirely dissolved, leaving no sediment. It is best when newly prepared.

Chocolate has been recommended medicinally as a nutritious article of diet, and a good tonic. It has been found serviceable in hypochondriasis, and in cases of debility and emaciation. In the case of patients labouring under consumption and other lingering diseases, the use of chocolate has been attended with very beneficial results. It is sometimes given to disguise the taste of drugs such as quinine. When fresh ground and cooled in tin vessels, chocolate becomes highly electrical, but loses this property by being dried or powdered.

Cacao contains a great quantity of a thick whitish solid oil, which is separated by boiling water, and is commonly called *Butter of Cacao*. It is used as a cosmetic on account of its agreeable odour, and the rapidity with which it dries. It is also used medicinally as an emollient soothing application to sores.

The shell of the cacao-bean is sometimes employed as a tonic.

Cocoa is an oily and slightly bitter preparation, made in Britain from the seeds of the cacao tree. It is very nourishing, and is perhaps more easily digested than chocolate.

The seeds of *Theobroma Guianensis*, another species of the genus, are eaten in a fresh state.

Guazuma ulmifolia is a wide spreading tree like an elm, the fruit of which abounds in a sweetish mucilage. In Jamaica the leaves are somtimes used as food for cattle. The bark is employed as a sudorific, and an extract from it is used in Martinique to clarify sugar. The wood is light, and is used by coachmakers. *Glossostemon bruguieri* is interesting as being the only plant in the order which is found native in Persia.

Sterculia is an extensive genus of the order, consisting of fine umbrageous trees, the fruit of which is a good illustration of what is denominated by botanists a *follicle*. The seeds are in general large and eatable, and are filled with an oily fluid which can be expressed for use. *Sterculia urens* is a large tree, found native in the mountainous countries on the Coromandel coast. It has a soft spongy wood which the Hindoos use in the manufacture of guitars. The bark is very astringent and tinges the saliva of a reddish colour. The seeds are roasted and eaten by the natives. *Sterculia tragacantha* furnishes the gum tragacanth of Sierra Leone. The seed of *Sterculia acuminata* is the famous *Cola nut* of Guinea, mentioned by African travellers, which has the property, when chewed, of rendering bad water pleasant and agreeable. A decoction of the fruit of *Sterculia fœtida* is mucilaginous and astringent. The pods are used in Java in the cure of gonorrhœa. The seeds are oily, and are said to cause sickness and giddiness. The seeds or nuts of *Sterculia chica* are highly esteemed in Brazil as an article of food.

Waltheria douradinha abounds in mucilage, and is considered by the Brazilians a remedy for syphilis. The genus *Astrapœa* furnishes some of the most beautiful plants in the world.

From these details it will be seen, that this interesting family occupies an important place in the vegetable world, whether we regard it as furnishing nutritious articles of diet, or supplying the means of curing disease.

CAAPEBA. The name of a species of the genus *Cissampelos;* the root of which is used medicinally in South America, as a mucilaginous diuretic.

CABBAGE is the *Brassica oleracea* of botanists. Linnæan class, *Tetradynamia ;* natural order, *Cruciferæ.* Generic character : calyx erect and closed ; seed-vessel long, round, opening by two valves, and having a central dissepiment; style short, obtuse, seeds in one row ; cotyledons folded together.

This very useful culinary plant is a native of Britain, and found among the rocks on the sea shore. In its wild state it has comparatively small gashed leaves, and runs up to flower without any central turning in of the leaves. But small and unsubstantial as the leaves are, they are found to be wholesome, and particularly antiscorbutic ; and in all probability have in the course of time been raised from an article of medicine to a principal one of diet.

No plant shows the effects or repays the labour of cultivation more the cabbage; nor has any one sported into more useful varieties. There are above twenty different varieties and sub-varieties cultivated; and if all its alliances were included, double this number might be named.

The cabbage is particularly well adapted to the climate of this country, and in the same latitudes on the continent. In more southern latitudes they do not arrive at much perfection, owing to the higher temperature forcing them to flower before the heart is sufficiently formed.

The cabbage may be used in every stage of the growth ; when young they are the most delicate and sweetest of greens : and when the principal head is cut, the stems produce an acceptable supply of sprouts. The plant is variously useful; the smaller varieties are cultivated in gardens for kitchen purposes ; the red for pickling, and the large drumhead sort are grown in fields for cattle. Many of the large sorts are also manufactured into sour kraut, an indispensible condiment in Germany, and highly useful to the crews of ships on long voyages. For general usefulness it is next to corn and the potato; and over the last it has the advantage of being proof against the hardest frosts.

The cabbage, as well as most of its varieties, are biennials, that is, the plants require parts of two years to bring them to their seeding age. But as it is their leaves and not the seeds which is the object of the cultivator, he bestows such management as will bring the plants successionally into use, and so that they may be had for table every day in the year.

All the different sorts require strong and rich loamy land; they are what are called "gross feeders;" but their flavour when cooked is mild or rank, according as the soil is more or less rich. On a light sandy soil, the cabbage, though small, are sweeter flavoured than if grown on heavy highly manured land. Quantity is required in some cases, as for market or for cattle, for instance, while quality is the aim in other cases. For each purpose there are practical rules which are acted on accordingly.

The spring crop of cabbage, that is, such as come into use in the month of May, are most esteemed, and require more management than any of the following crops. The seed for this first crop should be sown on an open-lying spot some time between the 25th of July and the 5th day of August; or a better plan is to sow on both these days for security of having them as early, and as free from the risk of the plants running away to flower as possible. If the seed were sown on the 20th of July, nine out of every ten of the seedlings would probably run to seed in the spring instead of heading: and if sown after the 5th of August the crop would not come in so early as they otherwise would do. Therefore, any day between the 25th and the end of July is the best time for the latitude of London.

When the seedlings appear they must be kept free from weeds, and occasionally watered if the season be dry; and as soon as they have got four or five leaves, they should be carefully drawn and pricked out four inches apart on a rich well-prepared nursery bed to induce a stocky growth, and where they should remain till about the middle of October, when they should be planted out for good.

An open quarter should be chosen for cabbage, liberally dunged, and well digged. On this the plants from the nursery bed are put out in rows at distances according to the size of the kind. The early dwarf and York varieties are placed in rows eighteen inches asunder, and twelve or fourteen inches between plant and plant. The middle sized sorts, as the sugar-loaf and Battersea, may be put in rows two feet apart and sixteen inches asunder in the rows. The largest growers, as the drumhead, require three feet intervals between the rows, and two feet spaces between plant and plant.

It is usual to draw drills, or tread furrows for the plants to be dibbed into, letting them in as deep as the leaves, and pressing the earth firmly to the roots. The after management consists in keeping the surface loose and clean by the hoe, filling up blanks, and, when the plants require it, drawing earth to the stems to keep them steady and encourage the growth.

In April the plants will have gained a good size and will be beginning to head; this will be assisted by tying up the outer leaves round the centre with strands of matting, to blanch the heart.

Succession crops of summer cabbage are raised on seed beds sowed in March, April and May. These supply plants for putting out in May, June and July, which, with those drawn from autumn sowings, furnish a constant supply of either headed or open cabbage throughout the year.

Open plants or coleworts are preferred by many to close-headed or white cabbage. They are sweeter in flavour, and the green colour is inviting. Coleworts may be had at any time in the year; but for winter and spring use, seed-beds should be sowed in June, and again in July, to raise plants of any of the middle-sized varieties, viz., sugar-loaf, or early Battersea. These seedlings may be planted out on any vacant piece of ground during August and September, pretty thickly together, say nine inches apart every way, and thus to stand till pulled for use.

The enemies of the cabbage are the finches, which devour the seedlings, if not scared off; the turnip-fly in the spring, and slugs and snails all the year. The two last may be kept off by dusting the seed-beds and transplanted rows of plants with fresh slaked lime. For this purpose, a thin canvass bag, large enough to hold about half a peck, when full, is most convenient. This, held by the mouth, and charged with two or three pints of lime, jerked over the beds or plants, drives every fly, slug, or worm, from the place, and being repeated occasionally, especially after rain, will effectually defend the plants. The caterpillars of several butterflies live on the outer leaves all summer, but no preventive has yet been found for this injury. But the worst enemy is an insect called *Nedyus contractus*, which inserts its eggs in the stem under the surface of the ground, which soon become maggots, produce deformity, by raising large knobs over each of themselves—hence called "clubbing," or "fingers and toes,"—and sometimes in such numbers as always to weaken, if not destroy, the plant. At the transplanting season, if any such knobs appear on the root or stem, they should be pared off, and the roots dipped in a puddle of earth and soot before planting, to prevent future attacks. A dressing of marl, or soap-boilers' waste, is said to prevent clubbing; and, on the same principle, were the seed-beds watered with soap-suds once or twice during the growth of the seedlings, there is no doubt that it would go far to prevent the attack of the insects, the alkaline principle, it would seem, being offensive to them.

The large sorts of cabbage for cattle are generally sowed in the first week in August, and planted in the fields either in the autumn or spring, most commonly in the latter season. In the following autumn they come into use.

The red varieties have always a place in gardens. There are three sorts, viz., the common Dutch, the small red, and the Aberdeen red. The seed should be sown in August for the next summer supply; and again in March, to come in the autumn and winter. Red cabbage require wider intervals than the common sorts, and are usually planted in single rows between the beds of other dwarf-growing crops. The heads are chiefly used for pickling, or shredded in salads. They are also sometimes cultivated in fields for winter-keep for sheep, being much hardier than the white varieties.

The following are the varieties in cultivation:—

1. Early Emperor.
2. —— Dwarf.
3. Fine Screw.
4. Wellington.
5. Early York.
6. Large York.
7. Early Heart-shaped.
8. London Battersea.
9. East Ham.
10. London Hollow.
11. Early Sugar-loaf.
12. Early Flat Battersea.
13. Late ditto ditto.
14. Early Imperial.

15. Paington.
16. Drumhead, or Scotch
17. Fine Red Globe.
18. Thousand Headed.
19. Dwarf Drumhead.
20 Braganza, or Choux-trouchad.
21. Turnip-rooted above ground.
22. Ditto under ditto.
23. Green and Purple Kohl Rabi.

Of the above the most suitable for private gardens are numbers 1, 2, 5, 6, 8, and 11; for cottagers, 5, 6, 8, and 11; and for agricultural purposes, numbers 16, 17, 19, 21, 22, and 23. The other culinary articles belonging to the cabbage family, as Cauliflower, Broccoli, &c., are described under their proper names.

CABBAGE TREE is a West Indian palm, the *Areca oleracea* of botanists. Linnæan class and order, *Monœcia Monadelphia;* natural order, *Palmæ.* Generic character: flowers sitting on the same spadix, upper ones male, lower ones female; calyx three-parted; corolla of three petals; stigmas sitting; berry or drupe fibrous, one-seeded. Specific character: fronds pinnated; leaflets linear acute; fruit oblong. This species of palm is called the cabbage tree, not so much from its appearance as from the use the inhabitants put it to. The leaves are crowded together at the top of the stem, and when these are cut off, the central ones are found to be white and tender, and which, when boiled, are used as a substitute for cabbage—hence the name.

CACALIA (Linnæus). A genus of mostly succulent plants, of very grotesque form and habit. Linnæan class and order, *Syngenesia Æqualis;* natural order, *Compositæ.* Generic character: anthodium cylindrical, of many parts, scaly at the base; receptacle naked; pappus hairy, rough. The succulent species are of the same nature, and require the same treatment, as mesembryanthemums. The *C. kleinia* is called the cabbage-tree from the green gouty resemblance of the stalks to those of cabbage. In some countries the leaves of some of the species are used as salad, and the stalks are used as pickles.

CACHRYS (Linnæus). A genus of herbaceous perennial plants, chiefly natives of Europe. Linnæan class and order, *Pentandria Digynia;* natural order, *Umbelliferæ.* Generic character: involucre none; calyx none; corolla petals ovate, lanceolate, acute; seed oblong, rounded, smooth, and fungous. These plants have carminative qualities, approaching those of rosemary, on which account the latter-named plant was called cachrys by the Romans.

CACTEÆ. Indian fig family. A natural order of dicotyledonous plants, containing nine genera, and upwards of one hundred and fifty species. It is nearly allied in its characters to the *Grossularieæ*, or currant tribe, from which, however, it is completely different in habit. This order sometimes receives the names *Opuntiaceæ, Nopaleæ*, and *Cactoideæ.* It has been divided into two sections, *Opuntiaceæ*, in which the ovula and seeds are fixed to the parietes of the fruit, and *Rhipsalideæ*, in which they are attached to a central axis. The former includes the genera *Cactus, Melocactus, Opuntia, Cereus, Mammillaria, Echinocactus, Epiphyllum*, and *Pereskia*, while the latter contains the single genus *Rhipsalis.*

The essential characters of the order are,—sepals numerous, usually indefinite, gradually passing into petals, either crowning the ovary or covering its surface; petals numerous, arising from the mouth of the calyx, often more or less combined; stamens numerous, in many rows, more or less cohering with the petals and sepals; filaments long and slender; anthers ovate; ovary fleshy, one-celled; style filiform; stigmas many and clustered; fruit, a fleshy berry, smooth or scaly, or tuberculated; seeds enveloped in pulp, without albumen.

The plants belonging to this order are perennial succulent shrubs, presenting very various and singular forms. Some have angular tall stems, while others have rounded spiny ones, not above a few inches high. In general the stems and branches are jointed. The leaves are either very minute, or are altogether wanting, their place being supplied by spines. The flowers are generally white, scarlet or purple, and in some instances are showy and magnificent, frequently ephemeral. The fruit is sometimes small, at other times large, and resembling a fig in shape. From this circumstance the English name of the family is derived. From being succulent, and possessing few evaporating pores, the cacteæ are remarkably well adapted for hot, dry and exposed places. They inhabit the arid soils of the warmest parts of America, whence they have been transported to the rocks of Asia, and the burning sands of Africa. They extend only a short distance beyond the tropics on either side; their northern limit is said to be 33° or 34° north latitude.

The fruit of many plants of the order is esculent. It has sometimes an agreeable acid taste, and at other times is very insipid. Some of the plants yield an acrid milky juice.

The cacteæ is propagated by cuttings, offsets and seeds, and thrive best in dry sandy loam, or in loam mixed with a little brick rubbish.

One of the most important plants of the order is the *Cactus cochinellifer*, or *Opuntia coccifera*, the spineless cochineal fig. This is a large shrub nine feet high, bearing red edible berries, which are said to possess diuretic properties. It is cultivated extensively in the West India islands as food for the cochineal. The plantations of this cactus are called in Mexico *Nopaleries*, from the Indian name of the plant. The cochineal (*Coccus cacti* of Linnæus) is a homopterous insect, not unlike the mealbug of our gardens. The male insect is winged; the female alone is used as a dye. There are two kinds of cochineal, which are reputed to feed on different species of cacti. One of these, the wild or common cochineal, is covered with a silky envelop, and is not so valuable as the fine or cultivated cochineal, which has a powdery or mealy covering. The female insects, after feeding on the cacti for three or four months, are brushed off by means of a squirrel's or deer's tail, and are then killed by exposure either to the sun or to the vapour of hot water. When dried they are exported in large quantities for the purpose of furnishing a rich scarlet dye. The colouring matter is extracted easily by water, alcohol, or hartshorn. It is stated that 800,000 pounds of cochineal are annually brought to Europe; each pound containing about 70,000 insects. The annual consumption in Great Britain alone is estimated at 150,000 pounds, worth 275,000*l.* sterling, a vast amount, as has been observed, for so small a creature, and well calculated to show us the absurdity of despising any animal on account of its minuteness. Cochineal possesses stimulating properties. It was formerly used as an anodyne in hooping-cough, but is now employed chiefly for the purpose of colouring tinctures and lip-salves.

Opuntia vulgaris, or *Cactus opuntia*, is found growing abundantly between Rome and Naples. It bears a berry of a deep purple colour. Its prickly leaves abound in a mucilaginous matter, which is used as an emollient poultice in some countries.

Opuntia Tuna is cultivated in Mexico and Brazil as food for the cochineal. It is used for hedges in Spain, South America, and the West Indies. When the island of St. Christopher was to be divided between the British and French, three rows of this plant were planted by common consent between the boundaries. The stamens of this plant possess a peculiar kind of irritability. When a quill or feather is drawn across their filaments, they immediately begin to lie on one side, and then sink down gradually to the bottom of the flower.

Melocactus communis, great melon thistle, or Turk's cap, is like a large fleshy green melon covered with sharp prickles. It may also be said to have some resemblance to a hedgehog. The flowers and fruit grow in clusters around the upper part of the cap. In the West Indies this plant is met with two yards in circumference, and four or five feet high. It grows on the steep sides of rocks in the hottest parts of America along with the *Mammillaria simplex* and *prolifera*. The fruit of all these plants is agreeably acid, and is eaten as a cooling fruit in the West Indies. Cattle are said to eat the succulent parts of these plants in the time of drought.

The *Mammillaria simplex* is remarkable on account of yielding a milky juice, which has a sweetish taste, in place of being acid. The milky juice of the *Cereus grandiflorus*, *flagelliformis*, and other cacti, is used in St. Domingo to inflame and blister the skin, as well as to act as a violent purgative.

Cereus repandus, *lanaginosus*, and *Peruvianus*, as well as *Opuntia Braziliensis*, all yield edible fruit.

The best fruit, however, is furnished by the *Cereus triangularis*, or strawberry pear. It is much esteemed in Martinique and other West Indian islands.

Cereus speciosissimus, on account of its beautiful large pink flowers, is extensively cultivated in greenhouses. It is, however, inferior in beauty to the *Cereus grandiflorus*, or night-flowering creeping cereus. This species bears magnificent sweet-scented flowers, which only remain out for about six hours. There is seldom more than one flower expanded at a time. The flower-bud begins to open at seven or eight o'clock in the evening, is fully blown by eleven, and by three or four in the morning is faded and withered. When once the flower closes, it never opens again. The calyx is often a foot in diameter. Its inside is of a bright yellow colour, while the petals are pure white. The plant flowers in July.

The *Cereus flagelliformis* has also fine sweet-scented flowers, which are numerous, of a beautiful pink colour, and remain open for three or four days. The species of the genus *Rhipsalis* are curious jointed prostrate plants.

CACTUS (Linnæus). The melon-thistle, a genus of stove succulents, natives of the driest parts of tropical countries. Linnæan class and order, *Icosandria Monogynia;* natural order, *Cacteæ.* Generic character: calyx bell-shaped, imbricated; corolla, petals six or more inserted on the calyx; stamens numerous, joined to the calyx; filaments awl-shaped; anthers oval, and two-celled; stigma many cleft, berry many seeded. These plants being of remarkable character attracted the notice of travellers in South America, where they are chiefly found, and being tenacious of life, were easily transported to Europe, where some of them have been long cultivated in hot-houses. They are mostly destitute of leaves, and composed of thick fleshy stems entire or jointed, and of the most grotesque shapes. They are spiny; either ranged along the prominent angles of the stem, or growing in tufts on the surface. The Turk's cap (*C. melocactus*) is a regularly formed and curious production; the body being ribbed like a melon, with tufts of short spines along the angles, and bearing its flowers and fruit round the upper part of the tassel of the cap. Full grown plants are sometimes met with in the West Indies two feet in diameter. The interior is a soft green pulp, very full of moisture, and never changing to a woody consistence. The fruit of some of them are eatable, and resemble in shape and size the fig of Europe. This genus, which formerly comprised a great many plants supposed to be species, is now so much divided, that very few real cacti remain.

CADDICE WORMS. The larvæ of the species of insects composing the Linnæan genus *Phryganea*, or the modern order *Trichoptera* (Kirby), are thus named. They are found in the water, under stones, or crawling upon subaquatic plants, and are inclosed in a case of their own construction, the materials of which are very different in the different species. These insects are well known to fishermen as an excellent bait for several kinds of fish. Thus, Izaak Walton tells us, in his chapter on baits, "There be divers kinds of cadis, or case worms, that are to be found in this nation, in several distinct counties, and in several little brooks that relate to bigger rivers;" and he then proceeds to describe several species of them, as first, that which is called a "piper," whose husk or case is a piece of reed about an inch long. "And these be a choice bait for the chub, or chavender, or indeed for any great fish, for it is a large bait;" then there is the "cock spur, being in fashion like the spur of a cock, sharp at one end, and the case or house in which this dwells is made of small husks and gravel and slime, most curiously made of these, even so as to be wondered at, but not to be made by man, no more than a kingfisher's nest can, which is made of little fishes' bones, and have such a geometrical interweaving and connexion, as the like is not to be done by the art of man." Another is called a straw-worm, and by some a fur-coat, "whose house is made of little pieces of bents and rushes, and straws, and water weeds, and I know not what." Derham, in his Physico-Theology, quoted by Sir John Hawkins, states the proceedings of these insects, which he calls cadews: "one sort house themselves in straws, called from thence straw-worms, others in two or more sticks laid parallel to one another, creeping at the bottom of brooks; others with a small bundle of pieces of rushes, duck-weeds, sticks, &c., glued together, wherewith they float on the top, and can row themselves therein about the waters with the help of their feet; both these are called cad-bait. It is a notable architectonic faculty which all the variety of these animals have to gather such bodies as are fittest for their purpose, and then to glue them together, some to be heavier than water, that the animal may remain at bottom where its food is (for which purpose they use stones, together with sticks, rushes, &c.); and some to be lighter than water, to float on the top and gather its food from thence. These little houses look coarse, and show no great artifice outwardly, but are well tunnelled and made within with a hard tough paste, into which the hind part of the maggot is so fixed, that it can draw its cell after it any where without danger of leaving it behind, as also to thrust out its body to reach what it wanteth, or withdraw it into its cell to guard it against harms."

From this quotation a general idea may be obtained of the cases of these insects, but it is also worthy of notice, that it not unfrequently happens that small shells are affixed to the case; and it appears that the caddiee worm does not hesitate to seize upon them for its own purpose, even although they enclose living snails. Some species likewise are encased in a tube formed of a slender and narrow bit of grass, which they are enabled to roll in a beautiful spiral direction, the edges being so nicely fitted as to have the appearance of one continuous piece. In some modern popular works on insects, the various kinds of caddice worms are spoken of as constituting but one species, not at all choice in the ornaments with which it decorates its coat. As, however, there are nearly two hundred British species of the Linnæan genus *Phryganea* indicated by Mr. Stephens, it is not to be doubted that each of the varieties of cases belongs to a distinct species. Sir John Hawkins has indeed given a classification of the former, but it still remains for the entomologist to complete the table by the introduction of the different species of flies produced from the different kinds of cases. These cases are of the greatest service to the larvæ, the latter being very tender and soft, with the exeeption of the head and two first segments of the body, which are the only portions which are generally exposed in walking, the insects retain their situations in the case by means of two hooks at the extremity of the body, with which they keep their hold so firmly, that it is almost impossible to draw them out of their cases without hurting them. When full grown, these larvæ, in the first place, attach their cases to some large stone by threads, they then close the mouth of the case with an open net-work of threads, suffieiently close to prevent the entrance of insects, but with meshes permitting the water to run in. They then shed their skin, and appear as quiescent pupæ, having their limbs enclosed in distinct cases, and being furnished with a pair of small fleshy tubercles at the posterior extremity of the body, and two small hooks at the head, whereby, previous to arriving at the perfect state, they cut the threads of the mouth of the case, and being then (in a manner totally different from the majority of pupæ) endowed with powers of locomotion, they creep out of the water, shortly after which they cast off their pupa skin, and appear as perfect *Phryganeæ*.

CÆLESTINA (Cassini). A family of herbaceous and half shrubby perennials, natives of America. Linnæan class and order *Syngenesia æqualis;* natural order *Compositæ*. Generic character: involucrum cylindrical, many leaved, imbricated; receptacle convex, naked; florets all tubular; stigmas very long; pericarpiums five-cornered; pappus a membranous rim. These plants, of which there are three species, are kept in the greenhouse, where their bright blue flowers are highly ornamental.

CÆNOPTERIS (Bergius). A New Holland fern, formerly called *Asplenium*. There are two species.

CÆSALPINIA (Plumier). A genus of hot-house trees and shrubs, natives of the East and West Indies. Linnæan class and order *Decandria Monogynia;* natural order *Leguminosæ*. Generic character: ealyx five parted, lowest segment large and vaulted; corolla of five petals; stamens downy at the base; style filiform; stigma truncated and fringed; pod and seeds compressed. This family of plants is celebrated for the hardness and durability of its wood, and for its uses to the dyer. It makes the best trenails for ship-building. Both the *C. crista* and *Brasiliensis* yield the Brazil wood used in dyeing, though that of the *C. echinata* is said to yield the finest colour. The plants are thorny, and seldom flower in our stoves; they are propagated by cuttings, but with difficulty.

CÆSIA (R. Brown.) A bulbous rooted herbaceous plant from New South Wales. Linnæan class and order *Hexandria Monogynia;* natural order *Asphodeleæ*. Generic character: corolla of six spreading equal petals; stamens below the germen, having smooth filaments; anthers erect and margined at the base; style filiform; seed-vessel clubbed, of three cells with two seeds each; seeds bellying.

CÆSULIA (Willdenow). An inconspicuous creeping syngenesious plant found in India, never cultivated.

CAIRNGORUM STONE. The rock or mountain crystal known under this name is in reality a very beautiful form of rhomboidal quartz, procured in different parts of Scotland, but originally found in the greatest quantities at Cairngorum, in the county of Moray. The mountain stores are now nearly exhausted, and they are only rarely obtained among the debris washed down by the winter's torrent. The deep wine-yellow and clove-brown coloured varieties, are those most highly esteemed by colleetors, and those are the eolours usually made up into neeklaces, seal-stones, and brooches. It is an excellent stone for engraving upon, and on this account it is much sought after by the lapidaries. The rock-crystal of Brazil and Madagascar is in general of a deeper tinge than that of Scotland, and can be purchased at a cheaper rate. The consequence of this is, that many of the Brazilian pebbles are sold under the name of Cairngorum stones. The various degrees of hardness whieh distinguish mineral bodies furnish the collector with valuable data by which he is enabled to distinguish one mineral from another. Thus the Cairngorum stone is sometimes sold for the topaz; but if the one be brought in contact with the other, the topaz will act on the Cairngorum stone, but the latter will not scrateh the topaz. Another test is, that the topazes of Brazil and Siberia beeome electrical by simply raising their temperature, which is not the case with the Cairngorum stone.

There is a process sometimes resorted to by dealers in this mineral which very materially changes its external appearance. It consists in raising its temperature almost to a red heat, and then plunging the crystal into different coloured solutions, such as indigo or cochineal, and by this means the most beautiful tints are produced.

CAKILE (Tournefort). The sea-rocket, a plant indigenous to Britain, and in some places common on the sea-shore. It belongs to the class *Tetradynamia* of Linnæus, and the *Cruciferæ* of Jussieu.

CALABASH TREE is the *Crescentia cujete* of Willdenow and other botanists. The fruit are large, and either oval or round. When the pulp is scooped out the skin becomes so hard as to serve the purpose of bottles, basins, or other vessels. The plant is common in the West Indies.

CALADENIA (R. Brown). A tuberous rooted, green-house perennial from New Holland. Linnæan class and order, *Gynandria Monandria;* natural order, *Orchideæ.* Generic character: perianth gaping, of five sepals, glandular, upper one plane, four lower ones nearly equal; labellum hollow, clawed, somewhat three-lobed; disk ornamented with a series of glands; column membranaceous, dilated; anthers terminal and persisting.

CALADIUM (Willdenow). A genus of plants allied to the Arums. Linnæan class and order *Monœcia Polyandria;* natural order *Aroideæ.* Generic character: male flowers have neither calyx nor corolla; anthers many celled, disposed in a spike at the end of the spadix: females, no calyx nor corolla; seed-vessel attached to the base of the spadix; style none; berry one-celled, one-seeded. The plants have large triangular or arrow-head shaped leaves and spotted stems. The species called *Sagittifolium* is like the *Arum colocasia,* and is called by the French *Chou de Bresil,* because they, like those of the *C. esculentum,* are used like cabbage. The roots of the sagittifolium are large tubers, and are a favourite vegetable among the Chinese, who cultivate them extensively. Most of these plants have a strong bitter principle, which is dissipated by cooking, whether boiled or roasted.

CALAMAGROSTIS (Adanson). A family of European uncultivated reeds or grasses. Linnæan class and order, *Triandria Digynia;* natural order, *Gramineæ.* They are mostly found on bogs and moist ground; three of them are British.

CALAMINE. This mineral forms the basis of zinc, and is used to a great extent in the manufacture of brass. Calamine is the *zink-baryt* of Mohs, and is usually divided into two species, the prismatic calamine and the rhomboidal calamine. The first of these is usually of a white or yellow colour, occasionally passing into green. Its primitive figure is an oblique four-sided prism, levelled on the extremities. The crystallised varieties are much harder than those that are massive and opaque. When gently heated, the prismatic calamine is strongly electric, hence its name *electric calamine.* It occurs in many parts of England, especially in the lead mines at Wanlockhead; and also in Leicestershire and Flintshire. On the continent it is met with at Tarnowitz in Silesia, Tscheren in Bohemia, Rezleanya in Hungary, Bleiberg in Carinthia, Freyburg in the Bresgau, and Stolberg in the Tyrol. The rhomboidal calamine occurs to a considerable extent in the Mendip Hills, in Durham, Flintshire, and Derbyshire. It is also found on the continent of Europe, and at Alta in Siberia. The primitive figure is a rhomboid.

CALAMINTHA (Pursh). The common calamint, an inhabitant of our flower borders, natives of Europe. Linnæan class and order, *Didynamia Gymnospermia;* natural order, *Labiatæ.* Generic character: calyx after flowering closed by hairs; orifice of corolla inflated, upper lip emarginate; the lower three-parted, with the intermediate segment entire. This genus is allied to our common thyme, and ranks among pot-herbs, but is seldom used.

CALAMUS (Willdenow). The rattan reed, a native of the East Indies. Linnæan class and order, *Hexandria Monogynia;* natural order, *Palmæ.* Generic character: perianth chaffy, irregular; sepals six; berry dry, one-seeded, imbricated backwards. This genus is said to form the link between the palms and grasses; having the inflorescence of the former, and habit of the latter. The stems are regularly jointed, solid, and extremely tough, so that they are extensively used for binding bundles of goods, &c. They also furnish the beautiful walking sticks called rattans; and in India, where they grow spontaneously by the sides of rivers, the stems are put to many useful purposes. The Chinese prepare great numbers for exportation to Europe and America. The *Calamus Zalacca* is cultivated for the fruit, which is about the size of a walnut, containing two or three sweet kernels.

CALANDRA (Clairville). A genus of coleopterous insects belonging to the section *Tetramera,* and family of the weevils, having the antennæ strongly elbowed, the eighth and ninth joints forming a triangular or ovoid mass, the elytra shorter than the abdomen, and the body narrow and somewhat depressed. This is a genus of very destructive insects, the larvæ feeding upon various seeds and grains. Of these, the most injurious is, doubtless, the *Curculio granarius* of Linnæus, a minute species, not exceeding one-sixth of an inch in length, of a dark pitchy red colour; the thorax is punctured, and as long as the elytra, which are adorned with several rows of deeply impressed dots. This insect, which is called the corn weevil by the English, charançon du blé by the French, and gwyfyn-yr-yd by the Welsh, feeds, both in the larva and perfect state, upon housed grain; its ravages were evidently known in the days of Virgil, by whom it was called *Gurgulio*—
' Populatque ingentem farris acervum gurgulio."

M. Keferstein has recently published a series of experiments upon this insect in the ninth number of the Revue Entomologique de Silbermann, 1834, which cannot fail to interest our agricultural readers. The female deposits her eggs at one end of the grain of corn, from whence, when the larvæ is hatched, it works internally, so that it is impossible to know whether the grain be sound or not; generally each grain contains but a single grub, but sometimes there are two. The larvæ resembles that of the nut weevil, *Balanenus nucum,* being white, with a brown head, and destitute of legs. When the entire of the farinaceous matter of the grain is consumed, and a mere husk remains, the larva is transformed into a pupa of a white colour, in which all the parts of the future weevil are plainly to be perceived. The latter, in general, makes its appearance at the end of eight days, piercing a round hole through one end or the middle of the grain. At the approach of winter it descends into the ground, a circumstance of much importance, appearing again about Easter, and making its way to the granaries. From the various experiments made by M. Keferstein, he is induced to draw the following, amongst other, results, viz., that the duration of the life of the perfect insect does not extend beyond one year; that those insects of an advanced age are incapable of reproduction; that during the cold the ravages of these insects are stationary, reproduction not taking place during the winter, but only in warm weather, although it is dependent upon several circumstances not yet sufficiently understood; that the egg or larva of the insect may at times be observed in the grains during the winter, although in very small quantities; and hence, that corn, purchased in the winter months, cannot be considered as entirely free from the weevil.

Other species of this genus are scarcely less destructive than the preceding. One of these (*Curculio oryzæ* Linnæus), which nearly resembles the *C. granaria*, but has a yellowish spot on each wing cover, feeds upon grains of rice. A third (*Curculio palmarum*, Linnæus), whose size being an inch and a half long, renders it a most formidable enemy, lives in the palms of South America, where its larvæ are greedily sought after and devoured by the inhabitants. The same insect, as we are informed by the late Rev. Lansdown Guilding (in his Memoir upon the insects which attack the sugar cane, for which he was, in 1831, honoured by the Society of Arts with the gold Ceres medal), is also injurious to sugar cane plants lately stuck in the ground, to which the females are allured by the juices which are exuded. These they sometimes attack so vigorously, that a fresh planting becomes necessary. They, however, do not seem to deposit their eggs in full grown canes when palms are abundant in the neighbourhood. Another, but smaller species, *Calandra sacchari* of Guilding, in like manner attacks the cane, but confines itself principally to such plants as have been slightly injured, though it sometimes attacks the more vigorous plants, which it excavates to the very ground. The larvæ of these two species, unlike the corn weevils, form very perfect cocoons.

The only other species which we shall here notice is the *Calandra tamarindi*, described by Mr. Christy in the first number of the Transactions of the Entomological Society, and which was found in a dead state in the interior of the stones of prepared tamarinds, sometimes amounting to as many as thirty or forty in a single stone. How the insects found their way into the stones is a curious point for inquiry, since the latter exhibited no traces of puncture in the epidermis. Can it be, as Mr. Christy pertinently asks, that the female deposits her eggs in the fruit when very young, or in the germen when in flower? This knowledge, however, can only be obtained by observations made upon the growing plants in the West Indies.

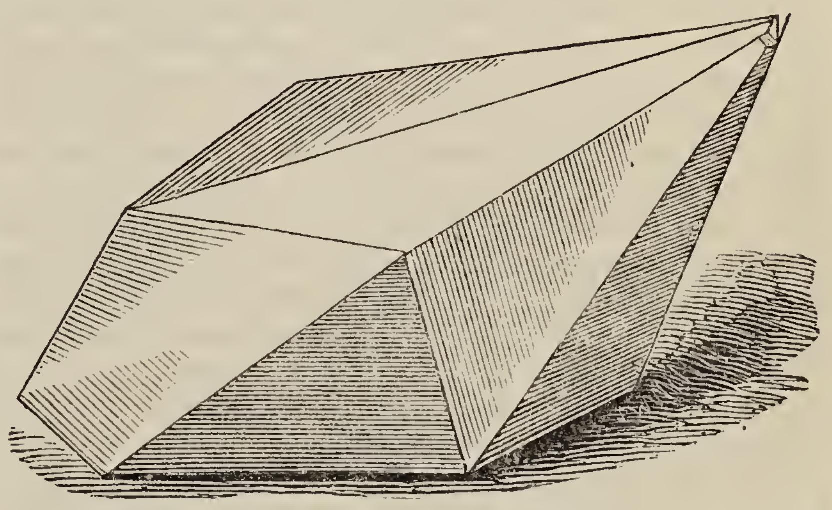
CALANDRINIA (Humboldt). An ornamental genus of herbaceous plants from South America. Linnæan class and order, *Dodecandria Monogynia*; natural order, *Portulaceæ*. Generic character: calyx of two persisting sepals; corolla of from three to five equal petals; stamens inserted into the bottom of the petals, in number four to six; filaments dilated at the base; anthers two-celled; style simple; stigma three-parted; seed-vessel elliptical, covered by the persisting calyx, one-celled, three-valved; many-seeded; placenta central. These rather showy plants have been but lately introduced into British collections, but they flower freely and are much admired.

CALANTHE (R. Brown). An orchideous genus lately introduced from India. Linnæan class and order, *Gynandria Diandria*; natural order, *Orchideæ*. Generic character: sepals distinct, upper ones erect, laterals declining; labellum spurred, appended to the column, hairy, three-lobed, middle lobe cleft; column obovate, turbinate; anthers behind. This, like all the others of its order, has flowers of the most curious structure, though not so varied in colour as some others. They are terrestrial plants, and may be cultivated like cymbidium.

CALATHEA (Meyer). A genus from Brazil, allied to the arrow-root plant. Linnæan class and order, *Monandria Monogynia*; natural order, *Canneæ*. Generic character: anther attached to a petal-like filament; style shaped like a petal; stigma like a cup. Flowers in close heads. The leaves of this plant are curiously striped green and white, hence the specific name *Zebrina*. It was formerly known by the name of *Maranta zebrina*.

CALATHIAN VIOLET is the *Gentiana pneumonanthe* of botanists, belonging to a beautiful tribe of herbaceous perennials cultivated in flower gardens. The tuberous roots are used in medicine.

CALCAREOUS SPAR. This beautiful mineral, which is in fact a crystallised carbonate of lime, occasionally combined with other bodies, occurs very abundantly in many parts of the world. The crystalline masses which are procured in Derbyshire are found in most mineralogical collections. Calcareous spar generally occurs of a white colour, inclining to red and grey. It is also frequently seen of a wax or ochry yellow colour; but the white and grey varieties are usually massive. Its primitive form is a rhomboid, but imagination can scarcely paint any thing more beautiful than the stalactitic varieties which are occasionally found in its natural state. It will only be necessary for us to furnish a graphic illustration of one form of this crystalline body. It is copied from a specimen in the British Museum, brought from Derbyshire.



Calcareous Spar has three characteristic forms, which may be briefly enumerated. The first in which it occurs is an acute double six-sided pyramid; in the second, it forms an equiangular six-sided prism, including the six-sided table; and in the third, it forms a rhomboid.

An interesting geognostic character of calcareous spar is the uniformity of its crystallisations in particular districts. Thus, in the mines of Derbyshire, the acute six-sided pyramid, and its congenerous forms, are the most frequent and abundant; at Schneeberg, in Saxony, and in the Upper Hartz, the prevailing forms are the regular six-sided prism and table; while in the mines of Freyberg, the most frequent forms are the regular six-sided prism, acuminated with three planes, set on the lateral planes, and the flat double three-sided pyramid.

The oldest formation of this mineral is that in veins, where it is accompanied with felspar and rock-crystal. It occurs also in beds, along with augite, hornblende, garnet, and magnetic ironstone, and frequently in veins in different metalliferous formations

Thus, it is associated with nearly all the metallic minerals contained in gneiss, mica-slate, clay-slate, and porphyry; seldomer in granite, more frequently, again, in greywacke, and along with cobalt and copper-ores in the oldest secondary limestone. Veins, almost entirely composed of calcareous spar, abound in the newest limestone formations; and it is a common mineral, either in veins, or in contemporaneous masses, in the various rocks of the secondary or flœtz-trap series.

CALCEOLARIA (Linnæus). Slipperwort, a handsome family of flowering plants, natives of Chili. Linnæan class and order, *Diandria Monogynia;* natural order, *Scrophularinæ.* Generic character: calyx four cleft, corolla gaping and inflated, capsule two-celled and four-valved. This genus has received its name from the remarkable shape of the inflated corolla resembling a shoe or slipper. Some of them are tender annuals, others deciduous under-shrubs. Two species have been long known in British gardens, but a great accession has been made within the last twelve years. From these last many varieties have been obtained by cross impregnation, so that they are now numerous. Above forty sorts are now cultivated and highly ornamental to the flower borders in summer, and greenhouse in autumn. Some of them will stand through the winter if placed in pots and kept in a cold frame; or if, in the open borders, they be sufficiently protected against severe frost. They, however, flower much better by having a good situation in the greenhouse or conservatory during winter.

All the annual species and varieties should be sown raised and treated exactly like what are called "tender annuals," such as the balsam, cockscomb, amaranthus, &c., pricked out from the seed-pans into very small pots, and repeatedly shifted into larger and larger up to twenty-fours, in which they may flower. Such of them as are biennials, as the *C. floribunda,* are best sowed in September and treated like greenhouse plants. The perennial species are propagated by division of the roots, and by cuttings and seeds, so are also the half shrubby species. Seeds sown as they ripen flower in the following summer; but not so strong as if sown in the spring, and not allowed to flower till the second summer.

CALDASIA (Willdenow). An ornamental hot-house annual belonging to the fifth class of Linnæus, and natural order *Polemoniaceæ.* It has pretty blue flowers, and is propagated by cuttings.

CALEA (R. Brown). A genus of hot-house evergreen shrubs, natives of the West Indies. Linnæan class and order *Syngenesia Æqualis;* natural order, *Compositæ.* Generic character: involucrum imbricated, receptacle chaffy, pappus hairy. The leaves are entire, and the flowers are yellowish purple, growing in terminal or axillary heads.

CALEACTE (R. Brown). A syngenesious plant found on the sea shore about Vera Cruz. This plant was formerly called *Solidago urticifolia.*

CALEMPELIS (D. Don). A perennial greenhouse climber from Chile, formerly called *Eccremocarpus* by Ruiz and Pavon. Linnæan class and order, *Didynamia Angiospermia;* natural order, *Bignoniaceæ.* Generic character: calyx bell-shaped, limb four or five parted, spreading; corolla tubular, upper part swollen, contracted at the mouth; limb short, in five reflexed lobes; stamens included; anthers free, fleshy and parted at bottom; stigma two-plaited; seed-vessel oval, compressed, one-celled, two-valved; seeds with membranous wings. This is a showy green-house plant, and seen in most collections.

CALEPINA (Adanson). A cruciferous annual plant heretofore called *Myagrum iberiodes.* It is a native of the south of Europe.

CALEPTERYX (Leach). A genus of Dragon Flies. See Agrionidæ.

CALEYA (R. Brown). Tuberous rooted plants from New Holland. Linnæan class and order *Gynandria Monandria.* Natural order *Orchideæ.* Generic character: calyx of five sepals nearly equal, and narrow; labellum clawed behind; lamina peltate, eaved; columna naked, somewhat dilated; anthers terminal; pollen in two masses.

CALIGIDES (Latreille). A family of parasitic *Crustacea,* belonging to the section *Entomostraca Siphonostoma,* or those which have the mouth formed into a sucker. The body is covered by an oval or semilunar shield, flattened above, with twelve legs, the four last pairs of which are feathered and pinnate, being admirably formed for swimming. The tail is more or less elongated and exposed, and terminated by two appendages. This family comprises only two genera, *Argulus* and *Caligus.* The first of these is established for the reception of a small but very curious (British) animal found upon various small fresh-water fish, upon the blood of which it subsists, sometimes to the destruction of its victim. It is the *Monoculus Foliaceus* of Linnæus, and its natural history and structure, in the different stages of its existence, have been detailed by the younger Jurine in the most satisfactory manner in the seventh volume of the Annales du Museum d'Histoire Naturelle. The insect is nearly a quarter of an inch long, and the body is covered with a large flattened, and nearly circular and transparent shield (through which the organs of the under side of the body may be seen), having two eyes near the front margin. It is notched behind, discovering the abdomen, which is extended beyond it to a short distance. The mouth is formed for suction. There are four small inferior antennæ. The legs are of singular construction; the first pair are large and short, and shaped somewhat like a cup, since it is by these organs, which probably act like a cupping machine, that the insect attaches itself to small fish. The four hind pairs of legs are formed for swimming, each being terminated by two long-feathered filaments. The young resemble their parents in form, though their locomotive organs are very differently constructed. The other genus, *Caligus,* is destitute of the large cup-shaped feet, the anterior pair being hooked. The tail is long, and terminated by two very elongated processes in the females, of which the use has not yet been determined. These animals are termed fish-lice, being parasitic upon various kinds of fishes. The genus has been subdivided into several sub-genera by Leach and Latreille.

CALLA (Linnæus). A genus of perennial herbaceous plants, natives of different parts of the world. Linnæan class and order, *Heptandria Monogynia;* natural order, *Aroideæ.* Generic character: spatha of one leaf; spadix cylindrical, and covered with styles and stamens; antheræ twinned and two-valved; stigmas sitting; fruit a berry containing strong-scented seeds. These plants in habit resemble the arums. The *Calla Æthiopica,* now called *Richardia Æthiopica,* is one of our commonest green-house plants, and very often seen ornamenting cottage windows. Its arrow-head-shaped leaves, elevated on long footstalks, surrounding its large trumpet-shaped white flower, is in figure very like that of the common spotted arum, called cuckoo pint, or wake Robin, frequent under hedges in many parts of Britain.

CALLICARPA (Linnæus). A genus of shrubby plants, natives of America, China, and the East Indies. Linnæan class and order, *Tetrandria Monogynia;* natural order, *Verbenaceæ.* Generic character: calyx of four sepals; corolla limb somewhat bell-shaped, with the border in four lobes; stamens protruding; berry four-seeded.

CALLICERUS (Gravenhorst). A small but curious genus of Rove-beetles (*Brachelytra*), belonging to the family *Aleocharidæ*, at once distinguished by the great length of the two last joints of the antennæ, and by the large oval penultimate joint of the palpus. The type *Callicerus Spencii*, named in honour of Mr. Spence, is exceedingly rare in England, but was captured, during the course of the last season (1834), in Battersea-fields.

CALLICOMA (Botanical Repertory). Of this genus there is only a single species, a native evergreen shrub from New South Wales. Linnæan class and order, *Dodecandria Digynia;* natural order, *Cunoniaceæ.* Generic character: calyx of four sepals; stamens below the germen; filaments long and hair-like; anthers oval, fixed by the back, two-celled; style divaricate; fruit two-seeded. Flowers are collected in heads, having an involucrum of four leaflets. This is an elegant green-house plant.

CALLIDIUM (Fabricius). A very extensive genus of beetles, belonging to the section *Tetramera*, and family *Cerambycidæ:* and distinguished by the comparative shortness of the antennæ, which are filiform rather than setaceous. The thorax is not armed at the sides with spines, being either globose, orbicular, or subcylindric, and (in the latter case) only slightly dilated at the sides, the palpi are short, and terminated by a somewhat triangular joint. Some of the species, which are generally of a moderate size, are elegantly ornamented with bands of various colours, whilst others are entirely of a red, or violet colour. They are found amongst timber, and it is not improbable that some of the species admitted into our catalogues have been imported in foreign timber, as is the case also with some of the *Buprestidæ;* others, as *Callidium bajulum*, are extremely destructive, the larvæ boring through posts, rails, &c. It is likewise very injurious to the rafters of houses, the larvæ making its way, by means of its powerful jaws, even through leaden coverings.

CALLIGONUM (Linnæus). A genus of one species, which is an ornamental under shrub. Linnæan class and order, *Dodecandria Tetragynia;* natural order, *Polygoniæ.* Generic character: calyx of five obtuse, reflexed, persisting sepals; corolla none; stamens inserted in the base of the calyx; filaments persisting; styles three or four, bearing stigmas; nut four-sided, four-winged, one-seeded, sometimes spinous.

CALLIMORPHA (Latreille). A genus of lepidopterous insects, as the name implies, of very elegant appearance, placed by Mr. Stephens in the family *Lythosiidæ*, but by Latreille amongst the *Pseudo-Bombyces.* The wings are deflexed (being somewhat of a triangular form); the antennæ are only ciliated in the males; the palpi are three-jointed, and but slightly clothed with small scales; and the spiral tongue is longer than the head. The type of the genus is the pink under-wing moth, a handsome, although common species, having the upper wings black, with a line and two spots crimson, the under wings of the latter colour bordered with black. The larvæ are slightly hairy, of a black colour, with yellow rings. It feeds upon the *Jacobæa Senecio.* The moth is stated to appear in May, but we have found it throughout the summer.

CALLIONYMUS (Dragonet). A genus, or, in its largest sense, a group of acanthopterygious fishes, belonging to the *Gobioidæ*, or gudgeon family, in Cuvier's arrangement. They have two very well marked characters; first, their gill-openings consist of only a hole on each side of the neck; and, secondly, their ventral fins are placed immediately on the throat, much extended and widely spread, and very considerably larger than the pectorals. Their head is oblong, and much depressed or flattened. Their eyes are placed near to each other, and directed upwards; their muzzle is capable of considerable protrusion; their gill-flaps are much extended backwards, and terminate in spines. They have no teeth in the palate. Their colours are in general brilliant, and often strongly contrasted. Their skin is smooth. Their first dorsal fin is supported by setaceous rays, which are often very much produced, and give their profile or side view a very peculiar appearance; their second dorsal extends as far as the anal; and they have a produced appendage behind the vent. They have no air-bladder. There are several species, or perhaps genera, not more than one of which is found, or at least common, in the British seas. That one is

C. Lyra (the gemmous dragonet). This species has the first ray of the first dorsal fin extending as far as the tail, the fin itself being much elevated. It is usually about a foot long, with the body rounded and smooth, the mouth wide, the gill-flaps with spines, and the last rays of the second dorsal and the anal fin the longest. Its colours are very bright, the prevailing one is yellow, but there are spots of white, and very bright ones of blue and purple. On the English coast, it is generally called the yellow gurnard, and on that of Scotland, "gowdie" (golden). A variety has been described as *C. dracunculus*, which has the same general characters and nearly the same colours, but the first ray of the dorsal fin is very considerably shorter. It has been supposed that this is the female of the other variety; and there is some probability in the supposition. This is perhaps the case with many of our rarer fishes; and therefore those who obtain specimens should always be careful to ascertain the sex, in order to prevent each sex from being regarded and described as a species. In this family in particular, and indeed in all fishes which have produced rays, or other appendages of which the use is not very well ascertained, there is generally some difference in those parts of each sex.

In the warmer seas, the Mediterranean especially, or rather because the fishes of that sea are more accessible, and have been longer observed than those of the wide oceans, there are some other species, among which we may notice

C. Lacerta, which has the first dorsal very much lower than in the former species, and the second (in the male) very much higher; and the caudal fin long and pointed. The sides are marked with lines of black and white, and with silvery spots.

The other divisions of the group which have received generic names are, *Trichonotus* and *Comephorus*.

The first of these do not differ very much from the dragonets, properly so called, only their bodies are more elongated in proportion to the thickness; but they have but one dorsal fin; the dorsal and anal fins are proportionally longer, and the first two rays of the dorsal are produced in slender filaments, which may be considered as answering to the first dorsal of the true dragonets. The *Trichonotus setigerus* of Bloch, is the species of this division which is best known.

Of *Comephorus* there is only one species, a native of the lake of Baïkal in Siberia, and is only known from specimens which are cast on the shores of that lake dead, after the violent storms by which its waters are often agitated. This is *Comephorus Baïkalensis* (*Callionymus Baïkalensis* of Pallas). It is about a foot long, soft and fat in its substance, so much so, that they who pick it up on the shores press it on account of the oil which it contains. It has two dorsal fins, the first very low; the muzzle large, oblong and depressed; the gill-flaps containing seven rays, very much divided from each other; the pectoral fins very long; but, different from all the rest of the family, there are no ventral fins.

CALLIOPEA (D. Don). A hardy perennial, a native of Italy. It belongs to *Syngenesia Æqualis*, and to the natural order *Compositæ*. This plant was thought to be a *Leontodon*, by Linnæus; and by others a *Hieracium*.

CALLIOPSIS (Reichenbach). A genus of ornamental annual and perennial herbs, natives of America. Linnæan class and order, *Syngenesia Frustranea;* and natural order, *Compositæ*. Generic character: involucrum of many leaves; leaflets short and erect; anthodium of many parts, and coloured; receptacle chaffy, and bearing protuberant glands; florets dilated at the base, and unequally toothed at top; seeds oblong and cylindrical. The genus has been separated from among the coreopsis family.

CALLISACE (Fischer). An obscure umbelliferous perennial from Siberia.

CALLISIA (Linnæus). A genus containing a single species; a creeping perennial from the West Indies. It belongs to *Triandria Monogynia* of Linnæus, and the natural order *Commelinaceæ*. The flowers are pretty, on which account it has been long introduced into European collections.

CALLISTACHYS (Ventenat). A genus containing four or five species of New Holland ornamental shrubs. Linnæan class and order, *Decandria Monogynia;* and natural order, *Leguminosæ*. Generic character: calyx, bell or funnel-shaped, cut into long slender divisions; corolla, petals inserted in the calyx, clawed, the upper large, the lower small, and standing apart; stamens inserted in the calyx, declining; anthers longish, and somewhat incumbent; style long and protruding; stigma capitate; germen stipitate; pod long, many seeded. These plants are usually found in green-house collections.

CALLISTEMA (Cassini). A genus of annuals long cultivated in European flower-gardens under the name of China-asters. Linnæan class and order *Syngenesia Superflua;* natural order, *Compositæ*. Generic character: anthodium loosely imbricated, rather foliaceous; receptacle hairy; ray of two colours; pappus double; exterior chaffy, the interior downy. No plant is better known than the China-aster as Linnæus called it. It ranks among those exotics called tender annuals, and as such are raised from seeds (which ripen in this country) in hot beds in the spring, and transplanted into beds or borders during summer, to flower in the autumn. Of late years, many new varieties have been raised from seed, beautifully varied in colour, having a greater number of ligulate florets, and the whole flower much increased in size, and even vying with those of the dahlia. The China-aster, or starwort, has always been regarded for its late flowering, it being one of the principal ornaments of the flower-garden when but few other flowers are to be seen.

Notwithstanding this exotic was introduced from China above a century back, it does not appear to have gained any greater degree of hardihood, from its long sojourn in Europe, than it had at first; so that the idea of the possibility of acclimating plants of warmer countries to the colder temperature of this, does not hold good with respect to the plant under notice.

CALLISTEMON (R. Brown). A genus of beautiful shrubs introduced into our collections from New Holland. Linnæan class and order, *Icosandria Monogynia;* and natural order, *Myrtaceæ*. Generic character: calyx with a hemispherical tube, and the margin divided into five lobes; corolla of five petals; stamens numerous, seated in the throat of the calyx, clongated; style filiform; stigmas headed; capsule three-celled, containing many seeds thickened and united to the tube of the calyx. The callistemons were first included in the genus *Metrociderος*, but separated by Dr. Brown. They are all fine greenhouse plants, partaking of the essential qualities and general appearance of their type, the common myrtle.

CALLITRICHINEÆ. A natural order of dicotyledonous plants, containing only a single genus, and three or four species. It is allied to the *Halorageæ*, and by many authors is looked upon merely as a section of that order.

The characters of the order are,—flowers monœcious, naked, furnished with two-coloured bracteæ; one stamen, consisting of a thread-like filament, grooved along the middle, and a kidney-shaped, one-celled anther; ovary solitary, four-cornered or four-celled; two awl-shaped styles; fruit four-celled, four-seeded, and indehiscent; seeds shield-shaped.

The plants included in this order are aquatic herbs, having entire opposite leaves, and very minute axillary flowers. They are said to exhibit the lowest degree of organisation in the dicotyledonous class of vegetables. They are found in still waters in Europe and America.

The only genus is *Callitriche*, or water star-wort, of which there are three British species, *verna*, *pedunculata* and *autumnalis*. These plants vary much in appearance, according to the depth and stillness of the water in which they grow. They are frequently met with in ditches and pools, to which, along with the various species of duckweed, they give a green and often thick covering.

Their properties are still unknown.

CALLITRIS (Ventenat) is a genus allied to the pine family, a native of New Holland. Linnæan class and order, *Monœcia Monadelphia;* natural order, *Coniferæ*. Generic character: male flowers in a small ament or catkin, somewhat round, with peltate scales, containing from two to five stamens united in a brotherhood; female flowers have a convex receptacle, with a double series of scales arranged circularly; germens numerous, sitting within the scaly calyces.

This tree has been hitherto kept in our greenhouses, and it is at present doubtful whether it may be naturalised in this country.

CALLORHYNCHUS. A genus of cartilaginous fishes, belonging to the *Chimæra* family, and containing only a single species (*C. antarcticus*), the Southern Chimera. The principal characters are: only one apparent breathing hole on each side of the body, though there are five which unite in that one, each leading to one of the cells in which the gills are contained (see CHONDROPTERYGII and FISH, for the structure of the breathing apparatus of the order); they have a rudimental gill-lid contained within the skin; their jaws are much smaller, and less capable of extended opening than those of the sharks; and they have, instead of teeth, four broad plates on the upper jaw, and two on the under. They have the muzzle produced considerably in advance of the mouth, as in the sharks; but it is perforated with pores in all the family. This formation of the muzzle gives them a very singular appearance, and has procured for them the name of Chimæra. In the species, or rather genus, under consideration, it is extended in a flat lamina, of the form of a spade or hoe, and of a fleshy consistency. There are two dorsal fins, the second commencing immediately over the ventrals, and ending over the commencement of that under the tail. They are found in the warm seas, and are ranging or discursive fishes.

CALLUNA (Salisbury). A new generic name given to one of our commonest heaths, which was supposed to be somewhat different formed from the generality of the heath family; but the name is not adopted.

CALOCHILUS (R. Brown). A new genus belonging to the *Orchis* family, introduced from New Holland. Linnæan class and order, *Gynandria Monandria;* natural order, *Orchideæ.* Generic character: calyx a ringent perianthemum, lateral sepals seated on the outside of the labellum, the inner ones sitting, small and erect; labellum sitting, elongated, pointed, and bearded; anthers parallel with the stigma. Like others of this curious order, the roots are tubers, and the plant requires greenhouse treatment.

CALOCHORTUS (Pursh.). A genus of bulbous rooted beautiful plants, from Columbia. Linnæan class and order, *Hexandria Trigynia;* natural order, *Liliaceæ.* Generic character: calyx of three sepals, coloured within; petals of the corolla inversely egg-shaped, bearded within; stamens short, and seated under the germen; filaments plane; anthers erect and arrow-shaped; stigmas recurved; capsule three-celled; seeds smooth. This is a very remarkable kind of lily; the flowers are splendid, though fugitive, but succeed each other for a considerable time.

CALODENDRON (Thunberg). This is, as its name imports, a beautiful tree, a native of the Cape of Good Hope. Linnæan class and order, *Pentandria Monogynia;* natural order, *Rutaceæ.* Generic character: calyx five-parted; petals of the corolla clawed; stamens alternately sterile and fertile, glandular at the apex; fertile stamens tuberculated; anthers bearing glands; style simple; capsule five-celled, five-valved, and cell containing two seeds. This tree is in European collections, and has a place in the greenhouse.

CALOPHACA (Fischer). A leguminous plant found in Siberia, allied to the *Cytisus,* and with which it has been ranked by Linnæus, and several other botanists.

CALOPHYLLUM (Linnæus). A genus of timber trees indigenous to the East Indies. Linnæan class and order, *Polyandria Monogynia;* natural order, *Guttiferæ.* Generic character: calyx of from two to four sepals; corolla of four petals, somewhat round, spreading; stamens numerous, and inserted below the germen; filaments like threads, slightly united at the base; anthers oblong and erect; style simple; stigma concave; drupe fleshy, globular, one-seeded; putamen fungous within. These are highly ornamental trees, both flowers and foliage being handsome; their juice is resinous, and applied to several useful purposes. In British collections they are kept in the hothouse, and are propagated by cuttings or layers.

CALOPOGON (R. Brown). So called from the lip of the flower being beautifully bearded or fringed. Linnæan class and order, *Gynandria Monandria;* natural order, *Orchideæ.* Generic character: calyx a perianth of five sepals; these are lance-shaped, the exterior ones oblique, the interior narrow: the labellum behind, clawed; the limb bearded; column jointed, incurved, winged at top; anthers terminal. This plant was long known in collections as the *Limodorum tuberosum,* and is well worth cultivating.

CALOSOMA (Weber). A very splendid genus of beetles belonging to the section *Pentamera,* and family *Carabidæ,* or Ground Beetles. It is distinguished from the true *Carabi* by being winged. The jaws are without teeth; the abdomen is broad, the maxillary palpi terminate in a large joint; and the four posterior tibiæ are curved in the males of some of the species. These insects are of highly-polished and metallic colours, and, unlike the majority of the family to which they belong, they are found in trees, notwithstanding their large size; hence the necessity of their being furnished with wings is perceived, and hence one of the incidental connexions between the splendour of their colouring and the exposed nature of their habits. Thus, if we look throughout nature, we find that, in every group of animals, those species which are more especially exposed to the light are more gaily ornamented with colours; and this generally holds good even between those species which reside in temperate climates and those which are exposed to the blaze of the tropical sun. The *Calosoma sycophanta* (Linnæus) is nearly an inch long, with the head and thorax of a fine dark blue, and the elytra of a rich copper colour. Its larva lives in the nests of various gregarious caterpillars, upon which it feeds, gorging itself to such a degree as to fall an easy prey to younger larvæ of the same insect. The perfect insect, as well as the other British species, *Calosoma inquisitor,* are generally found in oak-trees, but both are rare in this country. The genus is widely distributed, and Dejean enumerates twenty-eight species.

CALOSTEMMA (R. Brown). A bulb from New Holland, cultivated as a green-house plant. Linnæan class and order, *Hexandria Monogynia,* natural order, *Amaryllideæ.* Generic character: perianth funnel-shaped, six-parted; the crown, or nectarium is within the tube, twelve-toothed, each alternate one awl-shaped, and bearing versatile anthers; style filiform; stigma obtuse; berry roundish, with one seed. This bulb like others, is propagated by off-sets.

CALOTHAMNUS (Labillardiere). A genus of handsome New Holland shrubs, introduced into England about thirty years ago. Linnæan class and order, *Polyadelphia Polyandria;* natural order, *Myrtaceæ.* Generic character: calyx four-toothed, persisting; corolla of four petals; phalanges of the stamens elongated, coloured; anthers oblong and erect; half of the filaments sterile; capsule three-celled, many-seeded, and intimately connected with the thickened tube of the calyx. These are green-house plants and propagated by cuttings.

CALOTIS (R. Brown). A green-house perennial herb from New Holland, belonging to the natural order *Compositæ.*

CALOTROPIS (R. Brown). A genus of two species, natives of India. Linnæan class and order, *Pentandria Digynia*; natural order, *Asclepiadeæ.* Generic character: corolla somewhat bell-shaped; issuing from a kind of bag at the base; crown and limbs approaching and pressed together, revolute at the base, points two-toothed; follicles smooth. This plant has been long known in British collections as the *Asclepias gigantea.* It is one of the commonest jungle plants on the coast of Coromandel, and met with growing in loose sand.

CALTROPS. This is the genus *Tribulus* of Tournefort, and has its trivial name from its thorny seeds, which resemble those instruments of war thrown in the way of cavalry to lame the feet of the horses. One of the species is a common weed in the East Indies, and most annoying to the unshod natives. Linnæan class and order, *Decandria Monogynia;* natural order, *Zygophylleæ.* Generic character: calyx of five sepals; petals of the corolla spreading; stamens alternately inserted in the base of the petals, the others below the germen; filaments filiform; anthers oval, opening longitudinally; style thick, conical; stigma five-ribbed; seed-vessel or berries five, tuberculed or spinous on the outside, containing each one seed.

CALYCANTHEÆ. Carolina allspice family. A natural order of dicotyledonous plants, containing two genera and eight species. It is allied to the *Rosaceæ, Pomaceæ,* and *Myrtaceæ,* and is distinguished from these orders by its imbricated sepals, and its anthers being turned outwards.

The characters of the order are,—sepals and petals confounded, imbricated, and combined into a fleshy tube; stamens indefinite, inserted into a fleshy rim at the mouth of the tube, the inner ones sterile; anthers adnate, turned outwards; ovaries several, simple, one-celled, with one terminal style; nuts enclosed in the fleshy tube of the calyx, one-seeded; seed without albumen.

The plants of this order are beautiful hardy shrubs with square stems, opposite, rough leaves, and axillary yellowish or lurid purple flowers. They are found in North America and Japan.

Their wood presents a singular structure, which may be said to combine both the exogenous and endogenous mode of growth. Besides the usual deposit of concentric circles round the central pith, there are also four imperfect centres of deposition on the outside next the bark.

The Calycantheæ are propagated by cuttings and layers. Their general properties are aromatic, and their flowers are highly odoriferous.

The genera of the order are *Calycanthus* and *Chimonanthus.*

The *Chimonanthus fragrans* flowers early in spring, and diffuses a most delightful odour.

CALYCANTHUS (Linnæus). A genus of hardy shrubs, natives of America, and which form one of the orders of the natural system. Linnæan class and order, *Icosandria Polygynia;* natural order, *Calycantheæ.* Generic character: calyx a much divided coloured perianthemum; corolla none; stamens numerous, inserted into the neck of the calyx; anthers oblong, two-celled, adnate; styles many, compressed; stigmas glandular. Some of these plants have been long in our shrubberies, and are propagated by layers.

CALYCEREÆ. A natural order of dicotyledonous plants, containing three genera, and only a few species. It is allied to *Compositæ* and *Dipsaceæ,* differing from the former in its pendulous albuminous seeds and superior radicle, and from the latter in its united filaments, and partly distinct anthers.

The characters of the order are,—tube of the calyx adnate with the ovary, limb of five unequal segments; corolla funnel-shaped, with a long slender tube, and five segments, each of which has three principal veins; stamens five, monadelphous; anthers combined by their lower half into a cylinder; ovary one-celled; ovule pendulous; style simple, smooth; stigma capitate; fruit an indehiscent pericarp; seed solitary, sessile.

The plants of this small and curious order are herbs with alternate leaves, and terminal or axillary flowers collected into heads. They are natives of South America, and are not remarkable for their beauty. Their properties are not known. The genera of the order are *Calycera, Acicarpha,* and *Boopis.*

CALYCIFLORÆ is the second sub-class of the first sub-division (*Dichlamydeæ*), of the first class (*Dicotyledoneæ*) of the natural system. It contains all the polypetalous plants, which have the petals inserted in the calyx. This sub-class comprises one thousand one hundred and forty-nine genera, and eleven thousand four hundred and thirty-five species, arranged in sixty orders.

CALYCOTOME. The title of one of the tribes of the genus *Cytisus.*

CALYPSO (Salisbury). A genus containing two species of North American orchideous plants. Linnæan class and order, *Gynandria Decandria;* natural order, *Orchideæ.* Generic character: sepals of the calyx distinct, four turned down, and five erect; labellum ovally-oblong, slipper-shaped, with a spur; column jointed; pollen in two masses. This plant has borne several names since it was first discovered. Linnæus called it a *Cypripedeum;* Willdenow named it *Limodorum,* and others *Orchideum.* Salisbury's name is most generally adopted.

CALYPTRANTHES (Swartz). A genus of tropical trees, found in both Indies. Linnæan class and order, *Icosandria Monogynia;* natural order, *Myrtaceæ.* Generic character: calyx with an obovate tube, limb entire, and deciduous like a cap; stamens joined to the tube of the calyx; filaments capillary; anthers roundish, two-celled; style simple; berry one-celled, with strong scented seeds. This genus are handsome trees, and some of them furnish good timber.

CALYPTRION (Gingina). A genus of two

species of tropical plants, one a climber from Africa, the other an under-shrub from Brazil, The flowers resemble those of violets; and Aublet, a French botanist, named the African one, *Viola Hybanthus*. The genus is ranked in the order *Violarieæ*.

CALYSTIGIA (R. Brown). A new genus, separated from the genus *Convolvulus* of Linnæus. See Bindweed.

CALYTRIX (Labillardiere). A genus of New Holland ornamental shrubs, belonging to the Linnæan class and order *Icosandria Monogynia*, and of the order *Myrtaceæ* of the natural system. Generic character: calyx furnished with two bractæ at the base, tube cylindrical, elongated, limb in five oval divisions, terminated by bristles; corolla of five petals, inserted in the calyx; stamens attached to the throat of the calyx; filaments awl-shaped; anthers roundish; style filiform; capsule one-seeded, not opening; seed somewhat cylindrically club-shaped. All the plants of this natural order (*Myrtaceæ*) are in one respect or other estimable. It contains some of our finest fruits, and many of our most beautiful flowers.

CALYX is the name given by botanists to the outer coat or covering of flowers. It is the cup-like member which includes all the others. It is generally green, but sometimes coloured, sometimes entire, but much more frequently divided into parts called sepals, which remain erect or are reflexed. The calyx is said to be inferior if seated below the germen, and superior if seated on the side, or on the top of it: in the two last cases it is usually persisting, its base being swollen into a fruit, or seed-vessel. In some instances, the calyx is entirely wanting, or appearing only as a slightly raised rim. In the second subdivision of the class, *Dicotyledoneæ*, the calyx and corolla are united, in which case it assumes the colour of the latter. This member of the flower affords many pertinent distinctions in descriptive botany, and is usually the first which is noticed.

CAMEL (Cameleus, or rather Camelidæ, the camel family). A group of ruminant animals, partaking in part of the characters of the *Pachydermatous*, or thick-skinned animals, and also of those of the other ruminantia; but having characters which are peculiarly their own, and in consequence of which they form a very well-defined, and also a remarkable group.

There are two divisions of them, the one found only in the more arid portions of the Eastern continent, and the other only in those of the Western,—the former being entirely, and the latter chiefly, in a state of domestication. These two divisions have characters sufficiently distinct for warranting the arrangement of them as separate genera in the system; but we shall save time and also render the account of them more clear, by including both in one article, and stating first those characters which are common to both genera.

The most remarkable of these characters is that of the feeding apparatus, more especially of the teeth: these are as much tearing teeth as those of the carnivorous animals, but they are tearing teeth of a different description; those in the anterior part of the mouth are not formed for wounding, neither are the false grinders suited for bruising flesh; they and the incisors and canines are all adapted for tearing vegetable matter of harder texture than that on which the rest of the ruminantia feed; though, like these, they subsist entirely upon vegetable matter. This structure of the teeth will, upon examination, be found the very best adapted for enabling them to feed upon the hard and prickly plants which, in the deserts, form at all times the principal, and at some times the only vegetation.

The characters and structure of the several families which form the order Ruminantia, can be better explained in their resemblances and contrasts to each other, in a general article upon the order, than in detached notices of each family; but still it may not be amiss here to state that the incisive teeth of those ruminants which browse upon grass, or other soft vegetable matter, are in the lower jaw only; that they are chisel-shaped, ranged in an even curve, and act against a callosity, or hard cartilaginous surface on the upper jaw. Teeth thus formed are not adapted for biting, as those of the last pachydermatous animals, the horse tribe (*equiænide*), all of which have six incisive teeth in each jaw acting against each other, and though they are not adapted for tearing, and have not the sharp nipper structure of the teeth of rodentia, as in the hare for instance, they give a very strong dividing bite; but the animals which have them, have little or no lateral grinding motion of the jaws, and thus their food is not returned to the mouth to be chewed, as in the ruminant animals. In the browsing ruminantia, on the other hand, the grass is brought to the callosity on the upper jaw by a circular sweeping motion of the tongue, and then, pressing the incisors of the lower jaw against the food so brought, they divide it, partly by the pressure, and partly by a twitch of the head.

The camel family have the mouth of a character intermediate between these, but differing in many respects from both. Their teeth vary in the two genera of which the group is composed, but they all have three, or, strictly speaking, four kinds of teeth; namely, two incisors in the upper jaw and six in the under, in all the species; two canines in the upper jaw in all the species, and two in the under jaw in the camels only; two false grinders in the upper jaw of all the species, and two in the under jaw of the true camels; and five grinders in each jaw of all the species; making thirty-six teeth in the true camels, and thirty-two in the rest.

They all have the lateral or grinding motion of the jaws, by means of which the food is reduced to a sort of pulpy mass, as it is brought up from the "hood" in rumination, previous to being carried to the true or digestive stomachs; thus these animals have a double operation in feeding as compared with most of the other mammalia: the first being merely the reception of the food into a portion of the stomach which answers merely as a receptacle or magazine, just as the craw does in gizzard birds. They can therefore take a larger quantity of food in the same time than those animals which do not ruminate, but they have afterwards to chew it; and this operation is carried on when they are in a state of repose. A particular account of the ruminating stomach, and the process of rumination, will be found in the article Ruminantia, so that we shall only notice here an error into which most authors have fallen, in treating of the stomach of the camel. It has been said that camels take in so large a quantity of water into their stomachs, and contrive by means, the explanation of which has never been attempted, to keep it so cool, that when travellers who use camels in the deserts, are reduced to extremities for water, they kill the animals and thus obtain a supply. It is somewhat singular that this opinion should have been held, or at least received by simple transmission from one to another, by even those whom we must suppose to have been acquainted with the structure and economy of the animals, at least so far as to be able to ascertain whether so curious a fact—a fact so perfectly anomalous—was or was not possible. Now, it would not be very easy to see how water could by possibility be kept cold, in any part of the body of a warm-blooded animal, even in Lapland, and much less in those burning deserts in which camels are used as beasts of burden. Farther, if even this impossibility were got over, or if it were admitted that the water were of the same temperature as the body of the animal in which it was contained, it is not easily seen either how it could get there, or of what possible use it could be to the animal; for though Buffon and other describers of that class, have said that the hump or humps on the backs of camels are badges of their enslavement in a domestic state, and do not belong to them in free nature, yet, not even they have gone the length of saying that camels have, in consequence of their enslavement, been taught to carry this supply of water for their masters.

In the first place, the supply of water was said to be found in that which answers to the second stomach, that is, to the hood or honeycomb—that portion of the digestive apparatus which is reticulated or formed into cells; and it is probably on account of the larger size of the cells in the camels, than in those other genera with which we are more familiar, that the mistake has been made. But when we consider the general use of the reticulated portion of the stomach in all those animals of the order with which we are acquainted (and as they form a large portion of our food, we are much better acquainted with their structure and functions than those of any other animals), we find that a reservoir for water is not one of its uses. The solid or dry food which is received into the paunch or first stomach of the animal, is carried from that to the second, or reticulated part, which rolls it into small lumps or pellets, which are returned one by one to the mouth in order to be chewed, and they are again swallowed, and go directly to the third stomach, or foliated portion, and thence to the fourth or true gastric stomach. The general action of the reticulated part is therefore to form the food of the animal into pellets, and return those pellets to the mouth; and, in the same order of animals, the same general organ, however it may vary in different genera or different species, always has the same general use. If this were not the case there could not be any useful arrangement of animals, as the known would be no guide whatever to the unknown.

Well, let us suppose that this second stomach, or hood, is distended with water to the amount stated in the accounts and then let us consider, in the second place, whether the animal could by possibility ruminate, or receive any nourishment whatever, retaining the water in that viscus. Is it not evident that grass or leaves, or other vegetable matters, could not be formed into pellets in a bag full of water; but only by means of an apparatus that could divide its comparative dry contents into small portions, by bringing its sides in contact with them? It is unnecessary to answer this question by any lengthened argument, for to any one who reflects for a single moment, the perfect improbability of ruminating, and at the same time having any quantity of water whatever in the second stomach must appear. The water would equally prevent both functions of the organ—the formation of the pellets, and the returning of them into the mouth; and without this, food in the paunch or first stomach would be of no use whatever, because that stomach can neither digest the food nor carry it to the places in which it is digested. After the food is chewed it is returned to the third stomach, without passing into the first or second; and at this stage of the process, and not before, the water which the animal drinks is mixed with it. We have seen already that the second stomach could not act if there were water there, and when the food of the animal is green vegetable matter, water, even in very small quantity, in the first stomach, is attended with very serious consequences, as it ferments, and the paunch is so distended by the gaseous evolution that the animal is in danger of suffocation, or even of bursting.

Thus it is evident, that the third stomach, the one in which digestion begins, is the first one that receives the drink of ruminant animals, and that water could not be taken into the others without suspending the whole digestive functions as long as it remained there. This must have been known, or at least might have been known, from the time that mankind first began to observe, or, at all events, to kill sheep and cattle for food. It is, therefore, passing strange, that the story of water in the stomach of the camel should not have been exposed and exploded upon physiological grounds as early as anything was written upon the subject; and that it should still be continued in all the popular books, is a melancholy proof of how badly those who pretend to school us in natural history are qualified for the task.

There is a small quantity of limpid fluid in the abdomen of most or all ruminating animals; but this fluid is not water, neither is it contained in any of the digestive organs, nor can it be taken into these. It is an animal secretion, and the chief use of it seems to be to lubricate the very large and complicated intestines, and also to serve as a yielding support between them and the parietes of the abdomen.

This fluid is, in all the ruminantia, when in a healthy state, wholesome and pleasant to the taste; and it may be possible that travellers, when their camels drop down dead in the deserts, may sometimes moisten their parched throats with this fluid; but it is by no means likely that a camel is, in any one instance, killed for the sake of obtaining it. The camel, though a clumsy animal, according to our notions of animal beauty, is a very valuable, and consequently a very highly esteemed animal in those parched countries where it is used for carrying men or luggage. It is strong, though not swift; it is sure-footed; and it can endure fatigue and bear privations more than any other animal.

It can also subsist upon harder food than any other beast of burden: and its size, and the length of its neck, enable it to reach the branches of shrubs and small trees which are above the reach of the ass, which is the animal that comes nearest to the camel in the coarseness of its food. For all these reasons, the camel is most deservedly a favourite with those who use it, and is in no case the subject of wanton destruction.

No doubt, many camels perish in the deserts, but, as they can subsist a considerable time upon little food, and long without water, they generally perish with fatigue in crossing the deserts. Captain Bourchier, R.N., who was shipwrecked in the Red Sea in the end of 1833, and reached Suakin as a landing-place, and thence across the south of the desert to Berber, and thence down the Nile, and across the northern desert from Abu Hamet to Kroosko, travelled on camels the whole distance; and, in the northern deserts especially, where the days were hot and the nights cold, some of the camels employed by his party were left to perish; and he observed the skeletons of many more which had previously been left to feed the vultures in the wilderness. The Captain had opportunities of directly ascertaining whether there was any water in the second stomach of those camels, but he did not find any, or even the smallest indication that there had been any. On the contrary, the camel-drivers ridiculed the idea as one which could not be entertained by any one in the least acquainted with camels. When those animals are so much exhausted as to be unable to proceed farther, either with their burdens or without them, they are sometimes not even killed, but left to linger in the desert; and in order to hasten their death, their fore-legs are tied close together, to prevent them from crawling about and procuring a scanty supply of the hard and acrid plants, to protract the period of their suffering; for, as to hope recovery for any exhausted creature that may be left in those dismal places, there is none. But Captain Bourchier describes the cries of those abandoned camels, when the caravans leave them, as being among the most heart-piercing that are uttered by any animal; and this, coupled with the feeling, that without the camel man could not make his way across those deserts, but, if he once got into them, must remain there and perish, makes the death of a camel in those places one of the melancholy sights that can well be imagined—a sight that could be ill requited by the small quantity of fluid which is contained in the abdomen of the animal.

In remarking on this error, we have anticipated some of the observations which properly belong to the true camels, as distinguished from the other members of the group, but what has been here anticipated will save so much description afterwards; and we now proceed to the more particular information.

Camels (*Camelus*). There are two species of this genus, both, as has been said inhabitants of the Eastern continent, but neither of them at present exists, except in a state of domestication. But there have been reports of wild ones in different parts, both in southern Asia and central Africa, but it does not appear that any of these accounts rest on a sure or even a satisfactory foundation. The only places where camels could be looked for as free animals, living and breeding in wild nature, are the margins of those deserts, in crossing which they are employed as beasts of burden; and the only ruminant animals which are found there in a wild state are different species of antelopes. There has been much change in those countries however; and though the Arab, in the same identical race, has probably pitched his tent in them from the earliest period of human history, yet other nations have risen and fallen in succession, sometimes invading the Arab in the wilderness, and sometimes being invaded by them in return. Thus we may naturally suppose that, as has been the case with some of the domesticated oxen (see the article Bos), stray camels may sometimes have been left running wild, and may have bred in the wild state for a few generations. It does not however appear, that they have been capable of continuing their race, even in this way, for any length of time, and it is certain that they have never multiplied in this manner to any extent. Thus we must regard them in a zoological point of view as domesticated animals only, and as such we shall accordingly describe them.

But, as already noticed, the great distinguishing character is the teeth; and it will save verbal description of their appearance, to refer to Landseer's very spirited and accurate representation of the Arabian camel, or dromedary, in the plate "camels," and to a wood-cut after the same artist in the sequel of this article, for the Bactrian camel, the number of teeth, under different sorts, have been already mentioned. There are five grinders in both sides of each jaw, which have the same furrowed surface, arising from alternate laminæ of bone and enamel, as the grinding teeth of the other ruminating animals. In advance of these there are two false grinders in each jaw, which stand apart from the rest, and are subconical, and a little bent backwards. In front of these there are two strong canines, and in the upper jaw two front teeth which have also the form of canines; and these scattered teeth lock into the intervals of those of the lower jaw, and give the mouth, while the lips are opened, a very ragged and formidable appearance. Nor is the bite of the animal when enraged, (and the male is very apt to be so during the rutting season,) a very simple or very pleasant matter; for instances are mentioned in which an enraged camel has wrenched off a man's arm at one bite. These formidable teeth are not, however, intended by nature for assailing any other animal, their grand purpose is to wrench up the hard plants, and tear off the branches of trees which grow in those wild countries; and the length, and power of motion in the neck, give the animal great force in this respect; and, though the fore teeth of the camel are not adapted for wounding, or the first grinders for bruising, like those of beasts of prey, yet as they have to tear asunder very tough substances, the hold which they take is very firm, and the wrench which they give in order to separate that which they take hold of, is very powerful. The general form of their extremities will be seen in the figures. Their hind legs are considerably longer than their fore ones, though all four are long in comparison with the body of the animal, and the neck is proportionably long, in order that it may reach the ground, as well as those branches that are above them. Indeed, from the length and flexibility of the neck, the mouth commands a very considerable circle, of which the axis of the body is the centre.

As is the case in all ruminating animals the metatarsal and metacarpal portions of the extremities consist of only a single bone each; and the feet consist of two toes, free only at a portion of the points, and having a sole extending from the heel forward for the greater part of the foot, and consisting of a callous though not perfectly hard substance, intermediate between the pads on the feet of beasts of prey and horn. The extremities of the toes are fortified by flat nails, which have a very slight resemblance to proper hoofs. The joints of the legs are also armed with callosities, which prevent them from being injured when the animal kneels on the bare and hot sand; and there is a similar callosity on the sternum, or breast bone, which prevents injury to that part when it comes in contact with the hard and hot ground. There are no clavicles to the fore legs; and all the legs are articulated for motion parallel to the mesial plane, so that the animal cannot climb, or grasp between its feet. It has, however, very considerable action of the legs in that plane in which they do act; and it can, in consequence, defend itself very effectually against jackalls and hyænas, which are the principal beasts of prey in its localities, both by striking out with the forefeet and kicking with the hind ones,—the first of which motions is not so extensively possessed by any other ruminating animal. In the use of its long legs upon ordinary occasions the camel, according to our common notions of grace in walking, manages its long legs a little clumsily. When rising (and it is made to kneel when mounted or loaded), it rises first on the hind legs, and supports itself whilst doing so on the callosities on the fore knees or the sternum; and while it is doing this, the rider if he has not some knowledge of camel-riding, is very apt to be bumped across the ears with the load on the top of him. In walking, too, the rate of which on the ordinary march is about three miles an hour, the camel has a very jolting motion; and it requires practice before the rider can so accommodate himself to the riding as to have anything like an easy seat; but after he once acquires the habit of moving in concert with his beast, his seat is very secure, and by no means an unpleasant one.

As may be seen by the figures, the whole appearance of the camel is ragged. Its abdomen is large, and so much drawn in at the flanks, as to give it an appearance of weakness and constriction there, which it does not in reality possess, for the bones of the hind legs are, by this means, left much more free for motion than in animals which have a more firm and full appearance at that part. The neck is long and bent; the eyes are large and dull; and the lips are projecting, but thin and flap-like, the upper one being divided, and the two lobes prehensile and capable of separate motion. These moveable lobes of the lip are of considerable service to the animal. They serve as organs of touch, and also for compressing any substance, or conveying it into the mouth.

The nostrils are in the form of slits, which the animal can open and shut at pleasure; a species of action which is of great service to it when the wind blows strongly and loaded with drifting sand, as it often is in these deserts. The form of the enlarged sole of the foot, which has been already mentioned, is very convenient for marching on the loose sand, as it has the shape of an oval cushion, which is less apt to sink than any other form. The height, too, to which the feet are lifted, and which occasions the bumping motion, is of great advantage in walking over the loose sand; and it is worthy of remark that the ostrich, which is an inhabitant of similar places, has the feet of an analogous structure, and lifts them in a similar manner.

One of the most singular external characters of the camel, is the hump on the back, which is double in the Bactrian camel, and single in the Arabian one or dromedary; this hump consists of the same kind of substance which is found in humps upon some of the genus bos, in some temperate, but more especially in warm regions, as in the Braminy bulls of India, both in the larger and smaller varieties. It is an accumulation of a peculiar species of fat, which is not liable to be melted, or very much acted upon by the great heat to which the animal is exposed. It consists chiefly of *stearine*, or hard fat, which is not reduceable to liquid oil at any temperature to which the animal can be naturally exposed; and it is not a deformity produced by servitude, as has been foolishly said, neither is it in itself of any use in the economy of the animal. It is a store of nourishment, most wisely provided by nature against the day of want, to which the camel in a wild state would be often exposed, and from which he is not entirely exempted in a state of domestication; and a camel can exist for a considerable time upon its own hump without any other food, nor does it die of want until that hump is entirely absorbed, and applied to the general nourishment of the whole system.

Animals which exist chiefly upon vegetable matter, and which are subject to seasonal vicissitudes in their supply of food, all make accumulations of fat on some part of their bodies, and have some provision or other, against the season in which their outward supply of food fails; and their tendency to do this is exactly in proportion to the need they have for it, considering the average in the seasons of those places in which they inhabit. The parts of the body in which this accumulation is made, and the consistency of the accumulated substance, are both very important points in the geography of animals, which is one of the most interesting departments of their whole history. If the animal winters in cold latitudes, as is the case with the bears, then the accumulation of fat is generally distributed over the surface; and it is of a soft and oily nature, or what is termed lard. If, on the other hand, the animal inhabits the very warm latitudes, where the season of want is one of heat and drought, the accumulation of fat, as in the hump of the camel, contains a maximum of crystallisable fat, and is accumulated upon some particular part of the body, generally that part in which it can be carried with least inconvenience to the animal, and least interruption to any of its working structures. In the intermediate latitudes, where there is a supply of vegetable food all the year round, the distribution of fat is more general through the body of the animal, both externally and internally,—accumulating on the kidneys, on the mesentery, and often on the surfaces of the muscles, and even upon those of the bundles of fibres of which the muscles are made up; but in animals which do not accumulate fat on any particular part of the body, as many do in a hump, a dewlap, on the rump, or even on the tail as is the case of some species of sheep, then the accumulation of fat is always more internal as we advance into warmer latitudes. Thus the sheep and pigs of France never, by any feeding, acquire the same external plumpness as those of England; and the difference is so great, that those of some places of France, even when in the very best condition to which they can be brought, would hardly be marketable in this country; but when they are opened they are found to contain more fat internally than ours do.

If we consider the ruminating animals only, the range of which in latitude may be considered as extending from the reindeer to the camel, we have a regular gradation in the kind of fat, which is no bad indication of the native localities of the animals; it being understood that the genera which are found nearest the pole keep more and more to the mountains, as they extend nearer and nearer to the equator; and that the genera which are first met with in the savannahs, in the northern parts of the temperate latitudes, follow the lines of the rivers, and the margins of the forests. Among these, the accumulated fat of the deer tribe is the softest; then follows that of the ox, afterwards the sheep, and lastly the camel; but some species of the intermediate groups accumulate crystallised, or at all events curdy fat, according to their nature, and that of the places which they frequent.

The antelopes, which are in general light and fleet animals, and thus much more capable of shifting seasonally after their food, have not such a tendency to the accumulation of fat; and the same might be said of the kangaroos of Australia, which, though not ruminating animals are vegetable feeders, and the only native animals which supply the place of the ruminantia in that part of the world.

The only other general characters which it is necessary to mention in the true camels are, that the females go twelve months with young, produce only one at a time, which is dropped with the rudiment of a hump and with the eyes open, but it has not the callosities on the sternum or the joints of the legs; the female has four teats, and continues to suckle her young one for twelve months, as it is a considerable time in being able to support itself by browsing. As already hinted at, the males become very fierce during the rutting season, and they undergo certain other changes which are peculiar. The humps in a great measure disappear, owing in all probability to the animals then ceasing to feed; they become less strong than at other times; their eye sare inflamed, they discharge a fœtid liquor from the glandular openings on the back part of the head; they foam at the mouth, and occasionally at least protrude the uvula between the teeth, as if it were an inflated bag of a deep red colour.

There is little difference between the Bactrian and the Arabian species, other than that the former is proportionably longer in the body and lower on the legs, and has two humps. It is generally understood that the two breed together, but the fact as to whether the progeny will again breed with each other, and thus establish a specific identity, or whether they be mules, which, like those between the horse and ass, will breed back to the pure blood of either parent, but not with each other, is not yet settled.

The Arabian Camel (*Camelus Dromedarius*) may be considered as the camel *par excellence*; as it is the one which is best known and employed on the most difficult, and therefore the most important journeys. To the Arab in the desert, especially those parts of it in which neither sheep nor goats can be kept; the camel is an exceedingly valuable animal, and in this respect approaches nearer to the ox, where kept for draught and burden, as well as for food, than perhaps any other animal. The flesh of the camel is eaten; and the milk is applied to all the common domestic purposes. Their hair is manufactured into clothing, and also covering for tents. The hide, which is very thick and strong, is used for making sandals, saddles, pitchers, shields and various other articles. The owner, with his family, and all their little appointments, are carried from place to place on the backs of the camels. When the camel kneels down for repose during the night, his side forms a pillow; and when the sand drives before the storm in the desert, the rider takes shelter in the lee of the kneeling camel. Upon occasion, the camels are sometimes ranged round the encampment, forming both a shelter, and at least a temporary means of defence in cases of attack during the night; and those countries which are separated from each other by wide extents of desert, could have no communication with each other but by means of the camel. The camel and the desert thus appear to be made for each other; and though the appellation of "the Ship of the Desert" no doubt partakes of little of the high hyperbole of eastern speech, yet that animal is the only ship by means of which the desert can be navigated either with certainty or with safety.

An Arabian camel can carry a load of between 700 and 800 pounds, and travel with it at the rate of about two miles and a half in the hour. When less heavily laden it can travel faster, though not above three miles in the hour; and in the deserts it is not customary to load the animals very heavily, or drive them more than about eight hours in the day. Though the eye of the camel is heavy, his senses, especially that of smelling, are very acute: and though there is some trouble as well as some skill necessary in breaking a young camel, yet when properly broken they are docile; with proper treatment they last much longer than the horse, being serviceable to the age of forty or forty-five years; but in India, where they are heavily laden, and not so well treated as in the countries to the westward, they do not last above half that time.

Camels have been partially introduced into some of the warmer parts of the South of Europe; but they are not properly at home any where except on surfaces of dry sand or mud; on hard ground their feet get beaten, on rocks they get cut, and on both kinds of surfaces the planting of the feet shakes them violently, and they run some risk of dislocating the joints of their legs; their manner of walking, and also the convex form of the soles of their feet, render a surface which yields partially to the tread necessary to their walking with comfort; and when one sees a camel led about for show in paved streets, the animal seems to walk in great pain, and looks sickly from the constant jolting of its weighty body, and the tendency which its feet have to slide, especially if the pavement is wet, or glazed by the traffic of carriages in dry weather.

Camels are sometimes used in war, and small pieces of ordnance are occasionally mounted on their backs; but the principal use of them are for more pacific purposes. When a horde of those nomadic tribes, which depend much on their camels, remain stationary in any locality, they let their camels pasture together in considerable flocks; but the males and females are kept in separate pastures, by which means they all remain tractable, except during the rutting season, and then the males often fight desperately with each other by biting, striking, and kicking, in the course of which they endeavour to throw each other down, and the one which goes to the ground is sure to be trampled under foot by the other. They are even exhibited in combat among the coarse spectacles of the place. This is not, however, very common.

As is the case among horses, and indeed among all animals which have been long in a state of domestication, there appear to be considerable "differences of blood" among camels. Those which are used in common caravan travelling, with heavy loads, and at a slow rate, bear nearly the same relation to the smaller, lighter, and fleeter breeds, which are used in reconnoitering or on swift journeys, that our heavy dray and cart horses bear to roadsters, hunters, and racers. It is to this small and fleet breed that the name dromedary, or *mahairy*, properly applies. By means of these, no doubt with relays at the different stages, a journey at the rate of more than four miles an hour may be kept up night and day for several days. It has sometimes been alleged that this difference of speed in different individuals should be considered as arising from a difference of species, and there have not been wanting attempts to show that these different species originated in different parts of the country, but there is little reason to suppose that either the one or the other of those suppositions have the slightest foundation in truth; though there is no doubt that camels, like all other animals, are affected by differences of climate, pasture, and treatment. And, as the swifter ones are said to be more in the hands of the wandering Bedouins than of those who have comparatively fixed abodes, it is highly probable that the farther into the desert, the camel is the fleeter, and the smaller in size. This accords with what is observed of animals in our own country; and as is the case with these, it seems to be in hardihood and power of endurance more than in absolutely greater speed, for a short time that the mahairies are superior to the larger camels which are employed to carry loads at slower rates and at shorter distances.

The Arabian camel is, in the largest breeds, about seven feet in height; but the smaller and swifter ones are lower. The legs are long and slender, and what are considered "clean made." It is very much drawn in at the flanks, but the abdomen is rather too large, and the length of the intestinal canal and size of the stomachs, rendered necessary by the coarse nature of the animal's food, require that it should be so. There is but one hump, which is nearly in the middle of the back, broad and rather flat in the upper part; and it does not waste so much in the rutting season as the hump of the Bactrian camel. Independently of the different breeds which are reared for different purposes in the domestic economy of those people who use camels, there are considerable differences arising from the characters of the countries in which they are bred. In this respect they follow the law of all domesticated animals which find their food in the fields; that is, the richer the pasture is the breed runs the larger, and the breed gradually diminishes as the pasture becomes bare and dry. So that if large camels are wanted in Arabia or in the African deserts, the breed has to be obtained, or kept up by periodical crossing, from Turkey; and on the other hand, if light and fleet camels are wanted in the richer places, they have to be obtained by means of the breeds of the deserts. Independently however of this, there appears to be some difference of size connected with difference of latitude, as they are smaller in proportion as they are bred in places nearer the equator. From this it has sometimes been argued that the Arabian camel is not a native of Arabia, but of Syria, and even the northern part of that country toward the mountains of Armenia; and that of the two species of camel, the one are natives of the country immediately to the south of those mountains which range from the Himalaya to the shores of the Archipelago, and that the others are natives of the northern slopes of the same mountains

That this mountain ridge is the natural boundary of the localities of the two species or varieties may readily be admitted, because the hair of the Bactrian camel follows the general law of that of all animals of Central Asia northward of the line of the Himalaya. Toward the winter it grows very long, as if to serve as a thatch against at least occasional snow storms; and when summer sets in, this winter coat of long hair is shed, so that during the summer, which is very hot and dry in those places, as compared with the winter, the animal is nearly naked. In the Arabian camel, on the other hand, there is no such seasonal change in the hair. No doubt it is longer in winter than in summer, and the coat is annually changed as well as that of the other; but the change is gradual in comparison, and the difference in the winter and summer appearance of the animal is not nearly so great. In this respect, however, there is a considerable difference between the camels of the northern and the southern parts of their range, or more strictly speaking, between those that inhabit countries which are subject to periodical rain and drought, and those which inhabit where the climate is habitually dry, and with the exception of difference of heat (which is not very great), the weather may be said to be nearly the same all the year round. This is very much the case on the borders of the western or rather the central deserts of Africa, and it is partially also the case in some of the northern parts of Arabia. These are the places where the smallest and fleetest camels are bred, and also where their hair is shortest and most uniform in length throughout the year.

There is thus a wonderful accommodation to climate in the camel, as well as in all the other ruminantia, which are so very serviceable to man in a domestic state; and from this we may infer that, in so far as its general health is concerned, the camel might in course of time be domesticated, and thrive in a domestic state, in any latitude, from Lapland to the equator. There is something very remarkable in this universal adaptation of those animals which are the most serviceable to the human race, so remarkable that it is impossible not to see that God has created those animals for a double purpose. First, for their general use in wild nature, in which they agree with all other natural productions; and secondly, in their peculiar use to man in all stages and degrees of civilisation. And we may remark that the very same law holds good in the vegetable kingdom. All those plants which are more eminently necessary for human food can, with proper management, be grown in perfection over a vast range of surface. Wheat, which is probably (though the fact is one which cannot be ascertained with certainty) a native of Northern Africa, can be profitably reared in the north of Scotland; and the potato, which is originally from Central America, forms a large proportion of the vegetable food even of Northern Europe, and is much better there than in any part of that continent of which it is a native.

Animals and vegetables which are not serviceable to man, or of which the possession partakes more of the character of a luxury than that of a necessary life, do not so readily accommodate themselves to different climates; and in order to have them in places which are not native to them, a good deal of art must be practised, and a good deal of expense incurred. But though the valuable animals accommodate themselves to different climates, there is still one part of their organisation which keeps them to that peculiar kind of surface on which food most nearly resembling that of their native places is to be found; and, as the camel is a native of very peculiar kinds of surface, the camel is a very remarkable instance of this. These animals use their feet only as organs of motion, and except in kicking or striking in their own defence, they use them for no other purpose; and, therefore, the structures of their feet keep them more to their proper localities than those of any other animals, as for instance, the buffalo to the swamp, the ox to the meadow, the sheep to the hill side, the goat to the rocks, and the camel to the desert. Therefore, though it is possible to rear any one of those animals over a very wide extent of latitude, there is still some one better fitted for every particular place then any of the others are; and thus, though nature has been exceedingly bountiful to man in the valuable qualities in those animals, the advantage is not given to him as an ignorant and indolent savage, but as a means of rational study and wholesome labour. Hence, every department of nature, as well as every difficulty and distress by which man is overtaken on his progress through life, impresses upon him the necessity of being intelligent and industrious—proclaims to him, in language not to be mistaken, that if he would avoid being wretched and miserable he must learn to know and to do, and continue steady in the practice of both, during the whole period of his life.

The Bactrian Camel (*Camelus Bactrianus*) can be very easily distinguished from the Arabian one, by comparing the annexed figure with that on the

plate "Camels." It will be seen that it has two humps, one over the shoulders and the other over the lumbar part of the spine. This, though lower on the legs, is altogether taller by about half a foot than the Arabian. It is also longer and stronger in the body, thicker in the legs, but not having the soles of the feet quite so large in proportion, or so convex on their surfaces. Thus it is better adapted for walking on hard surfaces than its southern neighbour. Still, however, it walks very badly upon rocks; and thus it is not a mountain animal any more than the other. The difference in the feet of the two species is, next to the difference in the coats already mentioned, one of the most characteristic distinctions between the two, and the difference in the length of the legs may be considered as a part of this character. The broad and rounded foot, the long leg, and the high lifting of the Arabian camel, together with the proportionally smaller weight of its body, adapt it in a peculiar manner for travelling upon loose sand; while the smaller and flatter foot, and the shorter and stouter leg, with the lower lifting in the Bactrian camel, adapt it better for walking on the surface of the ground, when dry and indurated, but not reduced to sand. The foot stands firmer, and the animal has less concussion when it walks, and thus, independently of its greater size and strength, this animal could carry a greater load than the other.

Now those two characters are in exact conformity with those of the deserts on different sides of that line, which has been described as separating the localities of the two species. From the absence of rain, and the continual heat of the day, in the southern deserts, the surface of the earth, even to the rock itself, is reduced to powder; but it is not washed, neither are those particles which would make a paste with water, either accumulated in such quantity as to form a paste, or supplied with so much water as would form them into one. The sand therefore remains loose on those deserts at all seasons of the year, and even where so much rain falls that their peculiar vegetation is produced; and that vegetation may be said to be wholly on the surface, very slow growing, and furnished with an *epidermis* so close and so little liable to be affected by changes of temperature, that the plants remain juicy, and even cool, in the burning heat of the desert. Those plants are generally saline, bitter, or have some principle in them too active for their being used as human food; but the few which can be so used are of a very refreshing character. We may mention, as an instance, the water-melon, which, in some places of the desert, where the surface is nothing but stones and sand, and where there is hardly another green thing to be seen, is sometimes met with as much as three feet in length, and the same in circumference; and though the sun is beating on it with the utmost intensity, it feels colder in the mouth than a prepared ice in the hottest of our summer days, so cold indeed, that those who are heated by travelling or otherwise, find caution necessary in indulging in this delicious treat which nature provides for man in the wilderness.

The northern desert, that of the Bactrian camel, is of a very different character. In the winter there is both rain and snow, and the rivers are not unfrequently so completely frozen over, that the people, and even the loaded camels, cross on the ice without danger. But the summer is very warm, and in many places vegetation wholly disappears from the surface. Still, the rains wash down the more soluble matter from the heights, and form it into a paste or mound on the levels; and there it is, in the summer, either a very fertile field, or a hardened surface, like our beaten paths in dry weather, according to circumstances.

A country so circumstanced is adapted to a very different vegetation from that which is found in the deserts southward. The portions of the plants above ground cannot endure the great difference which there is between the summer and the winter; and therefore it is in great part annual; or the plants have tuberous, or other strong and permanent roots. It is to this description of soil, when hardened, that the feet of the Bactrian camel are peculiarly adapted; and the adaptation is as perfect, and as clearly demonstrative of indescribable wisdom of design, as any other which occurs in nature.

Lamas (*Auchenia*). The animals which constitute this genus, or division of the camel family, differ considerably from those already described; but still they retain the general characters so perfectly as to belong to this family, and not to any other. What may be called the general system is the same in them as in the true camels; and all the differences between them are adaptations to difference of situation, and of the circumstances thence arising. They are all natives of South America, and of South America only; but they do not inhabit the plains. Their locality is on the different cordillera or ridges, which form the great chain of the Andes; and they inhabit those mountains as high as the commencement of the region of snow. From the great elevation of those mountains, and their lying nearly upon a meridian, there is perpetual snow upon the more lofty summits, through the whole length of the chain; and from various causes (some of which will be found noticed in the article America in this work,) they are subject to very violent storms.

The region of the Andes is so peculiar, and differs so much from those which are inhabited by the camels of the East, that no animal or other production of that region can be well understood, without some knowledge of the region itself. Indeed, no animal can be properly studied as a portion of the system of nature, the only point of view in which the study of it is any thing else than an idle amusement, unless the place of which it is a native, or for which it is best adapted, is studied along with it. This is generally omitted in works which profess to treat of natural history, and because it is so the public generally do not profit by those works, and therefore they do not care for them.

The slightest consideration will serve to convince any one of the necessity of studying the place along with the production. All the peculiarities of animals, or of nature's other productions, are adaptations of them to the places where they are naturally found, and consequently, without a knowledge of the situation, we can tell nothing of the use either of the different organs of an animal, or of that animal as a whole.

The Andes, as well as the eastern deserts, are in many places barren; but, in every other respect they are the reverse of each other. The eastern deserts are flat and monotonous, and unless when the winds drive the sands in the southern ones, or rain or snow falls in the northern ones, there is little natural action of any kind on them. They are not only in great part desolate of life, but they are deprived in a great measure of the action of dead nature. The Andes, on the other hand, are perhaps more diversified in their surface than any other portion of the earth of equal extent. Lofty peaks, frightful precipices, ravines cleft nearly mile deep, natural bridges, foaming torrents, thundering cascades, and every thing which is considered as forming part of the sublime of still life, is to be found there in the greatest abundance and the utmost perfection. Nor, independently altogether of vegetables and animals, is the working of nature any where, perhaps, upon so grand a scale as upon those wild mountains. Volcanoes are numerous, many of them rage incessantly, and Ætna would be but as a little hill by the side of the more lofty ones. Earthquakes are consequently numerous, and always fearful, and sometimes lamentable in their effects. Among the summits where man cannot comfortably inhabit, they rend and scatter the rocks with terrible destruction; and sometimes in the lower parts of the country they have, at a single vibration, shaken a city to pieces, and laid its ruins level with the earth. Nor is the action of the atmosphere less energetic. In the warmer parts, the lightning and thunder are awfully grand, and the rain falls so fast as to flood the ground in a few minutes; while on and near the summit, the snow storms darken the atmosphere, and drive with a fury unknown in any other part of the world, so that no other unsheltered animal can keep its footing, or even preserve its life.

In such a country, both animals and vegetables must be peculiar; and we may be prepared to expect very considerable differences between any race of animals, and those of the same race in the quiet deserts of the eastern world. This in part accounts for the little knowledge which we have of the animals under consideration, and there is another cause which has tended still further to limit our information, and also to render it inaccurate as far as it goes.

During the whole time that this part of the world was under the dominion of Spain, which was from our first knowledge of its existence down to a very recent period, the scientific world was studiously kept in ignorance of it; and even since it became independent, many parts have been too unsettled for enabling us to obtain any thing like correct information respecting a country so very extensive. Thus the little information which we possess respecting these animals refers more to single specimens out of their native country, than to their natural and proper habits within it.

Thus the Lamas were for some time studied as if they had formed part of the zoology of the eastern continent; and for a considerable time naturalists considered them as a kind of sheep, though in their true system they are camels. Even now, though there are living specimens at the gardens of the Zoological Society, and other places, the history of them is not yet perfect; though it may be said that they bear nearly the same relation to the true camels, that sheep and goats bear to oxen, or rather, perhaps, that some of them have more resemblance to the sheep, and others more to the goat. It is, however, to be understood, that the resemblance to these animals applies to the adaptation to the haunt only, and not to the system of the animal. There is however, one structural peculiarity in which the resemblance holds: the true camels have all four mammæ like the ox tribe, while the Lama division have two, like the sheep and goats.

Since the introduction of European cattle into South America, where they have thriven in a wild state to a degree quite unprecedented in any other part of the world, the lamas have become of comparatively small importance in a general point of view, though they are still much prized by the Indians and other mountaineers, in those wild places of the country which are not adapted for the pasturing of cattle. They are not now used as beasts of burden, except perhaps in some rare instances, where from the poverty and inaccessibility of the place, the colonists have left the Indians so much wealth as even a Lama; and it is probable that there are wild ones, especially of the smaller kinds, in many of the fastnesses of the Andes. The mule has in general, however, displaced them for carriage in the most difficult passages of the mountains, and the bullock and the horse in other places.

But, in earlier times, they were regarded as animals of great value; and it was probably as much owing to the possession of them as to any other cause, that the inhabitants of the Andes had made considerable advances in civilisation, while the inhabitants of the lower, and in as far as soil and climate are concerned, by far the richer parts of the country, remained in a state of confirmed and hopeless savageism. As beasts of burden, they are in some respects more stubborn than mules, and they have not either the strength or the sagacity of these animals; but still a full-grown lama will carry from a hundred to one hundred and fifty pounds weight for more than sixteen miles in a day, and over the most difficult passes, in so steady a manner as not to cast any part of the load. In this respect they are superior to the camel; they do not lift their feet so high, and therefore their march is not so dodging. When overloaded however, they become sullen, lie down under the load, and no good or bad treatment will make them get up till it is removed.

Their flesh is wholesome, their hide strong, firm, and useful for many purposes; and their hair, which is long and silky, and cast annually in the same manner as the fleece of the sheep, allowed to run unshorn, is of considerable value in the arts; so that though they are inferior to the domesticated ruminantia of the Eastern world in an economical point of view, they are still animals of no mean value; and it has been supposed that they might be introduced with considerable advantage into many parts of southern Africa, Australia, and other mountainous and dry districts of the Eastern world, which are too elevated for cattle, and too scanty of pasturage for sheep.

There are several species mentioned; and it is probable that the ones which have been longest in a state of domestication are, as is the case with all domesticated species of the order, very much broken into varieties, especially varieties of colour, upon differences of which, it is never safe to ground specific distinctions in this order of animals. There seems however, to be several species, though the differences between them are far from being clearly made out. Their history in their native country is very imperfect; and animals which are so obedient to climate, as those mountaineers which are produced in a climate so variable necessarily must be, are not to be safely judged of from the few specimens which are brought to Europe. We shall notice one or two of the principal ones.

The Lama (*Auchenia Glama*). These animals, as described by Humboldt and others who have visited their native country, and paid some attention to its native history as being wholly in a state of domestication, although, as they are not so attached to one another and to their homes as cattle and sheep, there are strays occasionally met with among the mountains, where it is possible that they may sometimes breed; but as, though sure-footed in the rocks, they are far from being fleet animals, they are soon recaptured. They are of all varieties of colour, from nearly a dull white to almost entirely black. They vary considerably in size; the largest being about five feet long in the body, and nearly four and a half at the shoulder. The neck has a bend downwards at its junction with the back; but it is long, and when the head is raised, the muscle is at least six feet from the ground. The head is thick in proportion to the length; the lips are thick, the tip of the ears (which are much longer in proportion than those of camels) are rather rounded. The legs are stout, the hoofs on the toes pointed, and capable of separating from each other so as to take a firm hold on the slightest inequality in the rock. Indeed the feet of these animals, unlike the round pads of the camel, are perhaps better adapted for keeping their footing on rocky places than those of any other family of ruminantia, except the goats. The back is straight, or rather bent down in the middle, and without any hump. This provision is not necessary in the mountains of South America, where, though there are considerable differences of seasons, these are nothing compared with those of the Eastern deserts. The lama is described as being a patient and good natured, though rather dull animal. Some notion of the general appearance may be obtained from a delineation of a black coloured one at the top of the plate "*Camels*;" but it is to be understood that this is not a distinct species, any more than the white, the rust-coloured, the dun, or the dull brown, the last of which is the most prevalent tint.

The Guanaco (*Auchia Hunaca*). It is very doubtful whether the animal described by this name be any thing else than mere varieties of the lama, produced by different pasture and climate, as they do not differ from each other so much as many of the breeds of sheep. These animals are chiefly from the southern parts of the Andes, where there is much more rain than in the parts near the equator. When full grown, the animal is said to be considerably larger, approaching in size to an ordinary horse; the hair on the upper part yellowish, that on the under part white; the head rounded; the ears straight; the muzzle pointed and of a black colour; and the tail short and sticking out like that of a deer. Altogether the animal is of softer expression, and appears as if better fed than the the lamas of the central Andes. It is also said to be much more abundant in the wild state, and indeed it is in that state that the greatest number are said to be met with, flocks of two or three hundred or even more being mentioned as occurring in the mountain valleys of the south, especially those in the interior of Araucania, between the western or more thickly inhabited part of that country, and the southern part of the Pampas. This is by no means improbable; indeed from the character of those countries southward of South America, and bordering on Patagonia, and probably in the interior of Patagonia itself, it is very likely that these ruminantia may be much more abundant, and thrive much better than they do in places near the equator. This part of America long lay under the brand of being one of the most dreary and inhospitable on the face of the earth; and there is no doubt that, immediately adjoining the strait of Magellan, it is rocky, rugged, and at certain seasons subject to violent storms. But Captain King, by whom it was lately explored, with more minute attention than it has been since the days of the earliest Spanish navigators (and it was their policy to conceal and not promulgate their discoveries), found many traces both of a tropical botany, and a tropical zoology; even along the very shore of the strait. We know also that great part of the Araucanian country westward is exceedingly fertile, though it is a country which has been but little explored; and as the Araucans kept up a continual war for their liberty with the Spaniards, and maintained their ground from the very earliest footing of the latter in Chili, it is not to be supposed they will, for many years to come, allow any Europeans, of whatever nation, very minutely to explore their country; and till that is done, we must be content with only a vague and traditionary history of probably several species or varieties of the lama family, some of which have been vaguely mentioned by Molina and others.

It is said that the animals, in this part of America, want some of the peculiar characters of the mountaineers: that, for instance, the pads of callous matter on the knees are much smaller, the hoofs much less adapted for holding on upon rocks; the hair longer and more silky, and the whole animal of a softer character.

The Alpaca (*Auchenia Alpaca*). A figure of this animal will be found in the plate already referred to, from which its general appearance can be more readily understood than from any written description. The general colour of the upper part is various shades of maroon brown, in some places inclining to black; and the upper part and breast are in general white, as also are the insides of the thighs. The hair along the back is very long and very silky, and almost as fine in the staple as that of the cashmere goat. It is an animal easily tamed, and quite harmless and docile; but when teased it assumes an attitude of defence, and blows and spits at its enemies. Several specimens have thriven well in Europe; and there is no doubt that this is an animal which might be introduced with advantage in many places. We are, however, not so much acquainted with its habits, as to know whether it would breed as freely and as profitably as the ruminantia of our part of the world.

Such are the bare outlines of what may be considered as one of the best defined natural families of ruminant animals, and also one of the most valuable in those places of the world to which their structure more peculiarly adapts them; and it is worthy of remark, that though the places of which they are native, are not the most tempting either for their spontaneous vegetation, or for cultivating, yet that, wherever they are found, mankind have, from the earliest accounts of them, possessed of at least some degree of civilisation.

CAMELEON, CAMELEONIDÆ, Cuvier's fifth family of Saurian reptiles, of which there is only one known genus, the Cameleon (*Chamæleo*). The name was applied by the Greeks, who were very well acquainted with those singular animals, though, how they came to call them "little lions," for that is the meaning of the name, cannot be very well made out, as there is not one point of resemblance. They have been celebrated from very remote antiquity for the power which they have popularly been said to have of changing their colours at pleasure, and especially of assuming the colour of the surface upon which they are placed, though much of what has been said upon this subject is, in all probability, exaggeration. Still they are very interesting, and at the same time very singular creatures, standing alone and peculiar among all the tribes of the order *Sauria*, numerous and varied in appearance as these are. The following is a brief outline of their general characters:—

The skin is granulated all over with little points of scaly matter, the interstices of which are, especially on the belly and throat, very elastic, and capable of distension, and when the skin is distended, the scaly points stand up; but the change of colour is in the intermediate parts of the skin, and not in the scales themselves. The body is compressed laterally, and with a toothed or notched ridge down the back. The tail is rounded and prehensile, and about the same length as the body. The head is short, and moderately thick, covered with smooth scales, some five-sided and some six-sided. The nose is generally blunt. The eyes are remarkably prominent, but they are covered by the common integument of the head, excepting a small hole over the pupil. They are capable of a good deal of motion, both in their own proper substance, and in the skin by which they are in great part covered. Each is capable of separate motion, and the two can move at the same time in opposite directions. Hence it is probable that the animal has a double sight, or can simultaneously perceive objects in two directions. But this is a point upon which it is impossible to obtain certain information, though it is probable that those insects which have *ocelli* in addition to their eyes, properly so called, have also a double sight. The teeth of the cameleon are three-lobed, the usual form of true insectivorous teeth. The tongue is fleshy, of a cylindrical form, and remarkably projectile, striking out to a great distance, and with so much celerity, that the motions of it are not easily observed. The tip of the tongue is covered with a very viscid and adhesive secretion, which is the only organ which the animal uses in the capture of its food. The motions of all the other parts of its body are slow; but so sharp and sure is the eye, and so rapid the shoot of the tongue, that it can kill insects with great certainty, and in quick succession, as they fly past it. In these respects it differs entirely from the *Agamis* of America, with which it has sometimes been confounded, as they catch their insect prey by agile motions of the whole body. Cameleons have no visible external ears, and the skin of the occiput is erected into a sort of pyramid. The feet have five toes each, which are divided into two fasciculi, the one containing three, and the other two—those which compose each fasciculus being united by membranes as far as the claws. They are terminated by moderately sharp claws; but the whole of the extremities are adapted rather for holding on with security than for rapid motions along those branches which these animals chiefly inhabit. The first pair of ribs are united with the sternum; the others are united to each other, and support the abdomen by an entire circle. The lungs are of very large size, and the animal can take in a vast quantity of air for its bulk, by means of which the elastic skin is extended till the granular scales are wide apart from each other, and the skin is nearly transparent. There is little doubt that this capacious breathing in the cameleon is the foundation of the very old mistake that the animal feeds on air. As already said, insects are its food, and it captures them in great numbers; and indeed, as the waste of the bodies of animals is generally very much in proportion to the quantity of respiration, the air which the cameleon takes into the lungs is a means of hunger, and not of nourishment. The tongue, the eyes, and the organs of respiration themselves, are, however, the only parts of the system in which there can be much waste, for the action of all the other parts is remarkably slow; and indeed, as the cameleon, from the mode in which it captures its prey, can be more successful by lying in wait in those places where insects pass on the wing, than in pursuit after them, rapid motion of the limbs would be of little use to it. But though the cameleons catch insects with great dexterity, those insects are generally of very small dimensions, so that many of them are necessary to make a full meal even for the "thin cameleon."

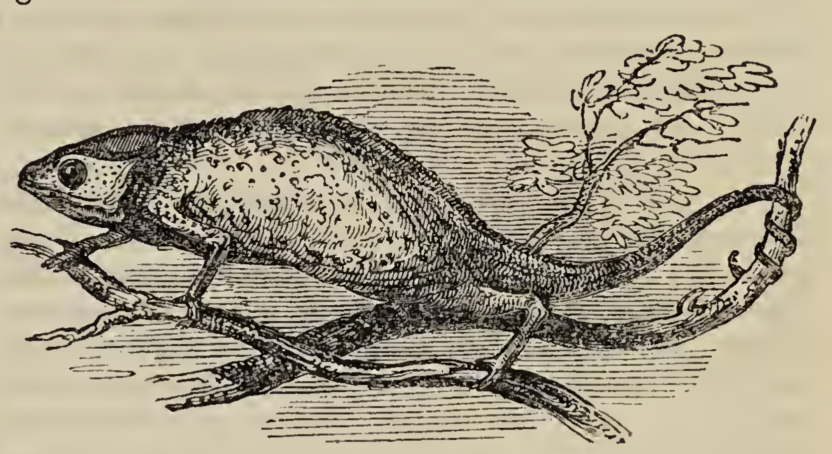
Cameleons may be regarded as almost exclusively tree animals, of very delicate nature, seldom on the ground, and perfectly innocuous, excepting to those small insects which they lime by means of the glutinous matter on the tongue. They are animals of warm climates only, and they are confined to the eastern continent, but in the hotter parts of that they are very generally distributed, being found in Africa, in India, and in the south of Spain. The structure of the feet, which bears some resemblance to that of zygodactylic birds, renders these animals but ill qualified for moving on the ground. Indeed, they are usually found on the branches of trees, with the body in a state of perfect repose; and they might be considered as dead, were it not for the rapid motion of the eyes, and the frequent darting out of the tongue; for, unless they are alarmed, or otherwise excited, they do not inflate the body by full respirations of air. In this state of repose, in which they can exist a considerable time without food, cameleons become a prey to the smaller species of the cat tribe; and in Spain, especially about the bay of Cadiz, where they are very plentiful, they are sought after by domestic cats with as much assiduity as small birds are by the same animals in Britain.

When they are at rest in the trees, their colour is white, with a trace of yellow; but when the skin is distended, and rendered thin and transparent by the inflation of the body, the colour of the blood, which is violet blue, appears through the whitish yellow of the skin, and gives the animal a green of various shades and intensities, according to the degree of excitement. The colour varies between white and blue, but never becomes exactly the one or the other; but there are some of the variations that appear almost black, and others in which it is brownish. There is not much iridescence in the colour of the cameleon, nor does it appear to change with age.

There are several species, of which, as they very much resemble each other in their manners, and do not differ much in other respects, very brief notices will suffice.

The Little Cameleon (*Chamæleo pumilus*), Smaller than the common cameleon. The colour light blue in a state of repose, but subject to variation from the same causes as in the other ones. It is found in southern Africa, Mauritius, and the adjacent islands. The occiputal crest is flattened backwards; the flanks, the tail, and the membranes of the toes, are thinly scattered with warty tubercles; on the throat there are numerous laminæ, finely denticulated in their margins, the number of which varies in different individuals, and the back is furnished with an acute slender crest.

The Common Cameleon (*Chamæleo vulgaris*). The general colour of this species, when in a tranquil state, is brownish grey, but the shade is said to vary in different countries. It has a spiny crest on the back and throat. The occiput rises in a four-sided pyramid, and there are prominent tubercles under the skin of the back. The scaly granulations on the skin are of equal size, and very closely set. The common cameleon rarely measures so much as two feet in length, and half of that is occupied by the tail. It is very plentiful in all the north of Africa, the south of Spain, and many parts of Europe. Some notion of its general form may be obtained from the figure.



The Senegal Cameleon (*Chamæleo Senegalensis*), is, as the name implies, found in western Africa, between the Senegal and Gambia. The general colour in a state of repose is pale yellowish ash, tinged with blackish toward the back; the crest is triangular; there is an acute crest on the back, and a serrated one on the belly.

The Striped Cameleon (*Chamæleo Zebra*) is rather larger than the common species, the crest on the occiput is more produced, and there is an elevated crest along the head; the throat has a row of tubercles along the middle; and the scaly granulations on the body are larger and more wide apart from each other than in most of the other species. The general colour, in a state of repose, is yellowish, but marked with black bars on the back, which descend toward the flanks, and are the occasion of the trivial name. It is a native of India, more especially of the lower and warmer parts of the valley of the Ganges.

The Spotted Cameleon (*Chamæleo pardalis*) is found in the Isle of France. The crest on the back of the head is flattened like that on the Senegal species, but there is a small border on the muzzle which projects beyond the opening of the mouth. The granulations are large and wide apart from each other, and the body is all over irregularly marked with round black spots, having white margins.

The Forked Cameleon (*Chamæleo bifurcus*). This species is a native of the Molucca islands. It has the muzzle divided into two parts, which are compressed laterally, and project equally. It is larger than most of the other species; the occiput is without a crest, or has only a small one; the granulations are uniform all over the body; the skin is marked with closely set blue spots; and on the lower part of each flank there is a double row of white ones.

Some other species are mentioned, and, as is the case with almost all the families of the Sauria, there are many undescribed specimens in cabinets. As the whole family are inhabitants of the woods, and as the woods of most foreign countries have been very imperfectly explored (the exploring of a wood is no easy matter); there may be many more which have hitherto escaped notice.

CAMELLIEÆ, or CAMELLIACEÆ, a natural order of dicotyledonous plants, containing only two genera and eight distinct species. It is closely allied to *Ternstrœmaceæ*, and by some authors is considered merely as a subdivision of the order, from which it differs only in its exalbuminous seed. The essential characters of that order are: sepals from five to nine, with an imbricated æstivation; petals five to nine, alternate with the sepals, often slightly cohering at the base; stamens indefinite; filaments filiform; anthers roundish; one ovary, with from three to six filiform styles; capsule three-celled and three-valved; seeds large, fixed to the central margin of the dissepiments; no albumen.

The plants of this order are smooth evergreen trees or shrubs, with showy axillary flowers. They are found in China, Japan, Cochin-China, or India. The leaves of many of the species are astringent and stimulating, and some possess slightly narcotic properties. The only genera of the order are *Camellia* and *Thea*, which are highly important as affording some of the most beautiful of our greenhouse plants, and as furnishing the *tea*, which is such a valuable article of commerce among the Chinese, and which is now so extensively used all over the civilised world.

Thea Bohea, or *nigra* and *viridis*, are said to be the principal species from which tea is obtained. The leaves of *Camellia sasanqua*, and other species of that genus, are also frequently used. These, however, must probably be looked upon as adulterations. The tea districts in China extend from the twenty-seventh to the thirty-first degree of north latitude, and in Japan they reach the forty-fifth degree. Some attempts have been made to rear the tea plant in Europe, but they have not been attended with any degree of success. It thrives well at Rio Janeiro, where it has been lately cultivated.

The tea plants are raised from seeds, and suceeded best in sandy or stony soil on the sides of mountains. The leaves are first gathered when the planes are three years old. After six or ten years, the plants are either removed or cut down, so as to throw out new shoots and leaves. The leaves are usually plucked at two seasons of the year, spring and September, the finest and most esteemed being those which are gathered first. They are picked one by one, and after being carefully selected, are exposed to the steam of boiling water, and then heated to a considerable degree on iron pans placed over furnaces, so as to be dried, and deprived of any acrid juice which they may contain. They are then transferred, while warm, to large tables covered with mats, where they are cooled by means of large pans, and at the same time rolled up with the hand. This process is repeated several times, a smaller degree of heat being applied each time, until all the moisture is completely expelled. They are afterwards mixed with some aromatic herbs, such as the leaves of the *Camellia sasanqua*, and the flowers and buds of the *Olea fragrans*, and are then put into boxes fit for exportation. In the finest sorts of tea, each of the leaves is rolled up separately.

It has not been fully ascertained whether the black and green teas are furnished by separate species, or whether the difference between them is merely to be ascribed to the age of the leaf and the mode of its preparation. It has been ascertained that they are cultivated in distinct districts, but many authors consider them as mere varieties. The green tea is said to be prepared from the leaf in an immature state, when it contains much of a narcotic juice, and to be dried by exposure to the open air in the shade.

Various varieties of tea are known in commerce which are designated by particular names. There are five or six different kinds of black teas, of which the chief are, bohea, congo or cong-foo, saotchong or souchong, and pekoa. Of the green teas the principal are, hay-suen or hyson, and tchu-tcha or gunpowder tea, which is rolled up in a round form. The green teas are chiefly prepared for exportation, as the Chinese only use the black.

All the teas ought to be carefully excluded from the air and light, in order to retain their flavour. They should be kept in wooden or leaden boxes, which are never left open.

Tea was first imported into Europe by the Dutch East India Company early in the seventeenth century. Some imported by them in the year 1666 was sold for sixty shillings a-pound. It was first used in Britain during the Commonwealth, and since that time its consumption has increased with amazing rapidity. In 1789, the tea retained in Britain for home consumption was 14,534,601 pounds, yielding a net revenue of custom and excise of 562,038*l.* 14*s.* 5*d.*; while in 1828, the quantity retained amounted to 26,790,481 pounds, and the revenue derived from it was 3,177,179*l.* 8*s.* More tea is consumed in Britain than in all the rest of Europe.

According to analysis, tea yields, by distillation, an astringent matter, and a bitter styptic extract composed of gallic acid and tannin. Tea is often adulterated with the leaves of other plants, more especially those of the *Camellia Japonica* and *oleifera*. The blossoms and buds of *Camellia sasanqua* are said to furnish a very strong and excellent tea. A kind of moss, found on the Chinese mountains, has been employed as a substitute for tea. In New Holland the leaves of the *Corrœa alba* are employed instead of tea, and in other countries we find those of the *Pedicularis lanata*, *Ceanothus Americanus*, *Ilex Paraguensis*, and *Symplocos Alstonia*, &c., put to a similar use. It was formerly stated, that the colour of green tea was owing to its being dried on plates of copper, but this is found to be an erroneous supposition.

Tea has now become a necessary article of food in Europe. This beverage, when prepared from the fresh leaves of the plant, is said to be narcotic, and hence the leaves are kept for twelve months by the Chinese before being used.

Good tea, taken in moderation, and prepared with cream and sugar, is highly refreshing and invigorating, and even produces a degree of exhilaration. The traveller, when exhausted by fatigue, and worn out by incessant toil, finds his strength renovated, and his spirits revived, by the timely use of this excellent beverage. It generally produces some degree o perspiration, owing probably to the quantity of hot water with which it is prepared. Tea sharpens the intellectual powers, favours digestion, and gives a new tone and vigour to the system. If tea, more especially green tea, is taken in large quantities, it is apt to produce nervous agitation, and to prevent sleep. In hysterical and hypochondriacal cases it may be productive of prejudicial effects. The infusion of tea is prescribed medicinally to promote the action of the stomach, to increase the flow of urine, and to cause gentle diaphoresis. Some authors have said that the habitual use of it prevents the formation of calculi, and favours the evacuation of gravel.

Camellia oleifera, oil-bearing camellia, a tree six or eight feet high, with white blossoms; is cultivated chiefly on account of its seeds, which furnish a limpid yellowish oil, used in China for domestic purposes. In order to obtain the oil, the seeds are reduced to a coarse powder, stewed and boiled in bags, and then subjected to pressure. The seeds of *Camellia sasanqua* also yield an oil which is used as an article of food in Japan.

Camellia Japonica, Japan rose; is a lofty tree found in the groves and gardens of Japan, and extensively cultivated in the greenhouses and conservatories of this country on account of its fine form, its rich green foliage, and its elegant red and white flowers. There are upwards of fifty garden varieties known in Britain. Of these the double red, double white, variegated waratah, double striped, peony-flowered, and fringed-white, are the chief favourites. The single red *Camellia Japonica* is propagated by cuttings, layers, and seeds, and is used as a stock on which the other sorts are reared. The camellias are the glory and pride of gardeners. They are best cultivated in houses expressly devoted to them. Some of them endure the winter well, when trained on a wall, and covered with mats. In order to make them flower freely, artificial heat and some degree of care is necessary. Their flowers, though remarkable for their beauty, are not at all fragrant.

CAMELOPARD. See GIRAFFE.

CAMERARIA (Linnæus), is the bastard manchineel; a genus of arborescent plants, natives of both Indies. Linnæan class and order *Pentandria Monogynia;* natural order *Apocyneæ.* Generic character: calyx of five teeth; corolla funnel-shaped, and hypocrateriform, gashes of the limb oblique; stamens inserted into the tube of the corolla; anthers acuminate, connivent, having their apices drawn out into threads; style scarcely any; stigma inconspicuous; seeds membranous, and peculiarly inserted. This genus is allied to the oleander of our greenhouses, and the periwinkles of our shrubberies. The flowers are beautiful, and fine ornaments of the stove, where the plants grow healthily in loam and moor earth. It is propagated readily by cuttings in sand, under a glass, in a little heat.

CAMMARUM is the title of a tribe belonging to the genus *Aconitum,* specifically distinguished by the sepals being deciduous; helmet conical, compressed; ovaries three or five; flowers blue, white or variegated, rarely flesh-coloured; root tuberous; lobes of leaves trapeziform, pinnate.

CAMPANULA (Linnæus). This is the bell-flower of our fields and gardens, a numerous family of herbaceous perennial plants, chiefly natives of Europe. Linnæan class and order *Pentandria Monogynia;* natural order *Campanulaceæ.* Generic character: calyx five-cleft; corolla bell-shaped or subrotund, limb in five divisions; filaments dilated at the base; stigma, in from three to five divisions; capsule three or five-celled, having lateral pores or bursting valves at the top. The campanulas are chiefly hardy, and grow in any common soil, in flower borders or on rock-work; and are easily propagated by parting the roots of the perennial species, and sowing the seeds of those which are annuals or biennials. The rampion, *C. rapunculus,* is cultivated for its roots, which are used as a culinary vegetable.

CAMPANULACEÆ. The bell-flower family. A natural order of dicotyledonous plants, containing twelve or thirteen genera, and about three hundred species. It is closely allied to the *Lobeliaceæ, Goodenoviæ,* and *Stylideæ,* from which it is, however, at once distinguished by its regular corolla. It approaches in habit, and in many of its characters, to the *Compositæ,* but differs from this order in its fruit and mode of inflorescence.

The essential botanical characters of the order are: tube of the calyx adnate with the ovary, usually five-cleft, equal and persistent; corolla monopetalous, deciduous or marcescent, regular, and generally five-cleft; stamens inserted into the calyx alternately with the lobes of the corolla, to which they are equal in number; anthers two-celled; pollen round; ovary two or many celled, many seeded; style simple, covered with collecting hairs; stigma naked; capsule inferior, opening by lateral irregular apertures or by valves at the apex; seeds small, and numerous, with a fleshy albumen

The plants belonging to this order are shrubs or undershrubs, with alternate simple and deeply-divided leaves, and flowers in racemes, spikes, panicles, or heads. Nine-tenths of the campanulaceæ have flowers of a blue colour, the remainder being white, and rarely yellow. They generally yield a milky bitter juice, possessing more or less acrid properties. When young, they abound in mucilaginous matter, and are much less bitter and acrid than when fully grown. The roots of most of them may be used as articles of food when young and properly prepared.

The campanulaceæ are natives of temperate countries, and are found in Asia, Europe, and North America. Out of three hundred species, only nineteen grow in tropical regions. Some curious species are found in the Canaries, St. Helena, and Juan Fernandez. Numerous species exist on the Alps, the Caucasian, and Altaian range of mountains, and a considerable number are found at the Cape of Good Hope.

The plants of this order are chiefly valued on account of their beauty, They constitute very striking ornaments of the fields, meadows, and forests of the countries which they inhabit. The chief genera are, *Campanula, Phyteuma, Canarina, Prismatocarpus, Trachelium, Jasione, Michauxia, Lightfootia, Adenophora, Wahlenbergia,* and *Roella.*

Campanula is a showy genus, the species of which are interesting, and easily cultivated. The name is derived from the circumstance of the corolla being in the form of a bell. In *Campanula,* or *Prismatocarpus speculum,* the corolla is like a small round mirror, and hence the plant is called *Venus's Looking-glass.*

Campanula rapunculus is cultivated in France, Italy, and Britain, on account of its white biennial roots, which are eaten as a salad under the name of *Rampion.* They are often gathered in spring before the stem appears, and in gardens they are frequently blanched. *Campanula persicifolia, Rapunculoides,* and *Trachelium,* are used in a similar manner. The last-mentioned species has bristles on its leaves, which are as pungent as those of a nettle, though not venomous. A decoction of the plant, which is bitter and somewhat acrid, was formerly employed in medicine as a garlic. *Campanula pyramidalis* is a tall handsome plant, which is cultivated in Holland as an ornament for halls and staircases. It was formerly very fashionable in this country, and is still frequently reared in drawing-rooms. It continues in flower for two or three months when left in the shade. *Campanula latifolia* is also a species which, from the beauty of its flowers, finds a place in our gardens. The young shoots, deprived of their epidermis, are boiled and eaten as greens about Kendal. *Campanula glomerata* is a very beautiful rock plant, well deserving of cultivation. In *Campanula linifolia*, before the panicle is produced, the leaves come out in a kind of rose on the summit of the stem. This appearance vanishes as the panicle expands. The roots are eaten in China both raw and boiled. The root and young shoots of *Phyteuma spicata* are used in Switzerland as articles of food. The roots and young shoots of the *Canarina campanula* are also used as food by the inhabitants of the Canaries.

CAMPELIA (Richard). An herbaceous perennial, indigenous to the West Indies, separated from the old genus *Tradescantia*. Linnæan class and order *Hexandria Monogynia;* natural order *Cammeliaceæ*. It differs from *Tradescantia* in having a three-lobed stigma, and a berry-like capsule.

CAMPHOR TREE is the *Cinnamomum camphora* of R. Brown, and the *Laurus camphora* of Linnæus. This highly fragrant forest tree is a native of the south-eastern parts of China and the neighbouring islands. Extensive groves of it are met with on both sides of the Canton river. The aromatic drug, camphor, is extracted from this tree, and it prevails more or less in the bark or wood, or leaves of all its congeners, viz. the cinnamon, cassia, sassafras, and even down to the sweet-bay of our gardens. All the species are propagated by layers and cuttings.

CAMPHOROSMA (Linnæus). A genus so called, because of its scent being like that of camphor. It contains one under shrub, and two annuals, natives of the south of Europe. Linnæan class and order *Tetrandria Monogynia;* natural order *Chenopodeæ*. They are plants of no beauty.

CAMPILODON (*Notacanthus* of Bloch). A genus of fishes, of which the history is very imperfectly known. There is but one known species, which is an acanthopterygeous or spinous-finned fish, belonging to the *Scomberoidæ*, or mackerel family, and as such an inhabitant of the surfaee, and a ranging fish, instead of being confined to the banks, as is the case with most bottom fishes. It inhabits more northerly than any other known species of the family, being found only in the polar seas, and there very near the ice. It is a poor fish, with the body very long in proportion to the thickness, and much compressed, covered altogether with small scales of a soft texture. The snout is obtuse, and projects forward beyond the mouth. The teeth are very fine, and closely and evenly set; there are two detached prickles, or spines, on the back; the ventral fins are placed backwards; the anal fin extends as far as the point of the tail; and the caudal fin is very short. Nothing whatever is known of its habits, or of the time or place of its breeding.

CAMPION. A name adopted from Pliny for the *Cucubalus baccifer* of Linnæus, and belonging to the class and order *Decandria Trigynia*, and in the natural order *Caryophylleæ*. Generic character: calyx bellying, cut into five revolute teeth, persisting; corolla has bifid petals, claws slender; stamens inserted alternately with the base of the petals, and round the germen; style like threads, persisting; capsule a berry, one-celled, with many seeds; placenta central and free. This is a common British weed, in hedges and in fields or poor ground, and is not easily extirpated, by reason of its long and tough root.

CAMPYLANTHUS (Roth). A genus of plants containing a single species found in the island of Teneriffe. It is a pretty little diandrious plant, and belongs to the order *Primulaceæ*.

CAMPYLUS (Fischer; Exophthalmus Latreille). A genus of coleopterous insects belonging to the section *Pentamera*, and family of the *Elateridæ*, or skip-jack beetles; being at once distinguished from the remainder of this extensive family by the exposed base of the head; the large and globose eyes, the long antennæ inserted beneath the elevated lateral margins of the head and the linear body. The genus comprises only one British species, the *Elater linearis* of Linnæus; but which is so exceedingly variable in colour, although not in form, that it has been regarded by many entomologists, including Linnæus, as constituting several distinct species, the *Elater mesomelas*, Linnæus, being one of these varieties. Mr. Stephens has, however, obtained the most complete evidence of the specific identity of these varieties. This insect is about half an inch long, varying in colour and spots from pale buffish red to black. It is generally distributed throughout England and Wales, and is found in hedges.

CANADA RICE. Is the *Zizania aquatica* of Linnæus, belonging to *Monœcia Hexandria*, and to the natural order *Gramineæ*. It is a water plant resembling rice, but the seeds are smaller and inferior.

CANADIAN MUGWORT. Is the *Artemisia Canadensis* of Michaux; and only found in the botanical collections of this country.

CANARINA (Linnæus). A genus of two species of herbaceous perennials introduced from the Canary islands. They are allied to the campanulas; flowering in our stoves in autumn and winter when few other plants are in bloom. The roots rest during summer when they require but little water. At the commencement of their growth, the late Mr. Sweet advises, that the plants be moved into the stove, where they will flower much more strongly than if kept in the greenhouse. They are increased by dividing the roots; or by cuttings placed in a mixture of loam and moor-earth under a hand glass.

CANARY-BIRD. See Carduelis.

CANARY-GRASS. Is the *Phalaris Canariensis* of Linnæus. It is cultivated in England, and other places for the sake of its grain, chiefly for the purpose of feeding cage-birds and poultry.

CANCELLARIA (Lamarck). A genus of moluscs, blended with the genus *Voluta* by Linnæus. They are, however, very unlike the *Voluta*, properly so called, *Maitra marginella*, or any other of the newly-formed genera, now separated from the genus *Voluta*. Many of the cancellaria are sub-canaliculated at the base, which never takes place in any species of *Voluta*. The shell is oval, globose and rugose; the spire moderate, aperture oval, with a very short canal at the base, sometimes hardly visible; the interior of the opening grooved; the columella with a few, or numerous irregular plaits, the greater number transverse; the exterior striated, cancellated, and generally rough to the touch; it has a horny operculum, and all the species are marine.

De Blainville does not altogether agree with Lamarck's arrangement of the species, and has separated from them all such as have the aperture evidently canaliculated, as in the *C. lima*, which he considers to belong properly to the *Murices* and turriculated *Turbinellas*. Of twelve recent species, he says the habitat of such as are known is in the Indian seas and Senegal. De France enumerates twelve fossil species, but more have since been described. In De Blainville's system this genus is arranged with the family *Entomostomata* ; first order, *Siphonobranchiata;* second class, *Paracephalophora*.

CANCERIDÆ (Leach). A family of crustaceous animals belonging to the order *Brachyura*, and corresponding with the genus *Cancer* of Fabricius, or the *Crabes arqués* of Latreille (see BRACHYURA). In this family, of which the common edible crab is the type, the four posterior legs are terminated by a narrow pointed and simple claw or hook, which is not dilated into a plate for swimming, as in the *Portunidæ*, of which the small edible crab, sold in the streets of London, is an example. The shell or carapace is curved in front into an arc of a circle, and gradually narrowed behind, being squared off between the two hind legs. The claws of the fore legs do not differ in size in the different sexes. The abdomen in the males is five-jointed, the central one being the largest, and in fact composed of three joints soldered into one, that of the female being formed of seven distinct joints.

Mr. Milne Edwards unites this family and the *Portunidæ*, mentioned above, and which are certainly very nearly related (their chief difference consisting in the dilated claws at the extremity of the four pairs of hind legs in the latter, whence they are termed shuttle crabs) into one family, *Cyclometopes*. (See the article BRACHYURA.)

It is to be understood therefore, that the modern family *Canceridæ* does not, like the majority of the families of insects, correspond in its limits with the great Linnæan genus from which it takes its name, but comprises only a small portion of the genus *Cancer* of Linnæus, which has been raised to the rank of the order containing numerous families, sub-families, genera, sub-genera, and species.

This group of animals therefore, affords an opportunity of entering into a few observations upon the modern nomenclature of natural history, a subject respecting which we constantly hear great objections raised. Let us not be understood, however, to wish to give to the study of names more than its due weight. Natural history is not a science of names alone, we have living objects for the subjects of our contemplation; and blind indeed must he be to the beauties of the visible world, who could look at a plant or an insect with no other interest than that of ascertaining its scientific name. The astronomer would be worse than mad who would regard the great luminaries of the universe with no other feelings for the benefits which they bestow, than that of a desire to prove their place in the "heavens above." But whilst we thus uphold the superiority of the observations of the economy, and natural history in its legitimate sense, of the animated world ; let us not disregard one of its important, although subservient adjuncts—that of names. We apprehend, indeed, that no one will deny their utility, the supposed abuse, not the use of the system being objected to. Should, however, any one object to the latter, and affirm that nature may be studied in all its details without the technical machinery of names, we shall feel no disinclination even to agree with him in this latter observation, so far as his own experience is concerned, but how greatly is the case altered should he wish to impart his knowledge. We have, indeed, only to refer to the highly valued memoirs of Reaumur, for a confirmation of our observations upon the utility of names; since it has unfortunately happened that many of his most interesting histories, for want of a precise determination of the animals whose habits are thus recorded, have been lost to science.

Admitting then the necessity of names, we are now to show the necessity of that extended system of nomenclature which, from having been so much paraded, to the exclusion of natural history, has caused great clamour to be raised by those who were led to believe, first, that our science was but a science of names, and secondly, that the system of Linnæan nomenclature was amply sufficient for every purpose, hence that the great multiplication of the minor divisions of the Linnæan genera was but an unnecessary frittering of science, having not the least utility, and tending only to disgust the student. Let us, however, look more narrowly at the subject, and endeavour to ascertain what are the grounds for these opinions. It cannot be denied that the machinery of nomenclature, like that of every other apparatus, must have had both a commencement and a founder. Take, for instance, the machinery of a time-piece, which in the early stages of clock-making was most cumbrous, notwithstanding its simplicity. Still, to a certain extent, it fully answered the purposes of its construction, that of dividing the day into a certain number of portions. By degrees, as the additions of the minute hand, the striking apparatus, and that of the divisions of a minute, of the repeater and that of the chimes were made, the machinery became more complex; and instead of simply turning round once in a certain period, we find wheel revolving within wheel, to an extent which to a savage has the appearance even of life itself.

Such is precisely the case with the nomenclature of natural history. Linnæus, the great inventor of the system, was indeed so well acquainted with the general relations of the great divisions of nature, that, although it is certain that his botanical far surpassed his zoological knowledge, it is a tribute which is willingly bestowed upon him by all, that in the construction of his general groups the modern naturalist must be compelled to tread, for a great extent, in his steps. Look, however, at the progress of zoology since the days of this great master. Take a single genus of insects—for instance *Carabus*, of which he described fifty-three species, and we find not fewer than two thousand five hundred contained in the single collection of the Baron Dejean, whilst the more minute peculiarities of organisation, both internal and external, have been studied with the greatest zeal by numerous authors. The discoveries of later days have likewise presented numerous groups, equal with those of the genera of which he was ignorant. Now this torrent both of novelties and of science has rendered the old Linnæan genera of such amazing extent, and so unwieldy, that entomologists, in their own defence, have been compelled to institute subdivisions of various ranks; for instance, if a person wish to record some fact concerning one of the Linnæan *Carabi*, he is enabled, instead of wading through the descriptions of two thousand five hundred species, to reduce the objects of his inquiry to one of the great sub-families of the Linnæan genus, and thus by the assistance of three or four other still more inferior sections, to bring his inquiry into the lowest possible compass. In doing this, however, a sufficient regard has been paid to the authority of Linnæus, by converting his genera into families, terminating uniformly, according to the admirable plan of Mr. Kirby, in *idæ*. Sub-families have been introduced, as we have shown in the article BRACHELYTRA, which are again subdivided into genera and sub-genera, which present varieties in structure of their different organs, while they agree in possessing the characters of the great family to which they belong. Now the advantages of this plan of names are evidently these:—1st, The peculiar construction of an animal is instantly called to mind by the naming of its modern generic or sub-generic names, whereas if the old Linnæan (but now family) title were employed, a very indefinite idea would alone be obtained: for instance, if we were merely told that a friend had observed the habits of one of the two thousand five hundred *Carabidæ*, we should be almost as completely in the dark as to its precise structure, as though we had been told that it was a beetle. 2nd, The beautiful perplexity arising from the employment of stars, and daggers, and asterisks, for sections of the Linnæan genera, is entirely removed. Those who, for instance, have studied as we have done, the invaluable *Monographia Apum Angliæ* of Mr. Kirby, will readily agree with us, that the benefit arising from the use of names, which in general carry some structural idea with them, is alone sufficient to overbalance the difficulty of bearing in mind either the sectional marks of distinction noticed above, or the names employed in their stead: and 3rdly, The immense saving of time gained by the student in investigating the species of his collection; since, if two thousand five hundred species of *Carabi* composed but one genus, as they do according to Linnæus, what person can be found with either time or inclination to identify the species of even a local collection. For general purposes, indeed, the employment of the old Linnæan names would, in many cases, be sufficient but for the ends of science, not only the modern generic but also sub-generic names must be employed; and a plan has been suggested by Mr. Robert Brown, which has the advantage not only of not materially disturbing the names already existing, but also of insuring the co-operation of two classes of naturalists at present opposed to each other, namely, by introducing the modern sub-generic name in brackets between the old generic and specific name, thus we should call the devil's coach horse, figured as *Staphylinus* (*Goerius*) *olens*. "This," as Mr. Brown observes, in the appendix to the narrative of travels and discoveries in northern and central Africa, "is analogous to the method followed by the Romans in the construction of the names of persons, by which not only the original family, but the particular branch of that family to which the individual belonged, was expressed. Thus the generic name corresponds with the *nomen* (Cornelius), the name of the section with the *cognomen* (Scipio), and that of the species with the *prænomen* (Publius)."

Naturalists have agreed in retaining for the old generic name those species which were more striking instances of the Linnæan groups. Thus, returning to the animals which have led us into this long, but we trust not useless digression, we find the large edible crab of the European coasts (*Cancer pagurus*, Linn.), regarded as entitled to retain the old generic name of *Cancer* by most authors, although M. Milne Edwards has very injudiciously formed it into a distinct genus, named Platycarcinus. The other genera in this family are Carpilius, Zozymus, Lagostoma, *Xantho*, Chlorodius, Panopeus, Zius, Pseudocarcinus, Etisus, *Pilumnus*, Ruppellia, and *Perimela*. These genera are for the most part established by Leach and Edwards upon structural differences alone, scarcely any thing being known of their habits. Those printed in italics are natives of our coasts.

CANCRIDA (De Montfort). A genus of molluscs, united by other authors to the genus *Crepidulina*, of which it is manifestly a species.

CANCROMA (Boatbill). A genus of birds belonging to Cuvier's *Pressirostral*, or compressed-billed family of *Echassiers*, long-legged or stilt birds. There is only one known species, a native of the tropical parts of South America; but the manners, and especially the appearance of this species, are very peculiar. It does not appear that the name *Cancroma*, or "crab-eater," is very accurately applied to this bird, though it does live near the waters, and it is in all probability a feeder upon the crustacea which these afford, but it is an inland bird; and as we more exclusively apply the word crab to marine crustacea, it were desirable that another epithet should be given to this bird.

The boatbill bears a considerable resemblance to the heron family, more especially to the night heron. As is the case in those birds, its bill is of great power, and its neck capable of much and rapid motion, so that it can strike and seize with great force and much celerity. Its bill is, however, very different in shape from those of the heron, and the epithet *pressirostral* does not apply to it, as its bill is the very reverse of being compressed. This, by the way, shows how injudicious it is to name a family of birds from the form of any particular organ, and, indeed, the general incorrectness of a system which classes birds by the bills at all. The food of birds is so miscellaneous, and the parts of their feeding apparatus so few as compared with those of mammalia, that they do not form a sufficient number of distinctive characters. In the mammalia themselves it is not the form of the jaws from which we infer the feeding, and, consequently, the general characters of the animals; it is from the teeth. Birds have no teeth; and before we can come at any thing like a satisfactory conclusion as to that food on which they feed, we must take an average of three qualities—the form of the bill, the texture and substance of it, and the character of the tomia, or cutting edges of the mandibles.

Viewing the boatbill in this, the only rational way in which we can view it, it is more nearly allied to the herons than with any other birds; and, notwithstanding the dissimilarity in the shape of its bill, it might, without much impropriety, be included in the same family, if not in the same genus.

The bill of this bird has certainly a very singular appearance. It is very much extended laterally, and seems like two small boats, or rather perhaps two spoons applied with their concavities towards each other. These large mandibles are very strong, their cutting edges are exceedingly sharp; and though they are not serrated throughout the whole length, as is the case of those of the herons, yet there is a strong and sharp tooth on each side of the upper one, near the point. From this structure of the tomia, we may naturally conclude that the bird is not a fisher, at least so much as the herons are, and that it lives upon food which requires more powerful action in the bill to prepare it for the stomach. Hence it is probable that crustacea, and the smaller reptiles, with shelly or scaly coverings, which frequent the margins of the waters, constitute the food of this bird.

The other characters are, the nostrils near the base of the bill, but the nasal groves continued so near the point, the feet, which have the tarsi reticulated, have four very long toes, three in front and one behind, which are divided, and almost free of membrane to their bases; and the wings are loose and concave, and less adapted for long flight than for ascending and descending. The first quill is much shorter than the second, the third is a little longer, and the fourth and fifth are the longest in the wing, which gives it a rounder form when extended. The hinder toe is turned rather inwards, so that the whole foot presents a broad base to the soft surfaces on which the animal alights.

The boatbill inhabits those plains on the banks of the Orinoco, and other rivers in similar parts of South America which are subject to flooding in the rainy season; and when these are under water, it is usually found sitting on the stumps of decayed trees, on the margin, or in the middle of the deluge, from which it is ever and anon dashing into the water, and catching such swimming substances as serve it for food; but as its feet have no webs, it does not alight on the surface, neither does it plunge into the water like the darter, and other birds which fish on the wing. Its food is taken either in the shallows or on the surface, and it darts upon its prey with great rapidity, or dashes along the surface, scooping the water with its large bill, in order to drive at the smaller animals upon which it preys. When in a state of repose, it has the same gloomy air as the herons, but, like them, it has a very keen eye, and, when once excited, the motion of its head and bill are very rapid and very powerful. Its head, as in many of the herons, and partially in all of them, is furnished with a crest of long feathers, which are pendent when the bird is in a state of repose, but which it erects when excited. There is no doubt that these feathers assist in guiding the motion of the bill, as they are found more or less in all birds which obtain their food by striking out with that instrument in the water or on its surface.

When the plains are dry and burnt up, and for a considerable part of the year they are so much so that no bird can find food upon them, the boatbill resorts to the margins of the streams, where it sits watching upon the withered stumps, till something appears to tempt its eye, upon which it dashes down to the surface, glides along a little way, scooping the water with its bill, and then returns to its perch. From this habit of dashing down on the water, it is probable that the bird catches fishes, or at least the small fry, but its habits have not been very minutely observed, and it is a bird of the wilds, rather than in the neighbourhood of inhabited places. It does not nestle in trees like the heron, but in the tangled bushes on the banks of the rivers. Its nest is carefully made, consisting first of a considerable number of small twigs, then of leaves and vegetable fibres, and lastly with an internal lining of down and feathers. The eggs are of a greenish-grey colour, and do not exceed two, or at most three in one hatch. The time of breeding, and the moults and other changes of plumage, are but imperfectly known.

There is but one species, *Cancroma cochlearia.* The upper parts are dull greyish; the forehead white; the top of the head black; and the nape furnished with a long flowing crest. The belly and flanks are rust-coloured; the breast white; the upper mandible blackish, the lower one whitish; and the feet greenish-yellow. The length is about one foot five; and the wings, though broad, are rather short in proportion to the size of the bird. These are the characters of the male. The female has the upper part more inclining to blue, with scapulars, and the crest black. The forehead and chin yellowish; the neck and breast white; the rest of the under part mottled with white and rust-colour; the bill reddish, and the feet brown. In the immature male the colours are considerably different. All the upper part is reddish ash; the forehead is pure white; the crown of the head black; and the crest, which is very long, is of the same colour. The lesser coverts of the wings are bluish; the cheeks greenish; the chin brown; all the under parts, including the under tail-covert, whitish; the flanks reddish, the feet

Cancroma cochlearia.

brown, and the bill blackish-brown. Some notion of the general form of the bird may be obtained from the above figure.

CANDLEBERRY MYRTLE. Is the *Myrica cerifera* of Linnæus. There are thirteen species of this amentaceous genus, inhabitants of different parts of the world. One is the sweet gale of Britain, and the wax-bearing one of North America is made a useful plant, by yielding an inflammable substance which serves for making candles. Hence the trivial name.

CANDOLLEA (Labillardiere). Is the name plant of the celebrated Professor De Candolle of Geneva. It belongs to the Linnæan class and order *Polyadelphia Polyandria,* and natural order *Dilleniaceæ.* Generic charactei: calyx of five sepals which are unequally persisting; corolla of five petals, stamens in five brotherhoods; anthers linear oblong; styles five; capsules five, each having too seeds, bursting inwards; seeds membranous, and inversely egg-shaped. This is a New Holland genus, being discovered there by the French traveller Labillardiere.

It succeeds well in our green-houses, and is propagated by cuttings planted in sand under a glass, and assisted by a little hot-bed heat.

CANDY TUFT. Is the *Iberis semperflorens* of Linnæus. It is a genus consisting of above twenty species, some of them undershrubs and perennial; a few are biennial, and above a moiety of them are annuals. They are natives of the south of Europe, and have long been introduced into this country for ornamenting flower borders and green-houses. The shrubby sorts are readily propagated by cuttings, and the annual sorts only require sowing in the open ground about the end of March.

CANE-BRAKE. Is the *Arundinaria macrosperma* of Michaux. It is a large coarse growing kind of reed indigenous to North America, and is ranked in the third class and third order of the sexual system, and in the natural order *Gramineæ*.

CANELLA (P. Brown). A genus of two species of lofty growing tropical trees. Linnæan class and order *Dodecandria Monogynia;* and natural order *Guttiferæ*. Generic character: calyx three-lobed; corolla, petals five, roundish, somewhat leathery; tube shorter than the stamens, and truncated; stigma in two or three divisions; berry two or three celled; seeds in pairs, and heart shaped. These trees are highly ornamental; both foliage and flowers being ample and showy.

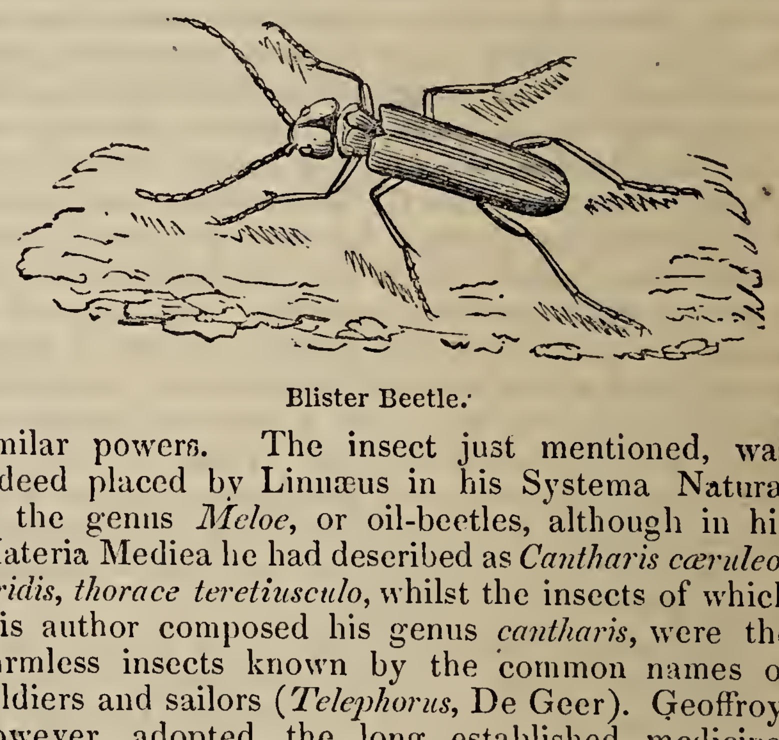
CANIS (the dog). A well known and exceedingly interesting genus, or, more strictly speaking, group of digitigrade mammalia, belonging to the carnivora, or flesh-eating division properly so called, of Cuvier's order *carnassiers*. The characters of this genus are: six incisive teeth and two canines in each jaw, six cheek teeth in each side of the upper jaw, and seven in the under, making in all forty-two teeth, of which there are twenty in the upper jaw, and twenty-two in the lower. The first three cheek teeth in the upper jaw and the first four in the lower are trenchant or tearing teeth. That immediately behind the canine in the upper jaw is very large, with two sharp trenchant points toward the outward edge, and a small tubercle on the inner side; the others are smaller, but they are all furnished with trenchant tubercles. The muzzle in all the wild varieties is elongated, the tongue is soft, the ears erect; the forefeet with five toes, the hind one with four only. Of the domesticated species the varieties are exceedingly numerous; and it is altogether impossible to refer them to any species at present known in the wild state. Particular accounts of them will be given in the articles Dog, Wolf, Fox, Jackall, and some of the allied genera; while their relative position in the system will be pointed out in the article Mammalia.

CANNA (Linnæus), commonly called Indian shot, perhaps from the roundness and hardness of the seeds. Linnæan class and order *Monandria Monogynia*, being the first genus of the sexual system, and gives a title to an order in the natural system namely *Canneæ*. Generic characters: calyx double, each three-parted, somewhat coloured, superior; corolla of one petal, three-cleft, irregular, rather gaping; stamens, filaments like petals, having an anther attached to the margin; pistillum also like a petal, with a linear stigma fixed on the edge; capsule inferior, membranaceous, roughly muricated, of three cells, and three valves; seeds many, globular; albumen hard. One species of this genus has been known in Europe ever since 1561; and many new ones have been introduced lately. The foliage of all of them is beautiful, and their high-coloured flowers are attractive. *C. patens*, and *C. speciosa* are hardy, but most of them, particularly the *C. Indica*, require a stove or warm green-house. All the species are increased by dividing the roots, or by seeds, which ripen well in this country.

CANNABIS (Linnæus). This is the plant which produces the hemp of commerce. Linnæan class and order *Monœcia Hexandria;* natural order *Urticeæ*. Generic character: male flowers in panicles, calyx of five sepals; corolla none; anthers four-furrowed, two-celled; female flowers aggregated, scales hollow, germen round; styles two, thick at the top, hairy; caryopsis or seed-vessel contains the seeds, which have the embryo inclosed between two thick cotyledons. Hemp has been long cultivated in the northern parts of Europe; its stem yielding the strongest filacious material of any known plant (except perhaps the *Phormium tenax*, or New Zealand hemp).

CANTERBURY BELLS. A large growing species of *Campanula*, common in gardens.

CANTHARIDÆ (Leach). A family of coleopterous insects belonging to the section *Heteromera*, and sub-section *Trachelides* of Latreille. The head is large and rounded posteriorly, the thorax is generally narrowed behind, and the claws of the feet are very deeply notched, appearing double; the wing covers are depressed at the sides. These insects counterfeit death when alarmed, and several of them emit from the joints a caustic fluid secreted by organs not yet observed by anatomists. The type of the family is the vesicatory cantharis or blister-fly of the shops. Many of the other species likewise possess



Blister Beetle.

similar powers. The insect just mentioned, was indeed placed by Linnæus in his Systema Naturæ in the genus *Meloe*, or oil-beetles, although in his Materia Medica he had described as *Cantharis cæruleo-viridis, thorace teretiusculo*, whilst the insects of which this author composed his genus *cantharis*, were the harmless insects known by the common names of soldiers and sailors (*Telephorus*, De Geer). Geoffroy, however, adopted the long established medicinal name of *cantharis* for the vesicatory beetles, but incorrectly called the *Telephori*, by the generic name of *Cicindela*. And in the former respect, the nomenclature has been retained by the French and English entomologists; but Fabricius having employed the name of *Cantharis* for the soldier beetles, and having given the name of *Lytta* to the vesicatory beetle, the Germans who have generally adopted his nomenclature, still employ the latter name.

The common blister-fly *Cantharis vesicatoria*, is generically distinguished by the possession of complete wings and wing covers, by having the joints of the tarsi entire and not bilobed, and the thorax nearly ovoid; the body is long and narrow, with the head rather larger than the thorax; the second joint of the antennæ is very small. This insect varies very much in its size, being sometimes not more than half an inch long, whilst others are twice that length. It is exceedingly rare in Britain, but has been occasionally taken near Cheltenham and elsewhere. Our figure is taken from a fine British specimen, purchased at the sale of Mr. Donovan's collection. It is of a golden or brassy green colour, very shining, and delicately punctured, with the antennæ (except the first joint) black. W. P. Audouin has published a valuable memoir upon this insect in the Annales des Sciences Naturelles, vol. ix., in which he has detailed in a very minute manner the external and internal anatomy, the sexual organisations &c. He states that the other species of this genus are numerous, being found in the south of Europe, Greece, China, India, and America, and very varied; but that since the time of Fabricius and Olivier, no one has undertaken their determination and description. The mandibles of the common species are strong, and terminated in a broad and oblique point, they are without teeth; but at the internal margin, below the middle, is to be observed a large notch filled with a yellowish membrane, which has escaped the notice of authors, but which is also found in various other heteromerous beetles. The legs also offer a curious peculiarity which do not appear to have been noticed before; in the female, the shanks (tibiæ) of all the legs, are terminated by two small moveable points or spurs, and the basal joint of the tarsi offers no material character; but in the males, although this character exists in the four hind legs, the two fore legs are terminated only by a large and strong spur, and the basal joint of the tarsi in this pair is strongly notched, so that the spur which is moveable, on being applied to the base of the tarsi exactly closes this notch, forming it into a sort of noose; this curious construction is employed by the males in coupling, to seize and retain hold of the antennæ of the females, a circumstance also noticed by Mr. Sowerby, to occur in *Meloe*.

But little is known of the early history of this insect. The female deposits her eggs separately, forming them into an agglutinated mass, they are buried under ground, and the larvæ there undergo their changes. It has been stated to feed upon the roots of vegetables, and to be soft and of a whitish colour, having six short legs. The descriptions given of the insect in this state are, however, very vague.

The perfect insect, although rare amongst us, must abound to a great extent in Spain and the south of France, where it appears about the summer solstice, being most abundant upon the ash and lilac, of which it devours the leaves, emitting a very penetrating odour somewhat resembling that of mice. This scent therefore leads to their discovery by the persons who collect them for medicinal purposes. When dead they are so light that fifty scarce weigh a drachm. It is necessary, however, to take various precautions in collecting them, since the odorous particles exhaled by them are very corrosive, that people have been violently affected whilst gathering them during the heat of the day with bare hands, or even when they have fallen asleep under trees, where swarms of them had settled. The ordinary mode of collecting these insects is to lay cloths under the trees where they abound, upon which they fall, upon the trees being violently shaken, they are killed by the vapour of vinegar, or they are collected in linen cloths previously steeped in vinegar. When dead they are carefully dried by exposure to the sun, or by lying in well ventilated apartments, being stirred about with short sticks or by the hand, covered however with gloves, since without this precaution the persons employed would be seriously affected by handling them. It is essential that they should receive a perfect degree of desiccation, otherwise they would contract a fetid odour, and be rendered unfit for medicinal purposes. They are preserved in close boxes or barrels, the insides of which are carefully covered with paper. It is not essential in this place to enter into a detailed notice of the well known medicinal properties of this insect, or the symptoms and mode of treatment when taken internally, or applied externally. It may be sufficient to state, that in the former case its powers are highly stimulating and dangerous, and that in the latter they first inflame, and afterwards excoriate the skin, raising a more perfect blister than any of the vegetable acids, and occasioning a more plentiful discharge of serum.

The Chinese employ another insect of this family *Mylabris pustulata*, for purposes similar to those of the *Cantharis vesicatoria*, whilst in North America the *Lytta vittata*, or potato-fly, and some other species appear to possess properties analogous to cantharides. For further details we must, however, refer our readers to the papers of Drs. Chapman and Woodhouse in the New York Medical Repository, vols. ii. and iii., and those of Drs. Schott and Dana in the Eclectic Repertory, vol. ii. The latter contains an analysis of the potato-fly, showing that cantharidam exists in it.

The other genera introduced into this family by Latreille are *Cerocoma*, *Hyclæus*, *Mylabris*, *Ænas*, *Meloe*, *Tetraonyx*, *Zonitis*, *Nemognatha*, *Gnathium* and *Sitaris*. Mr. Stephens has added another British genus named *Sybaris*.

The anatomical observations of M. Dufour, and the interesting researches of M. Bretonneau of Tours upon the properties of these tribes, allow us to dispose of these groups in a natural order, nearly agreeing with that stated above. The latter author having found that Sitaris is not vesicant, and the former, that it only possesses four instead of six biliary vessels, instead of six as in the rest of the family. They, however, in other respects, are nearly allied to zonitis, which are close to cantharis, so that by terminating the series with sitaris, it is easy by a comparison of other characters to ascend the series until we arrive at the other extremity, this progression moreover according with the progressive changes in the form of the antennæ. We shall notice the more remarkable of the above-mentioned genera in their alphabetical places.

CANTHARUS. A genus of spinous-finned fishes belonging to the *Sparoideæ*, or gilt-head family, but differing from the characteristic genera of the family in having teeth all round the jaws; those of the external row the largest, of a conical form, and more or less hooked. The body is elevated and thick; the jaws without any projectile motion; and the muscle short and rather blunt. There are two species, both in the Atlantic and the Mediterranean.

Cantharus Vulgaris (*Sparus Cantharus* of Linnæus). The general colour of this one is silver-grey, with longitudinal stripes of brown on the sides, and some small straight ones behind the bent ones.

Cantharus Brama (*Sparus Brama* of Linnæus). Nearly the same colour as the former but with all the teeth bent.

CANTHIUM (Lamarck). A single species of plants so called; said to be a Malabar shrub, belonging to *Pentandria Monogynia*, and to the natural order *Rubiaceæ*. Generic character: calyx of four or five sepals; corolla, tube short, limb in four or five divisions; stamens inserted in the throat of the corolla; stigma headed; berry dipyrena.

CAPE JASMINE. An English name given to the *Gardenia radicans*. It is one of the most fragrant of our green-house plants, and when healthy and in flower, one of the most beautiful.

CAPE PHILLYREA. Is the *Cassine Capensis* of Linnæus. It is an evergreen shrub with small roundish leaves, common in our green-house collections.

CAPER SPURGE. Is the *Euphorbia lathyris* of Linnæus, an herbaceous biennial indigenous to England. It receives its English name from the custom of using the seed-vessels as true capers, though much inferior in flavour.

CAPER TREE. Is the *Capparis spinosa*, or cultivated caper of Linnæus. There are nearly thirty species of this genus, mostly tropical plants, and some of them climbers. They belong to *Polyandria Monogynia*, and give a title to the natural order *Capparideæ*. Generic character: calyx in four divisions; petals four; stamens subperigynous, numerous or few; filaments like threads; anthers oblong and versatile; germen with a footstalk; style none; stigma obtuse and sitting; berry, barked, stipitate and many-seeded. The capers of commerce are imported from different ports of the Mediterranean and America; and in the south of Spain, France, and Italy, are extensively cultivated. See Capparideæ.

CAPPARIDEÆ (Caper Family). A natural order of dicotyledonous plants, containing seventeen known genera, and nearly two hundred species. It is closely allied to the *Cruciferæ*, from which it is distinguished by the stamens being scarcely ever, tetradynamous, and the seeds being kidney-shaped. De Candolle considers the order as intermediate between two sections of his arrangement, the *Thalamifloræ*, or *Calycifloræ*.

The essential botanical characters of the order are: sepals four; petals four, arranged in the form of a cross, and frequently provided with a distinct claw; stamens almost perigynous, definite or indefinite, and arranged in fours in several series; disk hemispherical, or elongated, and often bearing glands; ovary stalked; style wanting, or filiform; fruit, a single-celled, rarely single-seeded pod or berry; seeds generally uniform, without albumen; embryo incurved.

The plants belonging to this order are herbs, shrubs or trees, with alternate stalked leaves, which are either simple or palmate. They are chiefly met with in tropical countries, and abound in Africa. Some are found as far north as Canada. They are propagated by cuttings and seeds.

The *Capparideæ* resemble the *Cruciferæ* in their sensible qualities, being acrid, stimulant, and antiscorbutic.

The order has been divided by botanists into two sections; *Cleomeæ*, including the genera having capsular fruit and herbaceous stems; and *Cappareæ*, containing those with fleshy fruit and shrubby stems. The genera comprehended under the former are, *Cleome*, *Polanisia*, *Gynandropsis*, *Peritoma*, and *Cleomella*; while under the latter we have *Capparis*, *Cratæva*, *Niebuhria*, *Boscia*, *Stephania*, *Morisonia*, *Cadaba*, &c.

Capparis is the genus whence the name of the order is derived. *Capparis spinosa* is interesting on account of its furnishing the *capers* of commerce. It is an elegant, low shrub, having much of the habit of the bramble, and sending forth large white flowers with long purple stamens. It grows in the crevices of rocks, and on ruins, in the south of Europe. It is found adorning the walls of Rome and Florence, and is cultivated in the neighbourhood of Paris. In Britain it is generally reared as a stove-plant, and rarely succeeds in the open air. A plant, however, stood for nearly a century on a wall at Camden House, Kensington, and flowered pretty freely every year. Capers, so highly esteemed as a pickle, are the unopened flower-buds of the plant. During the proper season, they are picked in the morning before the petals expand, and are immediately put into vinegar and salt. The are afterwards carefully selected, and put into pure vinegar, and in this state are fit for exportation. The filings of copper are sometimes added, in order to give the pickle a fine colour. This addition, however, is highly dangerous, and ought never to be practised. The best capers are called *Nonpareilles*, the second-best *Capucines*. The chief supply of caper-buds is from the island of Sicily. The flower-buds of the *Caltha palustrus*, or common marsh-marigold, are sometimes used as a substitute for capers. In Italy, the unripe fruit is prepared like the buds. The root, got from the Levant by the Arabs, is used by them as a medicine, and as an external application to malignant ulcers. The bark of the root is said to be diuretic.

A species of *Capparis*, found near Carthagena, is said to yield poisonous fruit.

Capparis cynophallophora has large petals, and stamens upwards of four inches long.

Several species of *Cleome*, more particularly *Cleome rosea*, are very pretty and ornamental. Some of them have a very pungent taste. *Cleome icosandra*, or *Polanisia viscosa*, is used in some countries as a blister, or sinapism. The root of *Cleome*, or *Polanisia dodecandra*, is employed in the United States as a vermifuge, and its leaves are said to produce inflammation of the skin.

The bark of the root of *Cratæva Gynandra* produces blisters when applied to the skin. *Cratæva Tapia* yields a fruit of the size of an orange, having a garlic flavour, which it communicates to the animals that feed upon it.

CAPRARIA (Linnæus). A genus so called because goats are fond of the leaves. Linnæan class and order *Didynamia angiospermia*, and natural order *Scrophularinæ*. Of five species two are hot-house annuals, and three are under-shrubs. They are treated as stove plants; grow well in sandy loam, and are easily increased by cuttings planted in sand, and placed under a hand-glass in a warm temperature.

CAPRELLIDÆ. A remarkable family of crustaceous animals, belonging to the order *Læmodipoda*, and distinguished from the other family in this order which we have termed *Cyamidæ*, (and with which it was united by Dr. Leach, under the family name of *Caprellidæ*) by having the body of a very narrow and linear form, the composite eyes placed behind, the upper antennæ and ocelli wanting, and the legs long and slender, and variable in number, the end of the second pair being often toothed on its under side.

These curious insects are of comparatively small size, seldom exceeding an inch in length. They are generally found amongst marine plants, creeping along, according to Otho Fabricius, (*Fauna Grœnlandica,*) in manner similar to the looper caterpillars, throwing the head backwards in various directions, and vibrating their antennæ. When swimming they bend the extremity of the body. This family comprises three genera:—1st, *Leptomera* (Latreille), *Proto* (Leach), having the legs, fourteen in number, placed in a regular series. 2nd, *Naupredia,* having the legs, only ten in number, placed similarly, the second, third, and fourth pairs, being furnished with a basal vesicle. 3rd, *Caprella,* having ten legs, but placed at irregular distances, the second and third segments being destitute of legs. To the latter genus belongs the *Cancer phasma* of Montague, (*Cancer linearis,* Linnæus ?) described by Mr. Montague in the seventh volume of the Linnæan Transactions, by whom the following observations were made:—the

Caprella phasma.

female differs in possessing several plates or valves beneath the body, situated between the two pairs of fins, the use of which is to carry and protect its eggs or young, at which time they extend very considerably, and form a kind of pouch, distended with ova, fifteen or twenty of which are easily distinguished between the transparent plates. In this part a very strong pulsation is visible; whilst examining a female under a water microscope, this author was surprised to observe not less than ten young ones crawl from the abdominal pouch of the parent, all perfectly formed, and moving with considerable agility over the body of the mother, holding fast by their hind claws, and erecting their head and arms. On a fucus a vast number were collected of both sexes, and of all sizes, to three-fourths of an inch. When at rest they only held by their hind claws; in motion the arms were also used, and it also struck Mr. Montague that the progression was somewhat similar to that of the larvæ of the *Geometræ.* Some specimens are destitute of spurs on the body and arms, and differ somewhat in the formation of the latter, besides having that part extremely tomentose. These observations were made upon specimens taken on the coast of Devonshire. The writer of this article has received the same species from Weymouth, and Captain Ross has brought some very large individuals from his late North Polar expedition.

CAPRICORNES or LONGICORNES. One of the three great divisions into which the tetramerous beetles (or those having apparently only four joints in the tarsi) are divided, and corresponding in a great degree with the genera *Cerambyx, Necydalis,* and *Leptura* of Linnæus. These insects are generally of a large size, having the antennæ long, and generally exceeding the entire length of the body, filiform or setaceous, sometimes simple in both sexes, in others serrated or comb-shaped in the males. The eyes, in many of the species, are lunate, and enclose the base of the antennæ. The jaws are very robust, and the palpi short; the thorax is often spined at the sides. The three basal joints of the tarsi are dilated beneath, and cushioned on the under surface, the third* being deeply cleft at its extremity, receives a minute nodule or ball at the base of the slender and long terminal joint.

These insects are amongst the most active instruments in the economy of nature, in the warm climates of the globe, where, from their great size, they are of great service in checking the over-abundance of the vegetable world, the larvæ residing in the interior of trees or beneath the bark; in which state they appear under the form of a flattened white fleshy grub, broadest in front, with a scaly head armed with very powerful jaws, with which they bore their way through the hardest trees. From their habits in this state, it is evident that legs would be an incumbrance to them; they therefore are almost obsolete, and of a very minute size. The antennæ and the other parts of the mouth are likewise not exposed. Some species live upon the roots of plants.

This division comprises four great families, Prionidæ, Cerambycidæ, Lamiidæ, and Lepturidæ, which see.

CAPRIFOLIACEÆ (honeysuckle family). A natural order of dicotyledonous plants, containing twelve or thirteen genera, and upwards of one hundred and forty species. It is nearly allied to the *Rubiaceæ* and *Locanthaceæ.* From the former it differs chiefly in its irregular corolla, and the absence of stipules between the leaves; while it is distinguished from the latter by the stamens being alternate with the lobes of the corolla, and the corolla being usually monopetalous.

The essential characters of the order, as separated from all others are: calyx superior, limb five-lobed; corolla monopetalous, inserted on the calyx, sometimes irregular: stamens equal in number to the lobes of the corolla, and alternate with them, inserted on the calyx; filaments awl-shaped; anthers ovate, two-celled; ovary one to five-celled; one style and from one to three stigmas; fruit one or more celled, either dry, fleshy or succulent, crowned by the persistent lobes of the calyx; seeds generally solitary, pendulous; embryo straight; albumen fleshy; radicle superior.

The plants included in this order are shrubs, rarely trees, with opposite, simple or pinnated leaves, without stipules, and corymbose flowers, which are often sweet-scented. The colour of the flowers is white, scarlet or yellow.

The Caprifoliaceæ grow chiefly in the temperate regions of the northern hemisphere. They are found in shady cool places in Europe, Asia and America, and some are said to extend to the northern parts of Africa. They are propagated by cuttings, layers and seeds.

The plants of this tribe have often been celebrated for their beauty and fragrance, and on these accounts have secured a place in the garden of the amateur, as well as in the song of the poet. They possess acrid and astringent properties, and have often been applied to important uses.

* Latreille, in the second edition of the Régne Animal, has misstated the construction of the tarsi of this group, describing the second and third as being heart-shaped, and "le quatrième profondement bilobé."

The order has been subdivided into two sections: *Sambuceæ*, or the elder tribe, and *Loniceræ*, or the true honeysuckle tribe. In the former the corolla is rotate, the ovary three or four-celled, styles three or four, and flowers in cymes; it includes the genera *Sambucus* and *Viburnum*. In the latter the corolla is tubular, there is one style, and the berry is from two to four-celled, each cell containing one or many seeds. It comprehends the genera *Caprifolium, Lonicera, Triosteum, Diervilla, Abelia, Symphoricarpos, Linnæa*, &c.

The genera *Caprifolium* and *Lonicera* include many beautiful odoriferous flowering shrubs, which are highly prized in the garden or nursery. *Lonicera periclymenum*, or *Caprifolium Italicum*, the common honeysuckle or woodbine, has often been celebrated in poetry.

> "Watch upon a bank
> With ivy canopied, and interwove
> With flaunting honeysuckle."

It frequently supports itself by twining round other plants, and in doing so the stem invariably turns in one direction, from left to right;

> "So doth the woodbine, the sweet honeysuckle
> Gently entwine the maple."

Milton speaks of it under the name of the "twisted eglantine."—At other times it

> "loves to crawl,
> Up the low crag and ruined wall,"

and spreads over them an elegant and pleasing covering.

There are two other species of honeysuckle found native in Britain, the pale perfoliate honeysuckle, and the upright fly honeysuckle, but they are not so commonly met with as the species just mentioned. The bark of *Lonicera corymbosa* possesses astringent properties, and it is used in Chili to give a black colour to cloth.

Sambucus nigra, or common elder, is found abundantly in Britain. It blossoms in June, and ripens its berries in September. Sir James Smith says, that our uncertain summer is established by the time the elder is in full flower, and entirely gone when its berries are ripe. Its flowers are well known as a domestic medicine. They have an agreeable aromatic flavour, and possess laxative and sudorific qualities. They are chiefly, however, used in the form of ointment and fomentations. The smell from the plant is considered narcotic; it was formerly reckoned not safe to sleep under its shade. Cabbages, turnips, fruit-trees, or corn, whipped with the green leaves or branches of the elder are said not to be liable to the attacks of insects. The berries of the elder are poisonous to poultry, and the flowers to turkeys. The leaves, more especially the young leaf-buds, are nauseous, and act as violent purgatives. An infusion of the inner green bark in wine, and the expressed juice of the berries, act in a similar manner, although in a less marked degree. The berries contain malic acid, and have rather a pleasant taste. A wine is made from them, which is drunk warm with spices and sugar. They are used in the form of preserves, and are said sometimes to enter into the composition of adulterated port. The wood of the elder is hard and yellow, and is used by butchers, fishers, and turners. The pith, from its lightness, is used in a variety of electrical experiments. Sheep eat the plant, while horses, cows and goats, refuse it.

Sambucus ebulus, dwarf-elder or Dane-wort, another British species, possesses similar properties with the common elder. It has a fœtid smell, and is strongly purgative. Cattle refuse to eat the plant, and its leaves are said to drive away mice from granaries. The berries yield a violet colour.

The various species of *Viburnum*, two of which are natives of Britain, yield astringent fruit, which, after fermentation, is in some counties made into a sort of cake. The berries of the *Viburnum edule* or *oxycoccos*, are gratefully acid, and are used as food. The young shoots of *Viburnum lanata*, mealy guelder rose or wayfaring tree, are used in the Crimea for the tubes of tobacco-pipes. The leaves turn of a dark red in autumn, and the bark serves to make birdlime.

Viburnum opulus, common guelder rose, or water-elder, is cultivated in gardens under the name of the snow-ball tree. Its leaves, which are bright green in summer, acquire in autumn a pink or crimson tint.

Viburnum tinus, or *Laurestine*, is one of the most ornamental evergreen shrubs. Its showy white flowers appear during winter.

The genus *Triosteum* is intermediate between the *Caprifoliaceæ* and *Rubiaceæ*. *Triosteum perfoliatum* is a gentle cathartic when given in small doses. In large doses it acts as an emetic. Its berries, when dried and roasted, are used as a substitute for coffee.

The young branches of the *Diervilla* are used in South America as a remedy in some urinary affections. The roots both of the *Triosteum* and *Diervilla* are employed in America instead of Ipecacuan.

To this order belongs the humble and delicate, but highly interesting genus *Linnæa*, which has received its name in honour of the immortal Linnæus, to whom natural history and botany in particular are so deeply indebted. There is only one species, *Linnæa borealis*. It is a very elegant unassuming plant, found in native fir woods and in mountainous situations, in several parts of Europe and America, and eagerly sought by botanists, both on account of its beauty and its rarity. In Scotland it is found in several places, particularly in the counties of Perth, Angus, Inverness, and Aberdeen, while there is only one station as yet known for it in England. The plant has a bitter and astringent taste. It is used in some countries as a fomentation in cases of rheumatism, and an infusion in milk is esteemed in Switzerland in sciatica. The flowers are rose-coloured, graceful, fragrant, and drooping. Such, says Sir James Smith, is the little northern plant, the long overlooked object, flowering early, which Linnæus selected to transmit his own name to posterity. Few could have been better chosen; and the progress of practical botany in Britain seems to be marked by the more frequent discovery of the two-flowered *Linnæa*.

CAPRIFOLIUM (Romer and Schultes). Is the honey-suckle or woodbine, a sweet and well known plant all over Europe. Linnæan class and order *Pentandria Monogynia;* natural order *Caprifoliaceæ*. Generic character: calyx of five teeth; corolla tubular; swollen at the base, limb irregularly divided, two lipped, one in two, the other in three divisions; stamens protruding; berry one or two celled, sometimes three-seeded. A hardy plant like this, which is at every body's door needs no further description; but as there are above thirty species in the two genera of *Caprifolium* and *Lonicera*, and several varieties of each, it should be known that they are not all hardy; some of both genera requiring the shelter of a green-house. The caprifoliums (climbing like a goat!) are climbers; the loniceras (called after A. Lonicer, a German botanist) are mostly shrubby. All are propagated by cuttings planted in a shady place, and in almost any kind of soil.

CAPROMYS. A genus of Rodentia or gnawing mammalia, belonging to the rat family, and consequently to that division of the order which are furnished with clavicles. These animals have been known, in the island of Cuba, of which island they are natives, for more than three hundred years; but, as is the case with most of the natural productions of those parts of America which were, or are, in the possession of the Spaniards, nothing was known respecting them till within these few years; and we owe the best account of them to the indefatigable Desmarest.

The external characters of this genus place it intermediate between the rats, properly so called, which have their feet and toes slender, and produced, and their tails round, conical and scaly, and the marmots, which have their extremities stout and short. They are climbing animals, and not burrowing ones, as is the case with most of the order; they are nocturnal; and it is understood that they are chiefly or exclusively feeders on vegetable matter; but this is inferred rather than ascertained, for the manners of the animals are exceedingly obscure. They are plentiful in the woods of Cuba; but as they keep themselves carefully concealed during the day, it is rare indeed to get a sight of them. There is only one known species.

Capromys Furnieri, called the *Utia* or *Hutia* by the inhabitants of Cuba; and probably synonymous with the racoon rat of Brown's History of Jamaica. The size is about the same as that of a middling rabbit, but the head is rather longer, conical and a little compressed laterally. The extremity of the snout is truncated, and presents a large muzzle covered with fine skin of a deep black colour, free from any mucous secretion, and thinly sprinkled with very fine hairs. The nostrils are wide, placed obliquely, and approach near to each other at their inferior extremities, and their terminations are marginated. The upper lip is marked by a suture or furrow, very distinct. The opening of the mouth is moderate, as are also the incisive teeth, the only ones that have been examined. The eyes are also of a moderate size, very prominent, with brown irides, and they are situated rather nearer the basis of the ears than the point of the muzzle. The pupil, as in the greater number of nocturnal mammalia, is oval during the day, and has its axis vertical, as in the cats, thus indicating a climbing animal, or an animal which ranges for its food, in the vertical plane, and not the horizontal one. In this respect the animal is quite the reverse of hares and rabbits, and other rodent animals which seek their food on the surface of the ground. It does not appear that the eyes of this animal are able to bear the light; for during the day the pupil is closed to a perfect line, though in the twilight it is round and expanded, the iris appearing to have great sensibilility.

Sensibility in this part of the organ appears to be the chief reason why nocturnal animals, in general, see so badly in a strong light. This is very conspicuous in cats, and more so in owls, the pupils of whose eyes are so completely shut in clear sunshine, that the animals are helpless, and run themselves against any obstacles which happen to be in their way. It is, indeed, exceedingly probable that the power of vision in eyes depends much more on the sensibility of the pupil, or rather of the iris, than of any other part; and all animals, birds especially, which can bear to turn the eyes to the sun with unclosed eyelids, do not gaze on that luminary, or see it at all, but have the pupil entirely closed by the stimulating action of the light.

The eyelids and eyelashes of these animals are very handsome, the latter being long and neatly arranged. Their ears are rather more than a third part of the length of the head, shaped very similarly to those of rats: quite naked, of a black colour, and with a slight notch in the posterior margin. Their mustachios or whiskers are very long and moveable, and no doubt, as is the case with many other night animals, assist them in feeling their way. Their neck is short, the body much larger and thicker in the under part than anteriorly; and the back from the shoulders is considerably arched. The tail, which is equal to about half the length of the head and body, is very strong and muscular, conical, and surrounded by one hundred and fifty scaly rims, between which there are a few straggling coarse hairs. The legs are very stout, firmer in proportion than those of the marmots, especially the hinder ones. The fore paw consists of four toes, freely separated from each other, and furnished with strong and crooked claws; and there is a rudimental thumb or fifth toe, furnished with a small blunt claw, as is the case in most of the Rodentia. The second toe is the longest, the third the next, then the first, and lastly the fourth, as in the human hand. The hind feet have five toes, formed in a similar manner to those of the fore feet, but they, and also the claws with which they are furnished, are longer and stronger. The soles of the feet are covered with naked skin of a black colour, which is grained all over, and formed into tubercles or pads in the following manner:—four tubercles at the bases of the toes, three under the metatarsal bones, two on the middle of the toes, and one on the heel. The mammæ of the female are four in number, two pectoral and two abdominal, but they are of small size.

The hair is in general rough, and that on the part behind the head is turned forward, and forms a sort of crest at the nape. That upon the back and sides is long, and of two qualities, a fine one nearest the skin of a grey colour, and a coarser kind generally brown, but with yellowish rings near the point, and having the very points black. This gives a beautiful mottled colour to the whole covering, not unlike that of the agouti. The hair on the rump is harder than that on the other parts, it lies flatter to the body, and is of a reddish-brown colour. The hair on the breast and belly, which is very fine, but not very abundant, is sand-colour, a little inclining to grey. The hinder part of the belly is quite naked. The hair which forms the mustachios springs from the extremity of the muzzle. The feet are black; the hairs on the basal part of the tail are red, those on the distal part brown.

The name *Capromys* signifies a "hog-rat," the former part of the name applying to the rough and bristly hair on the upper part, their mode of walking on the ground, and various other characters; while in the form of their teeth, so far as known, and in that of their tails, they bear some resemblance to the rats, properly so called.

When in a state of nature these animals inhabit the woods, and climb trees with great facility. In reaching the leaves of those short plants which they do not require to climb, they make use of their tails as a third foot, something in the same manner as the kangaroos. Their expression is intelligent, their sight good; but it is probable that their sense of hearing is not so acute as that of the rabbits. Their natural cry is a squeak, not unlike that of rabbits; but when they are pleased, they express their satisfaction by a low murmuring grunt.

They live upon vegetable matter only; and in a state of domestication (for they are not very difficult to tame) they eat succory, cabbage leaves, aromatic plants, grapes, apples, and almost any vegetable. They drink tea; and do not refuse a bit of bread although soaked in anise-seed water or cherry-brandy; they are however somewhat mischievous, on account of their gnawing propensities. When a number of them are together and alarmed by any means, they gallop off with the same pace as hogs, and small as they are, their feet make a considerable degree of clattering. In consequence of possessing clavicles, these animals have a motion in their fore legs across the axis of the body, as well as a progressive motion, and thus they are enabled, like squirrels, and almost all the Rodentia which have clavicles, to bring their fore feet to their mouth, to lift their food with them, and otherwise to use them partially as hands.

CAPROS. A genus of spinous-finned fishes, closely allied to the doree (*zeus*), from which they were first separated by Lacepede. The dorsal fin is notched or divided as in the dorees, and the mouth is still more protrusile, but they have not the long fibres on their dorsal and anal fins. Their whole bodies are covered with strong scales. There is only one known species, a native of the Mediterranean, of a yellow colour, small in size, and of little value. It is the *Zeus aper* of Linnæus.

CAPSA (Lamarck). A genus of molluscs, separated from the genus *Donax* in consequence of some slightly defined differences, not, however, sufficiently well grounded, in our opinion, to sanction its adoption, as they may, with equal truth, be considered allied to the genus *Tellinides*, although without lateral teeth, as also the genus *Psammobia*, and to certain *Tellens*, by the similarity of the cardinal teeth; but they have not the flexuous bend of the *Tellens*; and if the hinge is to be the only certain guide, there are not any two species of *Donax*, or of Lamarck's *Capsa*, as he defines it, sufficiently well characterised to afford a certain rule; we therefore consider this genus no other than a section of *Donax*.

CAPSELLA (Moench). A new name and genus, separated from the old and well known British weed, the *Thlaspi bursa pastoris*, or shepherd's purse of Linnæus. This weed is luckily an annual, which with its five varieties found in England, are all easily destroyed by the hoe.

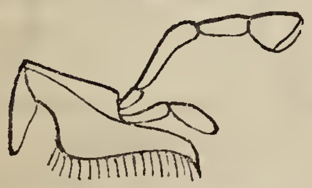
CAPSICUM (Linnæus). So called from its biting or pungent qualities. It is placed in the fifth class and first order of Linnæan botany, and in the important order *Solaneæ*, of the natural system. Generic character: calyx five-cleft; corolla rotate; limb plaited, in five divisions; stamens, filaments short; anthers conniving, bursting lengthways; berry assuming many shapes, two-celled, placenta fixed by the base, seeds adnate on the dissepiments. The fruit of the capsicum are universally used as a spice, as pickles, or as a preserve. In countries where it grows naturally, it is used by all ranks as a condiment to milder vegetables; and its action on the stomach is said to be necessarily stimulating, and sanatory in hot climates. In this country the capsicum was long cultivated as an ornament only; but is now become a material article of culture by the market gardener. Seeds are sowed in a hot-bed in March, and when advanced enough to handle, are pricked out into small pots of rich soil, and kept nursed in the hot-bed, and shifted as they grow into pots of larger size. In these they are suffered to produce their fruit in a green-house, or glazed frame; or about the beginning of June, the plants are turned out into a south border in the open ground, where they will flower and fruit abundantly. There are many varieties; some with very large, long, or heart-shaped fruit, others small and slender. The small fruited yellow sort, called in the West Indies hen-pepper, is by far the most pungent.

CAPSIDÆ. A family or rather sub-family of hemipterous insects, separated from the great Linnæan genus *Cimex*, and corresponding with the ninth family, *Astemmites*, described in M. Laporte's memoir upon this group of insects. We have, however, considered it more correct to employ the old Fabrician name for that of the family, and to adopt the ordinary uniform termination as proposed by Mr. Kirby. This group belongs to the section *Longilabres*, in which the rostrum or proboscis is four-jointed, with the upper lip long and acute, with transverse stripes. The joints of the rostrum are nearly of equal length, differing in this respect from the *Coreidæ*, the ocelli likewise are wanting, whilst the antennæ have the two last joints very slender and thread-like. These insects are very numerous, for the most part of small size, and of lively colours, amongst which yellow, red, black and green, are prominent. They are found upon trees and shrubs, the tender parts of which they suck: they are also said to suck the honey of flowers; they certainly are fond of some kinds of fruits, and it is not uncommon to recognise raspberries especially, which they have sucked, by the disagreeable taste which they impart to the fruit. Without being precisely social, it is common to meet with a considerable number upon the same plant. They walk and fly with much agility, escaping more quickly by the latter mode than the majority of the long-lipped *Cimicidæ*, or field bugs.

The family comprises the genera *Capsus*, *Heterotomus*, *Miris*, *Phytocoris*, *Orthonotus*, *Azinecera*, *Stenodema*, *Odontopus*. *Euryopthalmus*, and *Astemma*, the first six being British. The genus *Capsus* is distinguished readily by its oval form, lively colours, and antennæ having the second joint terminated by a club. The *Cimex ater* of Linnæus is the type; it is a very common British species, about one-third of an inch long, and entirely of a shining black colour. The genus *Azinecera*, of Stephen's catalogue (not yet described), is of a narrower form, with the antennæ of the males singularly curved and clubbed at the extremity of the second joint, whilst it is simple in the other sex. We have met with the type repeatedly at Coombe wood; it does not, however, appear to have been yet described.

CAPULUS. A genus of molluscs, of the family *Calyptracea*; the animal conical, but sometimes sub-spiral; the tentacula, foot, and branchia, as in the genus *Crepidula*, hereafter described. The shell is irregular and conical; the summit more or less inclined, and twisted backwards towards the posterior edge; the aperture is rounded, the margins irregular, the cavity deep, with a horse-shoe muscular impression open towards the front of the shell, and the termination of its ends rather unequal. Its trivial name is the foolscap limpet. The genus is divided into three species: those which have the summit slightly defined, and not inclined to one side, as in the *C. conicus;* those with the summit distinctly marked, and a little twisted, as in *C. ungaricus;* and those which are sub-spiral, as in the *C. intorta.* Four recent species are known, and six fossil. De Blainville does not admit of sufficient evidence to establish Lamarck's genus *Pileopsis* from the species of this family, and Sowerby considers the *Pileopsis ungarica*, commonly called the foolscap limpet, and its congeners, to belong more properly to the genus *Hipponix* of De France. They are found in all the seas of warm climates.

CARABIDÆ (Leach). A family of coleopterous insects belonging to the section *Pentamera*, and forming with the family *Cicindelidæ*, a sub-section named by the French authors, *Carnassiers terrestres* (*Adephaga geodephaga*), or voracious ground beetles. This family comprises the genus *Carabus* of Linnæus, with a few of the *Cicindelæ*, but which, as we have already stated, in our observations upon the modern system of nomenclature, under the article *Canceridæ*, has now become so extensive, that not fewer than two thousand five hundred species are possessed by the Baron Dejean alone; it has therefore become necessary to distribute this immense number of species into various minor groups, and accordingly Mr. Mc Leay, adopting the divisions, but not the names of Latreille, has divided them into four groups, which he terms families, named *Brachinidæ*, *Scaritidæ*, *Harpalidæ*, and *Carabidæ*, to which Mr. Stephens has added two others, *Elaphridæ* and *Bembidiidæ*. It appears to us, however, to be much more convenient to retain the family name in its original extent, and consequently to consider all these groups as subfamilies, to which the family name of *Carabidæ* may be jointly applied. We have, however, followed in the usual train, and have already given the BRACHINIDÆ (which see) as a family. In this article, therefore, we shall give a short sketch of the higher groups, *Adephaga* and *Geodephaga* (the family CICINDELIDÆ being so near at hand); we shall then characterise the *Carabidæ* in its Linnæan extent, and complete the article by a notice of the sub-family, as we propose to consider it of the *Carabides*, and its genera. In examining the organs of the mouth of the coleopterous insects, the greatest variety will be



Under jaw of Carabus.

found to exist in their construction. In none of the parts, however, is this so observable as in the lower jaw and its appendages. Theoretically speaking, this organ consists of a transverse base by which it is attached to the head, an upright stem supporting externally an articulated limb or the maxillary palpus, next an elongated lobe, and internally a second lobe. In many instances these two lobes are either quite soldered together, or one of them becomes obsolete; but amongst the predacious beetles, including the four Linnæan genera, *Cicindela, Carabus, Dytiscus,* and *Gyrinus*, we find the lobes not only perfectly distinct, but also the outer one transformed into an articulated feeler; hence these insects have been ordinarily described as possessing six palpi, in addition to which the internal lobe of the lower jaw is scaly, and terminated by an acute point or by a moveable claw, beneath which the same organ is ciliated with strong bristles. Now these characters clearly indicate a very increased power possessed by the parts of the mouth, the upper jaws being also horny, and very strong and toothed; and we accordingly find that these insects are amongst the most ravenous of beetles, preying for the most part upon living insects, being in fact the tigers and sharks of the beetle tribes; hence their names of *Carnassiers* or *Adephaga*: but another peculiarity amongst carnivorous animals is found in their increased powers of motion; and we accordingly find this character also strongly impressed upon these insects. The legs are generally long and slender, and well formed for activity; the anterior pair are inserted at the sides of the compressed prosternum, and implanted by means of a circular ball or rotule, which gives them great powers of motion; but here we find that although the organisation of the mouth indicated identity of predacious habits, the organisation of the legs as clearly evinces the nature of the element in which the different groups reside. The terrestrial species (*Cicindela* and *Carabus*) having the legs formed for running, are accordingly termed *Geodephaga*, whilst the aquatic species (*Dytiscus* and *Gyrinus*) having the legs formed for swimming, are termed *Hydradephaga.* In the former the legs are placed at nearly equal distances, the posterior coxæ being much smaller than in the aquatic species, and not soldered as in them, to the poststernum. The body is likewise generally oblong, with the eyes large and prominent, the jaws are likewise not concealed by the upper lip, whilst the breadth of the thorax never surpasses its length.

It would be a curious inquiry to trace out through nature the parallel analogies which these two groups of insects exhibit in their terrestrial and aquatic predaceous habits, but it is one which we have neither time nor space to enter upon at the present.

The predacious land beetles form two families corresponding with the Linnæan genera *Cicindela* and *Carabus.* The latter, to which we must now restrict our observations, is distinguished from the former by having the under jaws terminated in an acute but not articulated point. The lower lip is exposed with the labial palpi three-jointed only, the first joint being soldered to the lip and immoveable, and serving as a support to the long second joint. The character adopted from the toothed upper jaws, which has been employed to separate the two groups, admits of some exceptions, as in *Scarites, Pamborus,* &c., although generally speaking the mandibles of the Linnæan *Carabi* are but slightly toothed. The head is likewise in general narrower than the thorax. These insects are preeminently runners, whilst the *Cicindelidæ* are fliers; indeed in many instances the wings are entirely wanting in the former, the elytra being soldered together, but this character is by no means indicative of distinction of species, as has been asserted by various authors, since under peculiar circumstances, of the nature of which we are entirely ignorant, these wingless species, for some purpose or other, are found to possess wings fully developed. On this subject, respecting which our chief authors are at variance, Mr. Stephens justly observes :—" The most that can be alleged is, that certain species have a greater tendency to be apterous than others, and *vice versa*, e. g. *Omaseus nigrita* is generally winged, but I have several examples lately taken that are perfectly apterous. The same may be added of *Achenium depressum* (one of the *Staphylinidæ*), which is said to have mere rudiments of them, whereas the supposed males appear perfectly apterous, and among the females which I have examined are many with rudiments only, others with those appendages of greater bulk, and some with large and ample wings; these latter instances are evidently analogous to similar occurrences amongst the hemiptera, such as *Hydrometra, Stagnosum*, &c., which have also been found with ample ones."—Illust. Brit. Ent. Mand. i. p. 178. Our own observations upon Bolbocerus (which see) may also be referred to as affording a somewhat analogous instance of superiority of development in certain individuals of the same species.

The majority of the carabidæ emit a fetid odour, and discharge from the extremity of the body an acrid fluid, which, as already stated in Brachinidæ, is volatilised immediately on coming in contact with the air. By Geoffroy, as stated in our article Buprestidæ, these insects were regarded as the buprestes of the ancients, but which, from their stimulating powers, must rather have belonged to the family *Cantharidæ*.

These insects particularly inhabit the elevated regions of the northern parts of Europe, Asia, and America. Their chief metropolis appears to be in Europe, although in England we scarcely possess more than 400 species. Those of the restricted genus *Carabus* disappear as we approach the tropics whilst those of *Calosoma*, notwithstanding their evident affinity with the latter, reach even to the equator ; our observations upon this latter genus being thus amply confirmed. The species of another group nearly allied to the true carabi, *Procrustes*, appear to have established themselves in the countries washed by the Mediterranean, where likewise commences the region of the large brachini and scarites, which stretch to the equatorial countries, as well as certain species of *Graphipterus, Anthia*, &c., genera considered as more peculiar to Africa and the eastern parts of Asia.

These insects hide themselves beneath stones, the bark of trees, moss, &c.; other species frequent the margins of water or damp situations, whilst others, as some of the carabi, pterostichi, and helobiæ, frequent mountainous regions ; thus in the course of the last autumn we found numerous specimens of several of our rare British species within a few feet of the highest peak of Snowdon.

No group of insects has hitherto undergone so complete an investigation as the present. Paykull, Illiger, Weber, Clairville, Bonelli, Panzer, and Sturm, having devoted considerable attention to its elucidation, whilst more recently the descriptive work of Dejean, extending through six thick octavo volumes, will prove the assiduity of this author.

The following are the chief divisions, or as we would term them subfamilies, into which these insects are divisible—first, those with the anterior tibiæ notched.

1. *Brachinides*, having the elytra squared off at the extremity.
2. *Scaratides* having the elytra rounded behind and the abdomen pedunculated.
3. *Harpalides* having the elytra rounded, the abdomen not pedunculated, and the two last joints of the palpi equal.
4. *Bembidiides*, distinguished from the last by the minute conical terminal joint of the outer palpi.

Secondly, those with the anterior tibiæ not notched.

5. *Carabides*, having the antennæ long and slender.
6. *Elaphrides*, having the antennæ very short and stout.

Confining ourselves to the fifth of these groups, we find the carabides distinguished not only by the two characters above mentioned, but by the comparatively large size, brilliant metallic colouring, and extremely active and carnivorous habits of the species, as well as by the lower lip being small and conical, with lateral setæ or paraglossæ, the jaws very robust, and the large hatchet or spoon-shaped terminal joint of the external palpi, the eyes are prominent, and the abdomen in general large. Hence the terms abdominales and grandipalpi have been applied by Latreille to this section. The species are in general destitute of wings. The genera are Pamborus, *Cychrus*, Scaphinotus, Sphœroderus, Tefflus, Procerus, *Procrustes, Carabus, Calosoma, Nebria, Helobia, Alpæus, Leistus*, and Omophron. Those printed in italics are British genera.

The genus Carabus, notwithstanding the very restricted manner in which it is now regarded, is still a group of great extent, containing upwards of 160 species, of which nearly twenty are natives of our own country. They are generically distinguished by the dilated tarsi of the males, the bilobed upper lip, the absence of wings, the smooth jaws, and the entire tooth in the centre of the mental notch. The majority of the British species have the elytra soldered together, whilst *Carabus cancellatus* has them capable of motion, and is furnished with rudimental wings. Considerable confusion has arisen in the nomenclature of the British species.

C. clathratus.

Amongst the rarer indigenous species of this genus is the *C. clathratus* of Linnæus, a very handsome species, about an inch long, of a dark greenish brassy colour, with three elevated ridges upon each elytra, between each of which is a row of very deep golden excavations. It has been found in Norfolk and Scotland, but it occurs more plentifully in the neighbourhood of Dublin. Our specimens are from the neighbourhood of Belfast.

CARACALLA. Is the specific name of a sort of kidney-bean (*Phaseolus caracalla*) cultivated in India; it is also the title of a subtribe of that genus.

CARAGANA (Lamarck). A genus allied of plants to the *Robinia*, and so called from the aboriginal name given to the Siberian pear-tree. Linnæan class and order *Diadelphia Decandria*, and natural order *Leguminosæ*. Generic character: calyx, bell-shaped, five-toothed; keel obtusely erect, vexillum equal with the wings; style smooth; pod sitting, cylindrical, with a sharp point. This genus are mostly deciduous shrubs, with yellow flowers and fine foliage. They are rather difficult to propagate, and are most commonly worked on the *C. arborescens*, which is raised from seeds, and sometimes by layers.

CARALLIA (Roxburgh). An East Indian tree, so called by the natives of Hindoostan. Linnæan class and order *Dodecandria Monogynia*, and natural order *Rhizophoreæ*. Generic character: calyx globular at the base, limb six or seven-parted; petals six or seven, roundish; stamens inserted on the calyx; anthers erect; style simple; stigma three-lobed, berry, globular, one-seeded and crowned with the calyx.

CARALLUMA (R. Brown). A curious under shrub, so called in India, formerly supposed to be a *Stapelia*. Linnæan class and order *Pentandria Digynia* natural order *Asclepiadeæ*: calyx five-parted; corolla somewhat rotate, and in five divisions; corona round the seed-vessel consisting of ten leaflets; five of the folioles bear, and are opposite the anthers; gynostegium protruding. This ranks among our succulent plants, and thrives best in brick rubbish and loam. No water should be allowed to stagnate in the pot, very little of this being required, except at the time of flowering, when they want a good deal; but at this time they also require a high temperature. The plant may be increased by cuttings; but must be laid on a shelf to dry and get withered before they are put in dry soil. If potted as soon as cut off, the great discharge of sap from the wound instantly rots the cutting.

CARANX. A very numerous and widely distributed genus of spinous-finned fishes, belonging to the mackerel family, and so nearly resembling the true mackerel, at least in some of the species, as to be called by the popular name of *Bastard* Mackerel. They are very numerous, being found in all seas, and in all parts of the sea, or at least of those wide seas in which the true mackerel are found; but it does not appear that they collect in such numerous shoals on some parts of the coast as these fishes. As is the case with most of this very important family, they are wholesome and pleasant as food, but, as is the case with the others, they very speedily die when taken out of the water, and they as speedily become putrid. The large gill-openings, and remarkably free gills of these rapid-swimming surface fishes, are probably the chief cause of their speedy death when taken out of the water; and it is a very general law in the animal economy, that those animals in which the functions of life are most energetic, putrify the soonest after they are dead. We have a remarkable instance of this in trout and eels, the latter of which can be kept much longer wholesome without salt than the former; and we have a similar instance in mackerel and skate.

The general economy of the genus under consideration will be treated of in the article FISH and in the article SCOMBEROIDÆ, so that we shall here barely notice the generic characters.

The name *Caranx* means "keel" or "ridged," and this is very expressive of the principal distinction between these fishes and mackerel. Along the lateral line there is a series of scaly pieces or bands, with ridges or keels in the middle, and often with spines. These bands extend from the pectorals to the insertion of the tail; they sometimes consist of as many as a hundred separate pieces upon each line, and they are a very distinct and easily observed character. They have two distinct dorsal fins, with a detached spine bent downwards in advance of the first one. The last rays of the second dorsal are very slightly united, and sometimes entirely separated. There are also free or detached spines, forming a little fin behind the anal.

The seas of Europe contain many of these fishes, and indeed they range, with small difference in appearance, over the whole of the ocean. They are found in the Mediterranean as far to the south-east as Alexandria; they are to be met with on the shores of North America, on those of Brazil, at the Cape of Good Hope, in the seas of Australia, and indeed everywhere except in the extreme of the Polar seas. The earlier naturalists included them as a species of mackerel (*Scomber*); but they are not only different from all the species of that genus, but they differ so much from each other, as to require division into several species, if not sub-genera. The same species is, however, exactly the same in appearance in whichever part of the world it is met with. The chief difference is in the number of carinated plates on the lateral line, and in the flexure of that line itself. Some of them have those plates continued the whole way from the shoulder to the tail, while others have them on the posterior or straight part of the line only, while the anterior, or arched part, is covered over with small scales. They have all the spindle shape of the common mackerel, but they differ considerably in the number of what may be called the supplemental fins. Some have only one of these after the dorsal, and others have several, but the greater part have none; some have the body very much elevated, and the lateral line consequently very much curved, but even these have the forehead with a rapid descent. The species are so numerous, that a particular account of them would fill a volume; but we must barely notice two, one found chiefly in the western, and the other in the eastern seas, though both are met with in the same. These are called in the French West Indies the *Carangue* and the *Bastard Carangue;* and though the difference in appearance between them is not great, it is well worthy of attention, inasmuch as the true fish is always wholesome, and the bastard ones generally poisonous. The *carangue* is of a silvery colour, with the exception of a distinct black spot of a distinct gill; and the bastard is exactly similar in shape and in general colour, and hardly differs from the other in size, but it never has the least vestige of the black spot. In the warm seas the esculent fish is a very important one; it is caught readily and in great numbers, and often weighs from twenty to twenty-five pounds.

CARANXOMORES. One of the five subgenera into which the genus *Coryphæna* has been divided.

The only difference between them and the true *Corypheus* is, that they have their head oblong and a little elevated, and their eyes in a medium position, instead of having the head high and rounded, and the eyes much depressed. See CORYPHŒNA.

CARAPA (Aublet). A genus of tropical trees belonging to *Decandria Monogynia* of Linnæus, and to the natural order *Meliaceæ.* Generic character: calyx leathery, in four lobes; petals spreading, and somewhat leathery; urceolus bearing fleshy stamens, having eight teeth; filaments linear, emarginate; anthers oblong, attached to the interior side of the filaments; style thick and short; stigma broad, margin furrowed, disc perforated; drupe large, sapless, globular, four-valved; nut inclining to eight-sided, containing one seed. These trees grow strongly in our stoves; having large glossy foliage, for which they are chiefly admired. They are propagated by cuttings.

CARAPUS. A genus of malacopterygeous, or soft-finned fishes, without ventral fins. It is closely allied to the celebrated electric eel (*Gymnotus electricus*), but it is without the electrical quality, and also without the proper characteristic of the *Gymnoti,* as it has the body covered with scales, whereas the *Gymnoti,* of course, have none. Its tail is much pointed. It is found in the fresh-water rivers of North America, but it is a fish of small value or interest. It would seem that, as is the case with the common eel in England, there are two species of this fish—the one with the muzzle blunt, and the other with it pointed.

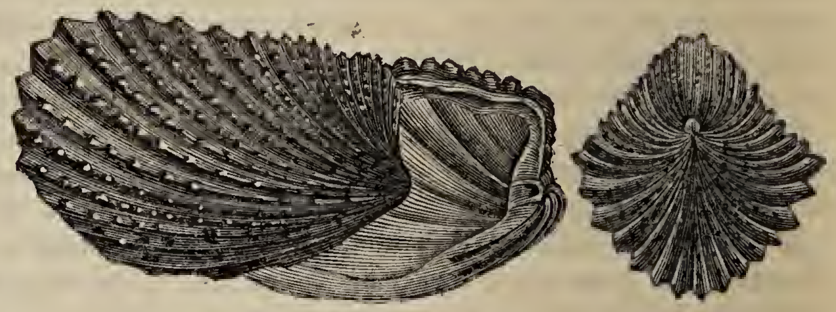
CARAWAY is the *Carum Carui* of Linnæus. It belongs to *Pentandria,* and to the natural order *Umbelliferæ.* It is an herbaceous biennial, and cultivated in England and other parts of Europe for its seeds, which are indispensable to the confectioner and druggist.

CARDAMINE (Linnæus). A genus of herbaceous annuals and perennials, growing in water or in moist ground. They belong to the *Tetradynamia* class of Linnæus, and to the natural order *Cruciferæ.* Generic character: calyx erect; pod linear; style very short, or none; valves plane, nerveless; seeds in one viscera. *C. pratensis* is the common cuckoo-flower, one of the earliest spring flowers frequent in damp meadows.

CARDAMOMUM is the *Alpinia Cardamomum* of Roxburgh. The seeds, produced by a perennial herb in India, are of a fine aromatic flavour, and much used as a spice in high cookery and confectionary, as well as in medicine.

CARDIOSPERMUM (Linnæus). A genus of ornamental climbing plants, chiefly natives of South America. Linnæan class and order, *Octandria Trigynia;* natural order, *Sapindaceæ.* Generic character: calyx funnel-shaped and four-lobed; petals four, inserted in the calyx; stamens inserted in a double order on the calyx, opposite the petals; anthers two-celled, bursting longitudinally; style acute; fruit nut-like, one-seeded; seed pendulous. Several of this genus are in our hothouses. They are grown on loam and moor-earth, and propagated by cuttings.

CARDITA (Lamarck), *Chama* (Linnæus). This genus of molluscs was included in the genus *Chama* by Linnæus, from which, however, it most essentially differs, the teeth being of another form; the valves are always equal, and the shell is never affixed by its lower valve to other bodies. The shell is equivalved, regular, and inequilateral, the greater number of species appearing longitudinal, from the great elongation of the anterior side. The hinge has two unequal teeth, one short, straight, and placed beneath the umbo, the other oblique, marginal, and prolonged, being inserted into a corresponding fossuli. The valves are more or less strongly ribbed, smooth, or imbricated; the internal margin crenated or plaited. De Blainville, in his System of Malacology, has arranged the species of *Cardita* in the following order: first, those that are elongated, slightly notched, or gaping at the inferior side of the ligaments, concealed as in the *C. crassicosta,* forming the group of *Mytilicardia;* secondly, the oval species, the inferior sides of which are nearly straight, or slightly arched, crenulated, and completely closed, forming the group *Cardiocardita,* as in the *Cardita Ajax;* thirdly, such as are nearly round, or suborbicular, the inferior side rounded, denticulated, still more equilateral, with the two teeth shorter and more oblique, constituting the genus *Venericardia* of Lamarck, of which the *V. imbricata* is an example; and lastly, the elongated species, very inequilateral, the summit turned forward, two short divergent cardinal teeth, besides the lamellar one; the ligament very long, slightly, or not at all salient; the abdominal impression sometimes a little placed backward, forming Lamarck's genus *Cypricardia,* an example of which is the *Cardita guinaic.*



C. caliculata.

Lamarck enumerated twenty-five species of *Carditæ,* of which one only is fossil; eleven *Venericadia,* all fossil, with the exception of one; and seven *Cypricardiæ,* four of which are recent, and inhabit the seas of warm countries.

Some of the species are presumed to spin a byssus, and it appears that they all of them live in situations only occasionally overflowed by the sea.

CARDIUM (Linnæus, Lamarck). From the constantly well-defined characters of this genus of molluscs, little or no change has taken place in the arrangement of modern naturalists and that of the great Linnæus. It is an interesting and elegant family of shells, whose symmetry of form is not surpassed by any other mollusc; they are variously sculptured, and the convexity of the valves, like the genus *Pecten,* is ornamented with numerous longitudinal ribs, more or less elevated, armed in many with spines; others are imbricated, or have hollow scales, and some merely marked with variously arranged striæ. The interior part is smooth, or only grooved at or near the margin, the valves are equivalve, subcordiform, apices protuberant, slightly curved forward; a complex hinge similarly formed of two cardinal teeth oblique and conical, and two other lateral teeth, inserted at a distance from each other, on each valve; the ligament is dorsal, very short, and the two muscular impressions on the valves generally but slightly marked; the increase of their growth is very distinctly visible, and each addition in some species overlaps the previous increase.

The animal is a *Tethys* of Linnæus, its body very convex, the mantle bordered with tentacular cirrhi round its inferior side, and more or less channelled on the outside, the tubes united, of a moderate size, and provided with cirrhi at their extremity. The foot very large, cylindrical, angular formed, and placed rather forward; branchia thick, rather small, particularly the external folds; the internal ones are united through their whole length.

This genus is arranged by De Blainville in the third class *Acephalophora*, third order *Lamellibranchiata*, seventh family *Conchacea*, and the species subdivided as follows: first, such species as gape more or less backwards, and the ribs as large as the grooves, of which the *C. exoticum* is an example; secondly, those with ribs similar to the first species, but the valves not gaping, as in *C. tuberculatum*; thirdly, the species not gaping, but whose ribs are greater than the channels, as in the *C. edule*, or common cockle; fourthly, the species smooth, or nearly so, as in *C. lævigatum;* and fifthly, such as have the anterior side very short and nearly flat, as in the *C. hemicardium*, forming Cuvier's genus *Hemicardium*.

Lamarck has made two divisions of this genus, distinguishing the first by having the anterior side as large or larger than the posterior, and without any very distinctly marked angle at the apices. The second, by the posterior side being often much larger than the anterior, and possessing carinated or angular umbones. In this division, as we have elsewhere observed, that elegant mollusc the *Cardium cardissa*, *Venus' heart*, as it is commonly called, has been placed with others of this genus, whose valves are angularly flattened, forming when closed a compressed heart-shaped shell, strikingly different to all other bivalves, in which the depression is in the opposite direction, where any exists. Though unacquainted with the anatomical structure of this mollusc, and not knowing any work in which it is described, we cannot but think that these species must be inhabited by an animal totally distinct from that which constructed the *Cardium costatum* and its congeners, and merits, from its strongly defined characters, the honour of a generic appellation; though modern malacologists do not appear to have made even a distinct division of them. There are several varieties of them, particularly those classed as *Cardium cardissa*, some very recently discovered; and it will be universally confessed that, amongst the many beautiful forms presented by other molluscs, not any is more truly pleasing and graceful, or altogether more wonderful in its structure.

The molluscs constituting the genus *Cardium*, with perhaps only one exception, inhabit the sea, where they exist, hidden at a small depth under the surface of the sandy beach, sometimes barely covered, the necessity of which appears obvious, from the shortness of the tube employed in drawing in and expelling the water. As a nutritious and agreeable food many are known, but the most common in this country is the *Cardium edule*, or common cockle. In the London markets it is not so often met with as in Scotland, where this mollusc is of a larger size, and far more generally an article of commerce.

The cardia inhabit the seas of all countries, and numerous fossil species indicate their having ever formed an important genus in natural history.

CARDOON is the *Cynara cardunculus* of Linnæus, a species of artichoke, the leaves of which are blanched, and used like celery. Like all the artichoke family, the cardoon contains a rank bitter principle, which is dissipated by blanching. The cultivation is simple. A piece of good rich light soil is prepared by digging, on which trenches are opened four feet apart, six inches deep and twelve wide. Along the middle of the trenches the gardener should drop patches of several seeds at eighteen inches apart.

When the seedlings appear, and have gained a little strength, they should all be removed with the exception of one from each patch. During summer, the growth of the plants is encouraged by keeping them free from weeds, and by occasional watering, if necessary. Towards the middle of October, the plants will be large enough, and ready for blanching. This is done on a dry day, by first gathering up all the leaves closely round the centre, and in that position binding them together with strands of mat or osier twigs. This done, each plant is earthed up in the manner of celery, so that the points of the highest leaves are only exposed at top. In two or three weeks the leaf-stalks will be sufficiently blanched and crisp, and then are fit for use, being digged up as wanted.

There are several varieties of the cardoon, namely, the Spanish, the common, the red, and the Tours. The first is esteemed the best both for size and delicacy of flavour. The cardoon is indispensable in French cookery, and is becoming much more generally used in England than formerly.

CARDUELIS (Auctorum). A genus of small conirostral birds, or rather perhaps a sub-generic division of the very extensive genus finch (*Fringilla*, Auctorum), and of which the common goldfinch and siskin of this country may be considered the standard. It contains several species, and the form, in one or other of them, appears to range pretty generally over the globe, although the distribution of each species separately is much more limited. They are about the most *typical* of all the finches, or, in other words, the various and peculiar characters which together constitute what we term a finch are more prominently observable in this particular division than in any other.

The bill is conical, longer than deep, compressed anteriorly, and drawn to a very fine point, the nostrils hidden by incumbent bristles. The wings are of mean length, the first quill-feather rather shorter than the second and third, which last are nearly equal, and the longest of all; tail rather short, and in general slightly forked; the tarsi slender and short; claws curved and acute; the hind toe tolerably strong, with the sole broad.

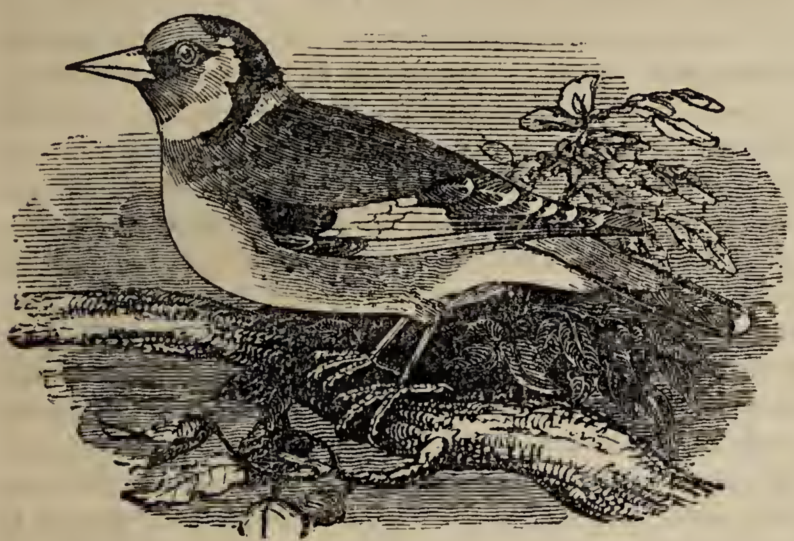
There are two principal modifications of this form, independent of the connecting links which, as is usual, intervene between this and a few other nearly allied divisions. These are distinguished by a slight diversity of form and habit, and by a different style of colouring. The species of one, which is exemplified in the common goldfinch of this country, are what are popularly termed *Goldfinches;* those of the other, which are far more numerous, and of which the common aberdevine siskin (see ABERDEVINE) may be cited as a typical example, are generally denominated *Siskins*.

The colours of the former are gay and brightly contrasted, having the back and under parts uniform spotless brown, shading off into white, or to a paler tint; the wings black marked with white and brilliant yellow, and the head richly adorned with crimson or scarlet, and in some species also with black. The sexes are very similar, and their plumage is altogether more tropical; and after the autumnal moult, they have no deciduous terminal edgings to their feathers. Their habits, also, are less arboreal, the different species passing their time nearer the ground, and subsisting chiefly on the seeds of thistles, and various other composite plants, whence, indeed, is derived their generic appellation *Carduelis* (from *Carduus*, a thistle). They are birds of the low country, and those resident throughout the year, familiar in their manners, building their exquisitely constructed nests in our gardens and orchards, and cheering us, winter and summer, with their sprightly, animated, and pleasing songs.

The siskins, on the other hand, are inhabitants more of the northern pine-forests, and of the more elevated districts in tropical parts, whence they descend in winter, and straggle in flocks over the low country. The character of their plumage corresponds; the hues of the more typical species are not so bright, and the feathers are in winter fringed with terminal edgings, which gradually disappear at the approach of the breeding season. Their wings, as might be anticipated from their more migratory habits, are longer in proportion than in the true goldfinches, and their bills are not drawn to so acute a point. We might from this safely infer that there is a difference in the general character of their food, and we find, accordingly, that they subsist almost entirely upon the seeds of various trees, our British siskin chiefly on those of the alder and birch. They appear to nidificate mostly about the margins of pine forests, at a considerable height from the ground, and the main colour of their plumage is always greenish yellow, brightest in those species which approximate most to the goldfinches, and more or less marked in the others with spots and streaks of dark-greenish brown, or dusky; the males are much brighter in their tints than the other sex, and are generally upon the crown of the head black, and this hue, in one or two species, extends over the whole head and geat part of the neck.

Deciduous terminal edgings to the new plumage, which is acquired at the general moult, in autumn, may be observed upon the throat and upper parts of very many of the smaller birds, but chiefly among the members of the finch family (*Fringillidæ*), and of certain divisions of the starling, thrush, flycatcher, and warbler families. These edgings are merely a continuation of the barbs of the feathers, and are, in many instances, of precisely the same texture, although generally of a rather warmer and more downy nature; they are usually of a pale dusky, or whitish hue, and, as may be often observed in the snowfleck, and sometimes in the bramblefinch, are very apt to become quite white when much exposed to intensely cold weather. In many cases they even entirely conceal the true colours of a bird's plumage, so that, in the spring, after they have disappeared, it would seem to a superficial observer that a general moult had taken place; and instances are not wanting in the books where such birds have, in consequence, been described to change their plumage twice in the year. When this fringe joins the ends of the feather, that is, at the extreme points of junction where the two colours meet, its texture is always considerably finer and weaker, so that, if we were to pull one of the little plumelets, or barbs of the feather, it would infallibly break at this place. Now, a feather, so long as it remains attached firmly to the skin, is part of a living structure, and a circulation takes place within it; but its vessels are exceedingly minute, and the action within them is very apt to be obstructed, more or less, by whatever affects the general health of the body, and this is always immediately shown by the diminished lustre of the tints of the plumage, which consequently affords an excellent test by which to judge of a bird's state of health. It would seem, however, to judge from the always comparatively dead appearance of the winter edgings, that this circulation is never very complete beyond the narrow part which joins the fringe to the extremities of the back; and when, in the vernal season, the action within the feather is either much increased, or the nature of the circulating fluids become changed, as is indicated by the very great increase of lustre, and not unfrequently decided change of hue which takes place at that season, the pores of the narrow connecting parts appear to be finally obstructed, and the edging, in consequence, dies and rubs off; and the brighter colours beneath, which had hitherto been concealed by these dusky fringes, become gradually exposed to view, until the bird becomes altogether in what is commonly termed "its summer plumage."

The very obvious purpose of this structure is to assist in preserving the bodily heat, and we see in it not only an additional supply of clothing for the winter months, but also a *hue* better calculated than that beneath it, both for preventing the bird's heat from radiating, and for concealing it, whilst the leaves are off the trees, from the observation of its enemies. We see also both these objects even further effected by extreme cold in the assimilating of the hue of this additional covering to the tint of the snow and frost; and yet, as white would be a conspicuous, and therefore a dangerous dress, before the snow was upon the ground, we find that the snowfleck (*Plectrophanes nivalis*), and one or two other species, which have much white upon their concealed, or summer plumage, have this actually covered in the autumn with dusky or brown edgings, which, however, have a tendency to become white whenever the weather shall be sufficiently cold to render this change a protection; and here, therefore, we have another, and a very striking instance, of the adaptations of the hues of animals to the colour of their natural haunts. It is worthy also of remark, that the young birds of the preceding season, which, of course, are comparatively tender, have their first winter plumage much more thickly covered with these deciduous edgings than those birds have which have moulted more than once, insomuch that they may easily be thus distinguished; and it may be also observed, that a black plumage, which, of all others, is the colour which most radiates heat, is more frequently thus concealed and fringed than any other colour. We do not mean to assert that *all* black-coloured birds have these terminal winter edgings to their feathers, but it certainly often happens, among species that are very nearly allied, that those which have partly black plumage are thus fringed, whilst others, which are grey or brown, are not. Thus the whinchat, and the common grey flycatcher, have never any edgings to their feathers, whilst the stonechat and the field flycatcher, the plumages of which are on the upper parts black, have; and the red bunting, which is the only British *Emberiza* with a black head and throat, has these parts much more thickly edged in winter than any of our other species. Again, the common robin is never thus edged in winter, whilst the different redstarts, which, physiologically, are very nearly allied to it, but are all of them more or less covered with black plumage, have the new feathers which they acquire at the autumn moult, in some cases almost wholly concealed by brownish tips.



Carduelis.

To return, however, now to the true goldfinches, which, unlike the siskins, have no additional covering to their plumage in winter. What more we have to say of them can be better introduced when giving an account of the different species. Perhaps the most beautiful of the whole genus is the common European goldfinch (*Carduelis elegans*), o which it has been well said, that elegance of form and beauty of plumage, docility of disposition, and sweetness of song, together with its natural hardiness of constitution, all combine to render it a general favourite, and it only requires to be brought from a far country, and to be sold at a high price, to be one of the most choice favourites of amateurs, and to supersede almost every other pet which luxury has imported from foreign parts. Happy for it, however, if its abundance could thus procure for it the neglect of bird-*fanciers;* but the fact is, it is a real matter of wonder how, amid the ceaseless persecution from which it suffers, after the many thousands which are annually captured by the wholesale mode with clap-nets and call-birds, and by various other contrivances and devices, that their numbers are not very considerably on the decline, that they should still be found, year after year, so numerous, so common as they always are. The species abounds in all parts of Europe, with the exception of mountainous districts, from the north of Sweden to the Mediterranean ; and they would in one year be quite common even in the immediate vicinity and environs of our large cities, if the bird-catchers would but suspend their operations for so long a period.

This beautiful finch is so well known, that a description of it is hardly necessary. The bill is pale flesh-colour, with a blackish tip, and continues to increase somewhat in size for two or three years ; the forehead and throat are bright crimson ; the cheeks, ear-coverts, and lower parts of the neck, white; and the occiput and nape of the neck are glossy black. The whole upper parts, with the sides of the breast, are of a bright and deep yellowish brown ; a little above which, on the breast, is a pale band across of the same colour ; remainder of the under parts white, shading into brown. The wings black, with the greater coverts, and basal half of the quills, bright gamboge yellow; the other half black, with a white spot at the tips. Rump whitish; six middle-tail feathers black, with white-pointed tips; the remainder also black, with a large oval white spot, occupying the middle of the inner webs. Legs and toes pale brown. The female is very similar, but her colours are not quite so brilliant; there is no difference in her markings from those of the male. In both, the browns of the plumage become much paler towards the approach of the breeding season, at which time the crimson of the head changes to scarlet, and the yellow on the wings increases in brilliancy; these changes, however, do not take place in captivity. The young, in their nestling plumage, are called by the bird-catchers *grey-pates;* they have then no black and red upon the head, and the plumage all over is streaked longitudinally, like that of a linnet; the wings and tail alone resembling the adult birds, the feathers of which do not appear to be changed until the second autumn.

The goldfinch is very partial to orchards and gardens, and shrubberies, especially if they are ill kept, as its principal food consists of the seeds of various weeds which grow chiefly in such situations; those of the different thistles, the burdock and the dandelion, are its favourite food, as well as the oily seeds of many of the cruciform plants. To obtain the former, it may be commonly observed clinging in various constrained and grotesque attitudes, often with the head downward, whilst the *pappus*, or vegetable down is made to fly in all directions; the bird reminding us, by its positions, of the titmouse tribe, which it further resembles in the habit of holding food with the foot, whilst pecking at it with the bill; a habit which is common to all the species of *Carduelis.* The goldfinch also feeds much upon various green leaves, more particularly on those of chickweed and groundsel, and it will sometimes sit and pick off the aphides from a plant with great assiduity; but it never feeds on insects in the manner of the chaffinches and sparrows, and, in confinement, it invariably rejects every thing of the kind. It is also very partial to the unopened blossoms of furze, and to the flowers of various other plants.

Its song, which may be heard at almost every season of the year, and as cheerily in the midst of a November fog as in the brightest sunshine, is brisk and lively, continuous, well kept up, and extremely musical and cheerful; and its common chirrup and call-notes are more pleasing than those of most other birds. " They seldom," as is observed by a distinguished naturalist, " alight on the ground, unless to procure water, in which they wash with great liveliness and pleasure; after which they pick up some particles of gravel and sand. So fond of each other's company are they, that a party of them soaring on the wing, will alter their course at the call of a single one perched on a tree. This call is uttered with much emphasis; the bird prolongs its usual note without much alteration; and as the party approaches, erects its body, and moves to the right and left, as if turning on a pivot, apparently pleased at showing the beauty of its plumage and elegance of its manners."

The goldfinch's nest is a very beautiful structure, generally situate in the fork of an old lichened fruit tree, and occasionally in hawthorn hedges; it is mostly described to be lined with down of the different thistles, although thistles are very rarely even in flower at the time the goldfinch builds. Grahame is more correct when he says—

> "The goldfinch weaves with willow-down inlaid,
> And cannach tufts, his wonderful abode;
> Sometimes suspended at the limber end
> Of plane-tree spray, among the broad-leaved shoots,
> The tiny hammock swings to every gale;
> Sometimes in closest thicket 'tis concealed,
> Sometimes in hedge luxuriant, where the briar,
> The bramble, and the plum-tree branch,
> Warp through the thorn, surmounted by the flowers
> Of climbing vetch, and honeysuckle wild."

It is of very elegant construction, composed on the outside of lichens, moss, and dry grass, smoothly interwoven with wool, and very warmly lined with a mixture of the last-named substance, hair, and the seed down of the willow. The eggs are four or five in number, of a bluish-white, with a few small orange-brown spots, chiefly at the larger end.

Like most other birds of this family, goldfinches associate after the breeding season in flocks, and traverse the open country; these, however, are never very numerous, their societies rarely exceeding twenty in number; they are in winter always wandering from place to place, often fly at a considerable height from the ground, and always against the wind; but their course is ever instantly arrested by the call of a single one from below. The same may be observed in all our native finches, and this call-note may perhaps be an invitation to food, though more probably it is merely expressive of its propensity to join in company. It is by means, however, of the wild birds being so readily attracted by this call, that so very many of them are taken by the bird-catchers.

Goldfinches are not generally subject to vary much in plumage, but individuals are occasionally taken with the throat white, and sometimes with a white spot on each side of this; these are termed by the bird-catchers *cheverels*, and are often sold at a high price. This species also is very frequently paired with the domestic canary finch, with which it readily breeds, and the mixed produce are commonly termed *goldfinch-mules* or *canary-goldfinches;* the hybrids preserve generally the markings of the goldfinch, with the yellow tint of the canary; and their song most resembles that of the former, but is much more powerful; they readily breed back with either of the parent species, but it does not appear that two of these hybrid birds will ever propagate together.

Among the different groups of finches (*Fringillidæ*), there is a remarkable diversity in the mode of bringing up the young; in the chaffinches, the sparrows, and one or two other divisions, these are wholly fed upon insect food; whereas in the grosbeaks (*Coccothraustis*), the goldfinches and siskins, the linnets, and the different canary finches, they are entirely brought up upon semi-prepared vegetable diet, ejected from the craws of the old birds. This difference is not, however, so important, but that species from each group will sometimes, in captivity, breed together; the writer of this has seen a hybrid production between the domestic canary bird and the common chaffinch.

Hybrid animals, it may not be amiss here to remark, are never produced by two animals both in a state of nature, but are invariably, either directly or indirectly, brought about by man's influence; that is, by the unnatural condition into which at least one (the female) parent had been placed by the direct agency of man. Some cases to the contrary have been mentioned, but they are exceedingly dubious and questionable; and the assertion may very safely be adhered to, that not a single instance rests upon what may be considered conclusive evidence, or satisfactory foundations. For the details, however, of this subject, we must refer to the article HYBRIDS.

There are two or three species of goldfinch, very similar to that of this country, especially one which inhabits the slopes of the Himalaya. This differs a little in the markings, and it has no black upon the head; its under parts, also, are of a more uniform pale brown than in our bird; but its general appearance, and most probably its habits, are extremely similar. There is, indeed, a very remarkable resemblance between a great many of the birds of the Himalaya mountains, and those which inhabit Europe; the same general types of organisation seem to prevail there as with us, but intermixed with a great variety of splendid tropical forms. We find there some remarkable counterparts, as we may term them, of the European jay, green and black woodpeckers, nutcracker, blackbird, great titmouse, nuthatch, and a host of others, much more similar to our species than any which are elsewhere known; yet all these are sufficiently well characterised to leave no doubt of their being separate and distinct species. Of these, one, and not the least remarkable, is the Himalaya goldfinch.

AMERICAN GOLDFINCH (*Carduelis luteus*). This is the *Fringilla tristis* and *Carduelis Americanus* of different authors, neither of which terms are very appropriate, not being sufficiently exclusive; *tristis* refers to the dull appearance of its winter dress, although its summer garb is very bright and showy. The species is intermediate between the goldfinches and siskins; having the habits and general proportions of the former, with the plumage and yellow colour of the latter, but much brighter than in the more typical siskins. Its summer plumage is a bright lemon yellow, fading into white about the rump; the crown of the head black, as are also the wings and tail, the former of which are edged and tipped with white. The female is of a dull olive-brown, marked with dull white, and yellowish; and the male, in winter plumage, is very similar. This species is said to moult twice in the year.

Its habits, as described by Wilson and Audubon, appear exactly to correspond with those of the common goldfinch of Europe. Wilson says, "They build a very neat and delicately formed nest, which they fasten to the twigs of an apple tree, or to the strong branching stalks of hemp, covering it on the outside with pieces of lichen, which they find on the trees and fences; these they glue together with their saliva, and afterwards line the inside with the softest downy substances they can procure. The female lays five eggs, of a dull white, thickly marked at the greater end; and they generally raise two broods in a season. The males do not arrive at their perfect plumage until the succeeding spring; wanting, during that time, the black on the head, and the white on the wings being of a cream colour. In the month of April they begin to change their winter dress, and before the middle of May, appear in brilliant yellow; the whole plumage towards its roots is of a dusky bluish black.

"Its song resembles that of the goldfinch of Britain; but is in general so weak as to appear to proceed from a considerable distance, when perhaps the bird is perched on the tree over your head. I have, however, heard some sing in cages with great energy and animation. On their first arrival in Pennsylvania, in February, and until early in April, they associate in flocks, frequently assembling in great numbers on the same tree to bask and dress themselves in the morning sun, singing in concert for half an hour together; the confused mingling of their notes forming a kind of harmony not at all unpleasant."

Sir W. Jardine well remarks on this, in a note to his edition of Wilson's work, the resemblance which subsists between the habits of the different *Carduelcs* and those of the true linnets (*Linaria*), "Every one who has lived much in the country, must have often remarked the common European linnets, in the manner above described of the American goldfinch, congregating, towards the close of a fine winter's evening, perched on the summit of some bare tree, pluming themselves in the last rays of the sun, chirruping the commencement of their evening song, and then bursting simultaneously into one general chorus; again resuming their single strains, and joining, as if happy, and rejoicing at the termination of their day's employment." M. Audubon has remarked the same trait in their manners, and confirms the resemblance of the notes of the American and European goldfinches. "So much does the song of our goldfinch resemble that of the European species, that whilst in France and England, I have frequently thought, and with pleasure thought, that they were the notes of our own bird which I heard."

Wilson continues: "About the last of November, and sometimes sooner, they generally leave Pennsylvania, and proceed to the south; some, however, are seen even in the midst of the severest winters. Their flight is not direct, but in alternate risings and sinkings; twittering as they fly, at each successive impulse of the wings. During the latter part of summer they are almost constant visitants in our gardens in search of seeds, which they dislodge from the husk with great address, while hanging, frequently head downwards, in the manner of the titmouse. From these circumstances, as well as from their colour, they are very generally known, and pass by various names expressive of their food, colour, &c., such as thistle-bird, lettuce-bird, salad-bird, yellow-bird, &c. * * * They are easily familiarised to confinement, and feed with seeming indifference a few hours after being taken."

The American goldfinch, it would appear, will not pair so readily with the canary-finch, as the European species does. There are instances of their being kept for many years together, without either showing any disposition to breed. A few cases, however, have occurred of their producing hybrids.

Birds of this species were seen by Mr M'Kenzie, in his route across the continent of North America, as far as lat. 54°; they are numerous in all the Atlantic states north of the Carolinas; abound in Mexico, and are found also in great numbers in the Savannahs of Guaiana. A species pretty closely allied to this is the

Black-headed or Olivarez Siskin (*C. Magellanica*), which also much resembles the aberdevine siskin of Europe; but may readily be distinguished from all its congeners by having the head entirely black. This species is said to sing finely, but there is nothing very peculiar in its habits to warrant a particular description. It inhabits the greater part of South America.

The aberdevine siskin (*C. spinus*), has been already noticed in its alphabetical situation in this work; and the general habits of the true siskins are there pourtrayed. Another European species, the

Venturon siskin (*C. citrinella*), approximates in form to the canary birds. The bill is rather short, the feet flesh-colour, the plumage of the upper parts yellowish-green, streaked with brown; the under parts and rump greenish-yellow, brightest about the breast; the quill and tail feathers blackish, with greenish edges; tail forked. The female bird is less spotted, and the general shade of colour is lighter.

The venturon siskin is a pleasing songster, and much sought after in the countries it frequents; has been thought by some to be the wild stock of the Canary bird, which, however, it is not. It is very common in many parts of the South of Europe, frequenting the lower slopes of mountainous districts, especially in Italy, Greece, Turkey, and along the borders of the Mediterranean; it abounds in Switzerland and in the Tyrol, but is rare and accidental farther to the northward. The nest is usually situate in mountain pine forests, and contains from three to five whitish eggs, speckled more or less with dull brick-red. This species breeds readily with the Canary.

The Chinese goldfinch, or siskin (*C. Sinensis*), is a species very common in the Celestial Empire, and in many of the eastern parts of Asia; not rare in some districts of the Himalaya. This bird is intermediate in form and habits between the true goldfinches and some of the smaller grosbeaks (*Coccothraustes*), of which the common green grosbeak (*C. chloris*), or greenfinch, as it is termed, of this country, may be cited as an example. There are several other true siskins inhabiting North and South America, the characters of some of which are not as yet very satisfactorily made out, which arises chiefly from their having hitherto been met with only in winter plumage. Two of these are winter visitants of the United States, namely,

The Pine siskin (*C. pinus*). "This little northern stranger," says Wilson, "visits us in the month of November, and seeks the seeds of the black alder on the borders of swamps, creeks, and rivulets. As the weather becomes more severe, and the seeds of the *Pinus Canadensis* are fully ripe, these birds collect in larger flocks, and take up their residence, almost exclusively among these trees. . . . . . Early in March they disappear, either to the north or to the pine woods that cover many lesser ranges of the Alleghany. While here, they are often so tame as to allow you to walk within a few yards of the spot where a whole flock of them are sitting. They flutter among the branches, frequently hanging by the cones, and uttering a note almost exactly like that of the" American "goldfinch. I have not a doubt but this bird appears in a richer dress in summer in those places where he breeds, as he has so very great a resemblance to the bird above mentioned, with whose changes we are well acquainted." Its winter plumage is very like that of the European aberdevine siskin, only the crown of the head is not black. The writer of this article once observed several pairs of these birds, and of American goldfinches, in the shop of a bird dealer in London. The other North American species is,

The Arkansan siskin (*C. psaltaria*). This was discovered by the naturalists who accompanied Major

Long's expedition; and Say, who wrote the zoological notes to the Journal, observes, "A very pretty little bird was frequently seen hopping about in the low trees or bushes, singing sweetly, somewhat in the manner of the American goldfinch. The tints and the distribution of the colours of its plumage resemble, in a considerable degree, those of the autumnal and less brilliant vesture of that well known species. It may, however, be distinguished, in addition to other differences, by the black tips of its tail-feathers, and the white wing spot." The Arkansan siskin inhabits the country near the base of the Rocky Mountains, south of the river Platte; and may probably be also found in Mexico. It is suspected that the Mexican siskin (*Fringilla Mexicana*) of Gmelin, and also the Black Mexican siskin (*F. Catotol*) of the same author, are referrible to the species in different states of its plumage.

Many of the smaller finches, but more especially the group to which all the little birds we have been just describing appertain, have long been celebrated for their docility, and, consequently, they are great favourites with bird-fanciers, by whom they are often doomed to undergo a severe, tedious, and cruel discipline. The feats they have been gradually trained to perform are almost incredible. Mr. Syme, in his "History of British Song-Birds," when speaking of the Sieur Roman, who some years ago exhibited a number of canaries, goldfinches, and linnets, wonderfully trained, relates, that "one appeared dead, and was held up by the tail or claw without exhibiting any signs of life; a second stood on its head with its claws in the air; a third imitated a Dutch milkmaid going to market, with pails on its shoulders; a fourth mimicked a Venetian girl looking out at a window; a fifth appeared as a soldier, and mounted guard as a sentinel; and the sixth acted as a cannoneer, with a cap on its head, a firelock on its shoulder, and a match in its claw, and discharged a small cannon. The same bird also acted as if it had been wounded. It was wheeled in a barrow, to convey it, as it were, to the hospital; after which it flew away before the company. The seventh turned a kind of wind-mill; and the last bird stood in the midst of some fire-works, which were discharged all around it, and this without exhibiting the least symptom of fear." These astonishing feats were repeatedly performed before hundreds of persons; and one is at a loss at which most to wonder, that irrational beings should be capable of being thus trained, or that beings who consider themselves rational should so patiently and cruelly waste their existence in drilling these unfortunate little creatures into submission.

Some naturalists have included in *Carduelis* the small finches which are commonly termed canary birds. Of these there are four or five original species, two of which have been multiplied in confinement into a very great number of varieties. We prefer, however, to arrange them as a separate sub-genus of *Fringilla*, under the general designation of *Canaria;* but they may, nevertheless, be introduced here, as they are physiologically very nearly allied to the *Carduelis.*

The general form of the canary is too well known to require a very particular description; it is longer, and not quite so compact as that of the goldfinch, and the bill is much shorter, and more bulky. They are somewhat intermediate between the goldfinches and certain of the linnets (*Linaria*), but have several peculiar characters of their own, and they appear to be more local in their distribution than either of these. We know very little of them in a wild state, as is the case with almost every animal which man has long kept in a domestic condition.

One species at least, which may be denominated the *C. communis*, is very abundant in Madeira, where it was observed by Dr. Heincken, who minutely describes it. The bill is about four lines in length, with the upper mandible dusky, the lower flesh-colour; legs brownish flesh-colour; the forehead, throat, line above and below the eyes, the breast, rump, and lesser wing-coverts, greenish yellow; the scapulars, and large wing-coverts, deeply shaded with the same; the back also similarly, but lightly shaded; abdomen rich golden yellow; remainder of the under parts whitish, marked about the flanks with large longitudinal brown spots; the back of the head, cheeks, back, larger wing-coverts, scapulars, and large tail-coverts, brown-ash, with a longitudinal brown spot down each feather; indistinct and faint about the head; large, dark, and defined on the other parts; the tertiaries, quill, and tail-feathers, brownish-black, with pale ash-coloured edges; the external margin of the first four or five quill-feathers white; of the rest, pale greenish yellow; length, five inches and a quarter; breadth, nine inches; weight, about half an ounce; tail forked. The colours and markings of the hen bird are more dingy and indistinct, and the rump is only greenish-yellow. The young males are very similar to the old female, but have the bill and legs darker; and the young females have no yellowish or greenish colouring.

"It builds," says Dr. Heineken, "in thick bushy high shrubs and trees, with roots, moss, feathers, hair, &c.; pairs in February; lays from four to six pale blue eggs, and hatches five times (not unfrequently six) in the season. It is very familiar, haunting and breeding in gardens about the city. It is a delightful songster, with, beyond doubt, much of the nightingale's and skylark's, but none of the wood-lark's song, although three or four skylarks, in confinement in Funchal, are the only examples of any of these birds in the island." These wild canaries, directly imported from the Canary Islands, may be frequently obtained at some of the London shops, but are sold at an enormously high price.

We know very little of the other species of this group; there may possibly be another sort in the Canary isles. Syme mentions one which he received from St. Michael's, which, he says, sung very like the linnet. There is also a very beautiful species in Brazil, entirely yellow, with an orange-coloured crown. This bird may sometimes be procured alive at the London shops; its chirp much resembles that of the domestic species, but its song appears to be very inferior.

"The Canary bird," according to Bechstein, "was brought into our climate as early as the sixteenth century. Its arrival in Europe is thus described:—A vessel, which, besides its merchandise, was bringing a number of these birds to Leghorn, was shipwrecked on the coast of Italy, opposite the island of Elba, where these little birds, having been set at liberty, took refuge. The climate being favourable, they increased, and would certainly have become naturalised, had not the wish to possess them occasioned their being caught in such numbers, that at last they were extirpated from their new country.

From this cause Italy was the first European country where the canary was reared. At first their education was difficult, as the proper manner of treating them was unknown; and what tended to render them scarce was, that only the male birds were brought over—no females."

CARDUUS (Linnæus). The thistle, an extensive genera of well-known annual and perennial weeds. Linnæan class and order, *Syngenesia Æqualis*, natural order, *Compositæ*. Generic character: scales of the anthodium prickly; receptacle bristly; pappus sitting and downy, falling off. Notwithstanding the hostile appearance and bad character of thistles in general, there are some few of them ornamental, growing to a considerable height, and bearing crimson-coloured flowers. Their use in the economy of nature is not very apparent. None of our domestic cattle, except the ass, relish them, but some of them are nibbled by both hares and rabbits while young and tender. Their seeds form a winter feast for many small birds, and they are the cause of the farmer ploughing much deeper to extirpate them than he would otherwise do, which, though oppressive to himself and his cattle for a time, turn ultimately to his advantage, in having a deeper tilth, and cleaner and heavier crops.

CAREX (Linnæus). A numerous genus of rigid herbaceous and grass-like perennials, mostly inhabiting waste sandy soils, bogs, or marshes. They differ from the common grasses in being monœcious, that is, in having their male and female flowers not altogether in the same calyx, but on different parts of the same plant. Sometimes, but rarely, the carex is diœcious, male flowers being on one plant and females on another. Hence they are not ranked with the true *Gramineæ*, but in the natural order *Cyperaceæ*.

CARINARIA (Lamarck). This singularly elegant mollusc has been considered by many authors a species of the genus *Argonauta*, from which it essentially differs, as the following description clearly points out. The shell is symmetrical, extremely thin, a little compressed, without a regular spire, but its summit slightly recurved backward; the aperture oval and very retired; the substance of the shell is semi-transparent, and of a glossy appearance, and may be at once distinguished from the *Argonauta*, by having a *single* keel, and the apex or spire *never entering the aperture*. It only partially protects the body of the animal, which is lengthened backwards from the nucleus into a true tail, furnished at its extremity with a vertical fin; the head is very distinct, with two long conical tentacula; it has two sessile eyes, the respiratory organs and the nucleus entirely enveloped by a mantle, with lobed edges. In De Blainville's system, this genus is placed in the second class *Paracephalophora*, fifth order *Nucleobranchiata*, first family *Nectopoda*. Three species are known, the *C. vitrea*, so called from its glass-like texture; the *C. fragilis*, from its extreme delicacy; and the *C. cymbium*, or boat-shaped carinaria, which is not larger than a grain of sand, and can only be seen by the aid of a magnifying power; one inhabiting the African seas, another the Mediterranean, and the third, considerably larger, is found in the Eastern ocean.

At one time this mollusc was incomparably rare, and large prices given for it, but one of its species has latterly been more frequently met with. Many specimens are now existing of the shell and its inhabitants, and one beautifully displayed in spirits may be seen in the splendid museum of the Royal College of Surgeons.

CARNASSIERS. The third order into which Cuvier divides the mammalia, or those animals which suckle their young. Though etymologically, this word has very nearly, if not altogether, the same meaning as the old name *carnivora;* and thus it appears as if the same word were applied in two different senses. Yet as the French term is not identical, either in spelling or in sound, with the Latin, and as a better arrangement is obtained by using the one word for a large class, and the other for a smaller division or sub-class of the same, the apparent anomaly of the words is more than compensated by the advantage of the arrangement.

Under the general name carnassiers, Cuvier includes all mammalia, of which the principal food is animal matter; though it is impossible to draw the line with perfect precision, in as much as there are few animals of any class which do not occasionally eat animal matter; and there is perhaps no animal of any class, but which might be made to exist, at least in part, on vegetable matter. But as Cuvier's classification is structural, and allows a considerable degree of latitude as to the use of the structure, it is exceedingly convenient, and at the same time as precise as the nature of the subject will probably admit. The following is a brief outline of his general characters of the class:—

The numerous animals which it comprehends, all have the extremities divided into fingers or toes furnished with nails; and they all have three kinds of teeth,—namely, cutting teeth in the front of their jaws, canines at the middle part, and cheek teeth or grinders behind these.

These animals, however, have no grinding motion like the ruminantia, the greater part of the quadrumana and all animals which live much upon vegetable food. Their jaws have a hinge motion only, that is they close one upon the other, and close very firmly; but the articulation of the lower jaw is so tight that it cannot be moved from side to side. There are considerable varieties in them, arising principally from differences in the cheek teeth. These cheek teeth are of three different forms; sometimes they are nearly flat on their summits, with only low blunt tubercles; sometimes again they have the tubercles more elevated and sharper at the points; and there are still others which have trenchant tubercles, by which means they are adapted for cutting and tearing at the same time. The first of these three forms is adapted for bruising or dividing vegetable matter; and one may observe, that when a dog gets a piece of hard bread, he takes it as far back between his jaws as possible, in order to reduce it to a state fit to be swallowed. The second kind are more exclusively fitted for insect food, which requires not to be chewed or torn, but merely to have its crust, or other tough or hard covering broken, so that the fluids of the stomach may act upon that part of it which is digestable. Those of the third form are adapted for tearing flesh; and in proportion as these predominate, the owner is found to feed more upon the flesh of warm blooded animals, and less upon vegetable matter of any kind.

Their brain, though it is considerably furrowed or convoluted, does not appear to be so well developed as in man, or in the quadrumana; there is no division of bone between the temporal foss and the orbit of the eye; their skull is narrow, and the zygomatic arch is wide and elevated, so as to give room for the powerful muscles which give motion to the lower jaw, the mouth being in most of them the grand instrument in seizing the food, and in all of them the one by which it is more immediately prepared for the stomach. Their food is of a much more nutritious character than that of the vegetable feeders; and their stomachs are in consequence simpler, and their intestinal canals much shorter.

The sense of smelling is described by Cuvier as being the most acute which these animals possess; and some of them have this sense in very wonderful perfection, of which there are remarkable instances in blood-hounds, and other dogs which follow on the scent. Many of them have also very acute sight; and the nocturnal preyers especially are very quick of hearing. These animals, though, as their food is of much more nutritious quality than that of those which feed upon vegetable matter, they require to take less of it, or at all events to take it less frequently, yet requires more address and energy in the capture. The food is endowed with the power of locomotion as well as the feeder, and the prey is endowed with arts and means of escape, as well as the preyer is with arts of capturing.

It must be borne in mind that, in the system of nature, the war which those predatory animals wage on the other races which are their prey, is not a war of extermination, but a war of preservation; and that in a state of nature, the ravages of the lion and the wolf, are as much a part of the system as the browsing of the antelope and the sheep. Hence, in the different powers which these predatory animals possess, in the modes and times at which they use them, and in the increase and diminution of the animals themselves, so that they may be always in the most exact proportion to the necessity which there is for them, we have some of the most beautiful instances of design, some of the most striking proofs that creation and creation's laws have emanated from an all-wise and almighty Creator, which are to be found in any part of the system. No doubt the system is equally perfect in all its parts; but, of course, the more energy is displayed in the working of any part of it, the more forcibly does it draw our attention, and the better is it calculated for enabling those who are just entering upon the study to turn it to the proper account. It would be very delightful here to enter into some details of the structure and the arts of predatory animals, and we are constrained to desist from doing so with no small reluctance and regret; but it is of far too great magnitude for finding a place in a miscellaneous work of moderate dimensions, in which notices of all the kingdoms of nature have to be included. In noticing the subdivisions of the class, in their order in the alphabet, we shall, as occasion offers, throw in a few hints; and we shall restrict the remainder of this article to a list of the families or tribes, into which Cuvier divides this extensive and very interesting order.

Family first, CHEIROPTERA (winged hands). These may be considered as the link in which may be traced, the connexion between the four-handed climbing animals, and the following families of this order. They have still many of the characters of the quadrumana—the pectoral mammæ, the perfect clavicles, the consequent action of the anterior extremities more across the axis of the body than in the direction of it; and thus they are not adapted for progressive motion on the ground; but make their way through the air by means of membranes of flight, put in motion by their anterior extremities. (See CHEIROPTERA and the references from that article.)

Family second, INSECTIVORA (feeders upon small animals, which are seldom of the warm-blooded classes). They are animals of the earth much in the same way that the first family are animals of the air. They live much under ground, and in cold countries they are dormant in the winter. Their bodies are in general flat, and their legs short: the anterior ones being capable of lateral motions from the possession of clavicles. They are all plantigrade, or walk on the soles of the feet. Their cheek teeth all have sharp conical tubercles; and in their incisive teeth some of them bear a resemblance to the rodentia, or gnawing animals. See INSECTIVORA.

Family third, CARNIVORA (animals which are, more or less in the habit of killing other warm-blooded animals, and eating their flesh). There are two divisions of them,—one plantigrade, or walking on the soles of the feet, and another digitigrade, or walking on the toes. They are the animals to which the popular name of "beasts of prey," is given. See CARNIVORA.

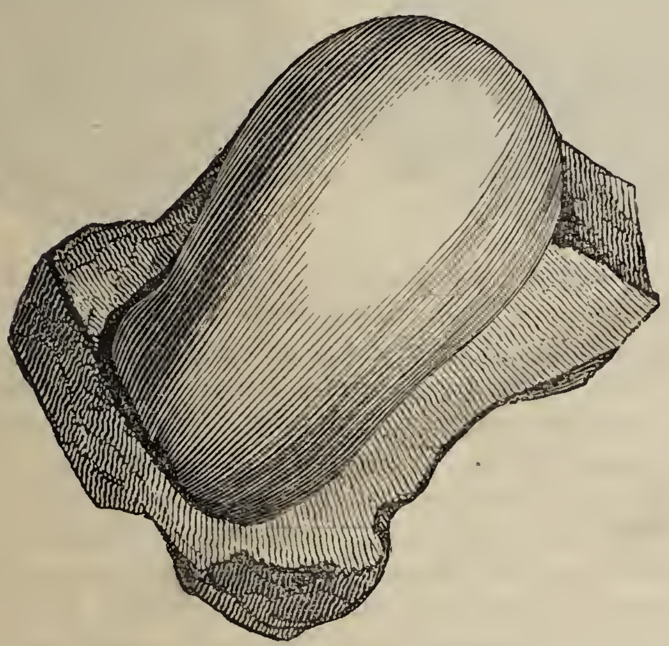
Family fourth, AMPHIBIA (animals which live both in the air, and under water). These animals do not perform the same functions of life in the air and in the water, so as to be equally at home in the one of these, and excluded altogether from the other. There is no known animal that can do this; for though some water animals, both reptiles and fishes are furnished with apparatus with which they can live a short time on land; and there are many land animals which can live a short time in water; yet the water animal cannot bear dry air to come in contact with its gills, neither can the land animal bear to take water into its lungs, however that water may be impregnated with air. The amphibia are all truly land animals in their breathing, and they merely seek their food, and spend the greater part of their time in the water. See AMPHIBIA.

Cuvier adds a fifth family, MARSUPIALIA, or animals of which the female is furnished with an abdominal pouch, into which the young are received, after they have been brought forward a longer or shorter time in an internal uterus. In strict propriety, however, these animals cannot be brought into any of the orders of those mammalia which are without the marsupium. Some of them are carnivorous, others feed on vegetable matter; some browse or nip the green herbage, in a manner not very different from that of ruminating animals, though they are not ruminants; and there are others which, in many of their habits at least, resemble the rodentia, though none of them have the proper rodent or gnawing teeth. Independently of the possession of the marsupium (of which there are many variations as to the degree of its development, and of that of the young when received into it, there are several general characters, which run through the whole of those animals, and seem to require the formation of them into a distinct sub-class of mammalia. See MARSUPIALIA.

CARNELIAN. A mineral forming a sub-species of calcedony. It is the *Sarda* of Pliny, and does not appear to have possessed its present name till comparatively modern times. The principal colour of carnelian is blood-red, of all degrees of intensity;

the dark tints sometimes incline to reddish brown but the paler one pass into flesh-red and reddish white, and also into a colour intermediate between ochre and wax-yellow. It also occurs sometimes milk-white and olive-green. It generally has but one colour; frequently, however, it exhibits concentrically-striped delineations, somewhat resembling fortifications, or red dendritic delineations.

It occasionally occurs in rolled pieces, which appear to have been original balls; sometimes in thin layers, and but rarely in kidney-shaped formations. The surface of the rolled pieces is rough and reddish brown. It is frequently found in fibrous concretions, which are straight, scopiform, closely aggregated, and collected into long and wedge-shaped prismatic and lamellar masses. A very perfect example of the kidney-shaped form of the carnelian is given in the subjoined wood-cut.



The specimen from whence the above figure was taken is of a deep blood-red colour, and the external surface is semi-transparent.

Carnelian is employed to a considerable extent by the jewellers. It is cut into seal-stones, ring-stones, bracelets, necklaces, brooches, and crosses; and figures are often engraved upon it. Artists distinguish three principal kinds of carnelian: the one, named *common carnelian*, varies in colour from white through yellow to red; the second, *sardoine*, displays on its surface an agreeable and rich reddish brown colour, but appears of a deep blood-red colour when held between the eye and the light; the third, named *sardonyx*, is composed of layers of white and red carnelian. In the most esteemed carnelians of the east, the colours are of a uniform tint throughout the mass, without any undulations, and are free from that muddiness to which the European varieties of this stone are so liable. The most highly-prized varieties are the white and red striped, or *sardonyx*, and the blood-red; the next in estimation are the pale red; and the least valuable are the yellow, white, and brown. As it is a softer stone than common calcedony, it is more easily cut, and splinters much less when cutting and polishing; and hence, independent of colour, it has always been preferred by artists to the common calcedony. The finest varieties of carnelian are named by French artists those of the *old rock* (vieille roche), because they are no longer to be found so perfect in colour and transparency. The finest pieces of common carnelian are brought from Arabia, and from Surat in India.

Formerly, carnelians used to be imported from Japan into Holland, and from thence carried to Oberstein on the Rhine, in order to be exchanged for the agates of that country, which were exported to China.

The carnelian was much esteemed by the ancients. Many fine antique engraved carnelians are preserved in collections, and these have been described by Count Caylus, De Geer, and others. The *sardonyx* was cut into cameos, and afforded by far the most beautiful articles of this kind. The finest antique cameo at present known is in the French Imperial Museum at Paris: it is cut in a *sardonyx*, is of an oval shape, and is eleven inches by nine in breadth. It represents the Apotheosis of Augustus.

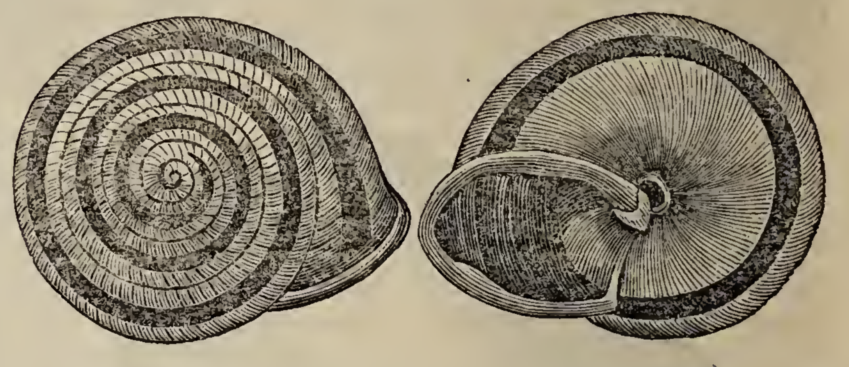
CARNIVORA. The third family of Cuvier's great order of *Carnassiers;* these animals have the teeth peculiarly adapted for wounding and killing, and for tearing, cutting, and bruising flesh. For the first of those purposes, they are provided with four large and long canine teeth, two in each jaw; between those there are in each jaw six incisors in front, the second of which in the lower jaw, is always more deeply seated than the others. Their cheek teeth never have their summits formed into small conical points or tubercles, like those of the animals which feed upon insects. A greater or smaller number of them have always trenchant or cutting edges, or ragged outlines, and are fitted for dividing tough substances. These, and not the canines or wounding teeth, are the proper carnivorous ones, by which the characters of the animals are best ascertained; for there are many vegetable feeding animals which have large and strong canine teeth, with which they can inflict more terrible wounds than many of the carnivora. But these last inflict those wounds only in self-defence, in the reality or the anticipation of danger; and their wounding is indiscriminate as compared with that practised by carnivorous animals. The instinct of those always guides them to select some vital part, or at all events some part which is adapted for causing the death of the prey in the most summary manner. Thus, the aim of the whole genus *canis* is at the throat of their prey; the weasel tribe divide the blood-vessels in the side of the neck, even of animals much larger than themselves, with as much accuracy and neatness as if they had carefully studied the anatomical structure of their prey; and though the larger cats throw themselves on the backs of those animals which they are unable to beat to the ground by the force of their spring, they keep tearing the muscles in those parts, on which this operation is calculated to bring the animal easiest to the ground, where they speedily despatch it by directing their weapons against the vital parts.

If the animals have several of the back teeth with the crowns nearly flat, or only with low blunt tubercles, they can in part prepare the more succulent kinds of vegetable matter for their stomachs; but those which have have few teeth of this kind, prepare such substances with much difficulty and labour. As even those which are best adapted for living upon vegetable food, and live most upon it, have no grinding motion of the jaws, they divide vegetable substances with much more difficulty than those races which have the grinding motion, and the short teeth true molars; and, as the number of comparatively flattened teeth diminishes, the difficulty increases. One case of this gradation may be seen in the domestic dog and cat. The dog is the less carnivorous animal of the two; and as he uses the mouth only in the capture and killing of his prey, he has much more powerful and varied action of the neck. He can divide a portion of tough vegetable matter, as for instance a crust of bread, only by repeated vertical bites; but if he has much labour with the substance, and his hunger is strong enough to induce him to eat it, he may be seen shifting his head, now higher at the one side, then higher at the other, alternately, in order to bring the whole under his teeth; and he also flings the head upwards or downwards, and gives a snap, so that the lower jaw may bite with a momentum, while the substance to be divided rests against the teeth of the upper jaw. The cat has a good deal more trouble in this imperfect mastication, as she cannot snap, and derive advantage from the momentum of the jaw as the dog does; thus with her, the division of hard vegetable food, so as to prepare it for the stomach is no easy matter. All the actions of those animals, with reference to their structures, are eminently deserving of the most careful study, as a highly interesting portion of nature's mechanics, and as eminently useful to man in understanding how to construct mechanical apparatus upon principles at once the most economical and the most efficient. But though we can and do recommend the study, our space will not admit the introduction of the details; we shall, therefore, close with a mere notice of the two leading divisions of this family, or rather sub-order of animals, those divisions are two:

First, Plantigrada; animals which walk on the flat of the foot, or apply the whole length of it to the ground in walking, and thus have the elbow and knee joints, the first from the ground on their march. Those animals, though they have a firmer base, especially when they stand upright, or rest the whole weight of their bodies upon the tarsi of their hind feet, are, in general, much slower in their motions than those which plant only the toes; and if they have much motion they require the two joints of which they have the command in each leg, clear of the ground, to be more free in their motions than they are in those races which have the advantage of an additional joint. The play which is thus required in the femoral bones and the scapulars, gives the animals a loose appearance, as if they were badly put together. They in many particulars resemble the insectivorous division; and many of them are, in part at least, insectivorous; and like those, some of them at least, are dormant during winter in cold climates. See Plantigrada.

Second, Digitigrada; or animals which walk upon the toes, or upon the toes and metatarsal bones; but have the tarsi clear of the surface. From having the ankle joint at their command in walking, in addition to those joints which are used by the former division, their motions are much more lively. This briskness is not confined to the mere motions of the legs, but extends to the spine, which is more elastic in them than in the plantigrades; their shoulders have also a greater appearance of firmness; and they remain active during winter. See Digitigrada.

CAROCOLLA (Lamarck). This genus of molluscs was constituted by Lamarck, from the Linnæan helices, to which, however, it is so nearly allied, that it has been restored by De Blainville to the *C. helix*, of which, in his system, it forms the first division. It is principally distinguished from the helix by the circumference of the shell being constantly carinated or sub-carinated at every stage of its growth; its form is discoid, sub-umbilicated; the lip thickened, and the shell more convex on the lower side than the upper one; the right lip or margin is consequently sub-angular, and frequently toothed within. The accompanying cut of the *Carocolla fasciata* fully points out these distinctions. They are all of them terrestrial shells, and the animal resembles that of the helix so nearly, as to need no separate description. Lamarck describes eighteen species; but a more considerable number is known. They inhabit all parts of the globe, as well in the driest situations, as on the banks of rivers and damp places. The fossil species are by no means so numerous as the recent.



This mollusc is placed by De Blainville in the second class *Paracephalophora;* first order *Pulmobranchiata;* third family *Limacinea.* Many attempts have been made by modern naturalists to subdivide the immense numbers of helices into well-defined groups, in order to facilitate a knowledge of the species: De Montfort commenced the task by forming about ten genera; Oken proposed others; but the Baron de Ferussac has published a magnificent work on terrestrial and fluviatile molluscs, in which a system of classification is pursued, exhibiting deep research and sound reasoning. Unfortunately, the expense attending such works on natural history, closes them to the generality of readers, and renders them more objects of luxury than utility; to obviate which is the study of all enlightened men in the present day, and the great end of the editor of this work.

CARYCHIUM (Müller). Phitia (Gray). A genus of molluscs, forming one of the divisions of De Blainville's and Lamarck's genus *Auricula.* It will be more amply described under the article Phitia.

CARYOPHYLLEÆ. The chickweed family. A natural order of dicotyledonous plants containing nearly thirty genera, and upwards of eight hundred and fifty species. It is closely allied to *Lineæ* and *Frankeniaceæ* as well as to *Elatineæ.*

The essential characters of the order are:—sepals four or five, continuous with the peduncle, at one time free, at another coalescing into a four or five-toothed tube; petals also four or five in number, hypogynous, but occasionally wanting; stamens usually twice the number of the petals, slightly united at their base; anthers two-celled, opening longitudinally; ovary inserted on the top of a pedicel or torus; styles varying from two to five; capsule one to five-celled, and from two to five-valved; placentæ central, in the two to five-celled capsules adhering to the edge of the dissepiments; seeds indefinite; albumen mealy; embryo curved round the albumen; radicle directed to the hilum.

The plants of this order are generally herbaceous, rarely assuming a shrubby character. Their stems are knotty, they are furnished with terminal flowers and opposite entire leaves. They inhabit the temperate and colder regions of the globe, and are found on mountains as well as in hedges and waste places. The few species which exist in tropical countries grow at a great elevation, generally close to the limit of perpetual snow. They are very abundant in Europe and Siberia. According to Humboldt the caryophyllea constitute a seventeenth part of the flowering plants of Lapland, a twenty-second part of those of France, a twenty-seventh of those of Germany, and only a seventy-second part of those of North America.

By De Candolle, the order is divided into two sections, *Sileneæ*, in which the sepals are united into a tube, the petals have elongated claws, and *Alsineæ*, in which the sepals are distinct or only coherent at the base, and the petals are not furnished with claws. The former includes the genera *Silene*, *Dianthus*, *Saponaria*, *Lychnis*, *Agrostemma*, *&c.*; while the latter comprehends the genera *Alsine*, *Stellaria*, *Sagina*, *Spergula*, *Arenaria*, *Cerastium*, *&c.*

The plants of the order are not remarkable for any active properties, being generally insipid. From some of them a volatile oil may be obtained, and a few have been used both medicinally and dietetically. In general they are mere weeds, and are not submitted to cultivation. Most of the species of *Dianthus* and *Lychnis*, however, possess handsome fragrant flowers, and are prized in the garden. They are propagated by cuttings, divisions, and seeds.

The genus *Silene* contains two hundred and seventeen species, ten of which are natives of Britain. *Silene arenaria*, common or Lobel's Catchfly, is a pretty border annual familiar to every one. It grows freely, and has been naturalised in some parts of England. *Silene acaulis*, moss campion, with its beautiful purple flowers, is a great ornament of our alpine districts. A decoction of the root of *Silene Virginicæ* is used in North America as a remedy for worms. The boiled leaves of *Silene inflata*, a very common plant in Britain, taste like peas, and proved of great use in a famine at Minorca in 1685, when the harvest was destroyed by locusts. The leaves are used as an external application in erysipelas.

Dianthus, or pink, is the most showy genus of the order. The elegant little maiden pink, so frequently found on our hills, is a species of this genus. Under it also is included the common Sweet-William, so generally cultivated as a garden flower. *Dianthus Caryophyllus*, clove pink, or clove gilly-flower, is the species whence the name of the order is derived. This plant is found native in Italy, and grows apparently in a wild state on the walls of some old castles in England. It is interesting as giving origin to those beautiful varieties of *Carnation*, so highly valued by the florist. The varieties of carnation amounted to nearly four hundred named sorts in the beginning of the eighteenth century, and since that time they have greatly increased. They have been arranged in three classes, *flakes*, *bizarres*, and *picotées*. Flakes have only two colours, and their stripes are large, going quite through the petals. Bizarres are variegated in irregular spots and stripes, and their colours are not less than three. In the picotées the colours are arranged like a fringe round each petal; they have a white ground, which is spotted with scarlet, purple, yellow, and other colours. New varieties are raised from seed, and are chiefly procured from Germany and Italy. Established varieties are propagated by cuttings or layers. Carnations thrive best in a rich but somewhat sandy loam, and they require to be protected by a frame during winter, and to be covered with an awning when in flower. The flowers of the clove-pink have a pleasant aromatic smell, and a bitterish, somewhat astringent, taste. They are used to give a pleasant flavour and a fine colour to a medicinal syrup.

The leaves of *Saponaria officinalis*, common soapwort, are employed to take out spots of grease. The plant derives its name from the property of forming a saponaceous compound with water, a property possessed by several other plants of the order, more especially *Lychnis dioica* and *Chalcedonica*. The root of the soapwort has a bitterish taste, and has been used in medicine for the cure of gout, rheumatism, jaundice, and other complaints.

Stellaria media, common chickweed, or stitchwort, is a well known weed, which has been used as a pot-herb, instead of spinach, and the seeds of which are eaten by birds. The flowers are upright, and open from nine in the morning till noon, unless it rain. After rain they droop, and continue to do so for several days. This plant illustrates the sleep of vegetables, the leaves approaching in pairs every night and inclosing the rudiments of the new shoots. In this way nature also makes provision for the protection of the young shoots.

Arenaria peploides, sea-side sandwort, grows abundantly on the shores of Britain. It is used in Iceland as an article of food, and forms an excellent pickle. The *Arenaria marina* is also used as a pickle in place of samphire, to which it bears some resemblance.

The berries of *Cucubalus baccifer*, berry-bearing campion, are said to be as poisonous as those of the deadlynight shade.

Spergula arvensis, common spurrey, called *Yarr* in Scotland, and *Pick-purse* in Norfolk, is considered as excellent pasture. It is said to enrich the milk of cows, and to form excellent butter.

CASNONIA (Latreille). An elegant genus of insects belonging to the order *Coleoptera*, family *Carabidæ*, and sub-family *Brachinidæ*, and distinguished by its long and slender neck-like thorax, brown head narrowed behind, antennæ much shorter than the body, tarsi with the penultimate joint bilobed. These insects are of small size, not exceeding one-third of an inch in length, they are inhabitants of the warmer climates of the globe, where they reside, according to M. Lacordaire, who observed their habits in South America, in moist places on the margins of brooks. They run very quickly, soon take flight, and when on the wing, are easily mistaken for small tiger beetles (*Cicindela*). They are generally prettily variegated. We have adopted the generic name given above, being employed by most authors, although we agree with Messrs. Audouin and Brullé in considering that the long previously proposed name of *Colliuris* of De Geer (which has been improperly used for a genus of tiger beetles) ought to be restored to this group.

CASSICUS (so called because, in the most typical species, the crest bears some resemblance to the feathers worn by a *cazique* or Indian chief). A genus or rather family of birds, placed by Baron Cuvier in the conirostral family of his order *Passeres*; but which, in a natural arrangement, would require a different place in the system. They are, in fact, omnivorous birds, bearing more resemblance to the starling, at least in their manners, than to almost any other British birds. They have also been named and described as *Orioles*, but they differ much more from the orioles, properly so called, than they do from the starlings, or even from the larks. The orioles have a notch in the bill, and thus come under the dentirostral division. But in truth, the presence or the absence of this same notch gives us very little information as to the feeding or the other habits of the birds; for some of those which have not the notch, are as insectivorous as those which have it; and some which have it feed as much on vegetable substances as some which have not. Thus there are, in this part of the system, difficulties which we do not appear to have, at present, any means of overcoming; and thus, as the arrangement of Cuvier is, to a very considerable extent, structural, and as it is simple, and serves as an index to the species, perhaps the wiser plan is not to attempt breaking in upon it by minor emendations.

These birds have a large bill, of a perfectly conical shape, very thick at the base, and remarkable pointed at the tip. Their nostrils are small and round, placed laterally in the bill near its base; and the tomia or cutting edges of the mandibles, form a broken or angular line as in the bills of starlings. They are all natives of America, inhabitants of the woods, or rather of their margins. In their manners they very much resemble starlings, assembling in flocks and building their nests near to each other. Those nests are often suspended from the extremities of branches of trees, and constructed in a laborious and even elegant manner. They live indiscriminately upon insects and upon the seeds of plants. In search of the latter, they commit very serious depredations on the cultivated fields, in return for which they make less amends than most races of similar habits, as the flesh is of no value for food, being tough and bitter, like that of the crow family; and having at the same time a disagreeable musty flavour.

There are several divisions or sub-genera of them, among which there are considerable varieties in colour, size, and other external appearances; but their habits and more essential characters are all very much alike. These divisions are, *Cassicus*, *Icterus*, *Xanthornus*, *Oxyrhinchus*, and *Dacnis*; and of most of these there are numerous species.

Cassicus. The distinguishing character of this division is the upper mandible of the bill extended upward and forward, so as to occasion a considerable notch or blank in the plumage of that part. The members of this division are also larger than those of the others. The following are a few of the species:—

Cassicus bifasciatus. This species, which is the crested oriole of British ornithologists, has two reddish bands on its black bill, from which it gets the name of bifasciatus, or two-banded. The general colour is black, but the long linear feathers of the crest, the lower part of the back, the rump and the vent feathers are chestnut; and the two lateral feathers of the tail are yellow. The colours of the female are not so bright as those of the male. This is considerably the largest of the tribe, though it varies considerably in size in different districts. Its length is from eighteen to twenty inches, and the extent of its wings from twenty-seven to thirty. But though a large bird it is of no value, as its flesh smells so rankly of musk as to be very offensive. It is very generally distributed over the lower and warm parts of South America, being found in Guiana, in Brazil, and Paraguay. When this bird utters its cry, which is very varied and singular, bearing some resemblance to the word "yapou," which is its name in some parts of America; it is usually perched on an inclining branch, with its body stretched out, its head lowered, its wings half extended, and its whole frame in a state of apparent excitement. In most places, these birds are met with singly or in pairs, but in some instances a hundred or more assemble in a flock, flying and working in concert, keeping time with each other with each stroke of their wings, and occasionally all halting at the same time on the tops of trees to rest themselves. In the time of nest-building and breeding, they follow a law which is very general, and which might be expected to be very general in those places of tropical climates, where there is little difference of seasons, and food can be obtained all the year round. There is no particular breeding season, broods being met with at all times of the year. They always breed in trees, and construct hanging nests of rather a curious description. They do not build in the thick forests; for their food is obtained not from the tall

C. bifasciatus.

trees, but from the lower vegetation or the ground, though they readily eat the fruit of several of the passion-flower tribe, and other climbing plants. The trees which they select are those in which enemies to their young are least likely to be concealed, or to which they appear to be least accessible. Trees about thirty or forty feet in height, of a smooth stem, before they put out any lateral branches, and of which the lateral branches are long and apart from each other at the extremities, are the favourites of the birds. Appended to the branches of such a tree, it is by no means uncommon to meet with from half a dozen to a dozen of their nests dangling freely in the air. The nest is about a yard in length, small at the top, but increasing in size to about ten inches in diameter at the bottom, where it terminates hemispherically. Such a fabric requires no small labour. It is the joint manufacture of the male and female, who make the principal part of it of the fibres of a species of aloe, which are very tough and firm; and with these they intermix small rushes and vegetable fibres, until the structure is very firm, and not un-handsome. The entrance to it is lateral, but near the top; and the lower part is bedded with the thickest rushes they can procure. The more delicate parts of the fabric, both in the nest of this species and of some of the others, is formed of the fibres of a parasitical epidendron, *Tillandsia usneoides*, popularly called "old man's beard." These fibres are very tough and flexible, and similar in appearance to the long hairs of a horse's tail. The extreme fineness of the point of the bill, and the firmness of the substance of the mandibles, enable the birds to weave these fibres more compactly together than could be easily done by a basket-maker. This singular nest is very firmly attached to the branch from which it is suspended; and notwithstanding the extent to which it is rocked when the wind blows, its depth is such that neither the eggs or young sustain any injury. The eggs are three in number, and the mother feeds the young carefully with worms and larvæ. It is probable that the same pair may have two or three broods in the same year. These birds, and indeed all the family, agree with omnivorous tribes generally in being very easily tamed, in being very general and hearty feeders in their captivity, and in being easily taught to imitate the sounds of other animals, and to articulate words.

Cassicus hemorrhöus. This is a smaller species than the former, but it is much more handsome; and though its colours are far from being so gay as those of many of the feathered inhabitants of tropical countries, it is still a very handsome bird. Its general colour, like that of the former, is black; but instead of the black fading into chestnut brown, it is in many places glossed with green reflections; and the lower part of the back, the rump, and the vent, are crimson. This species is (as indeed the whole are, though the contrary has been stated with regard to some of them) a native of the American continent only, and is most abundant in Guiana. Its nest is constructed in a manner similar to that of the former species; indeed they all build pendulous nests; but it is not so long, and is constructed with a curved entrance, it is usually on a branch which hangs over the water. This nest is only about half the length of the former one, but the internal cavity, in which the eggs and young are lodged, is nearly of the same dimension.

Cassicus icteronotus. This species has been called the Persian oriole; but the name is improperly applied, as this, like the rest of the family, is an American bird; and we may add, that there are no true orioles in America, all the birds on that continent which have been so named belonging to one or another of the sub-genera of cassicus. The present species is black, with the lower part of the back, a spot on the wing coverts, and the base of the tail feathers, yellow. From these colours, it has sometimes been called the black and yellow oriole; and it is the *grand troupiate* of D'Azzara, though it does not belong to the troupiates of Cuvier, which form the sub-genus *Icterus.* The male is about the size of a blackbird; the female is a little larger, but both the black and the yellow are duller.

This is a very social or gregarious species. Numbers of them assemble in the same places, after the manner of rooks in this country; and indeed more closely, for there are sometimes as many as three hundred, or four hundred nests, in the same tree. The nest is about the same size and shape as that of the second species; but if possible more elaborately formed. The eggs are dull white, marked with small dots of a pale brown colour; and there are at least three broods in the year. These birds resemble rooks in another habit besides their social disposition, they are exceedingly clamorous, but the sounds which they utter are not so monotonous as those of the rook. They have a sort of whistle, and also a warble, which is not unpleasant; and in addition to these they are apt to imitate every sound which they hear, such as the notes of other birds, the barking of dogs, and the laughing of human beings. Thus, in the places which they inhabit, they keep the margins of the forests quite alive with their noise. They are very easily tamed; and, when well treated, they are very amusing, as they can be taught to articulate words, to whistle tunes, and to imitate a great number of sounds.

Besides these, there are many other species of this genus; and perhaps there are many more in the forests which have not been noticed. Among the known ones we may mention *C. viridis*, with the bill orange, the crest, of which the feathers are very long, olive-green, and the wing-coverts with brown tips; *C. nigerrimus*, with the bill and body wholly black; and *C. ater*, black, with metallic reflections, and the feathers of the nape produced into a sort of ruff. The first and second of these species have been described as inhabiting Brazil, and the third Paraguay; but it is probable that they are all common to various parts of South America.

Icterus. The chief distinction between this sub-genus and the former, consists in the form of the bill, the portion of which that extends on the forehead being smaller, and the culmen of the upper mandible arched. There are a great many species, too many indeed, and differing too little in their manners from those of the preceding sub-genus, for it being necessary to give any particular account of them. They are all natives either of the warmer parts of the American continent, or of the West India islands. The names of the best known ones are as follow:—

I. varius: black, with the sides of the breast, the under part of the body, the rump and the margins of the wings, chestnut. All the colours very glossy, and varying in tint as the light falls upon them. *I. chrysopterus:* lesser coverts of the wings yellow, the tail wedge-shaped and black; the bill straight, slender, very sharp at the tip. This species is found in Paraguay, and inhabits more deeply in the woods than some of the others. *I. capensis:* is an inhabitant of the warmer parts of North America, and not of Southern Africa, as the trivial name would lead us to suppose. This is a small species, not exceeding seven inches in length. *I. flavigaster:* about eight inches in length, black, with the lesser coverts, the middle of the belly, and the vent feathers yellow. *I. chrysocephalus:* a native of Brazil. The general colour black; and the forehead, crown, sides of the hind-head, feathers on tibiæ, and lesser coverts, yellow; the bill rather long, slender, pointed, and considerably arched. *I. versicolor:* black, with bronze-coloured reflections; the outer feathers of the tail capable of being raised higher than the others. A native of the West India islands.

Xanthronus. This is perhaps the most numerous section of the whole. Structurally, the birds of which it is composed differ from the former ones only in having the bill entirely straight. The manners of some of these are, however, much better known, if not more interesting. We shall give short notices of one or two of the best known species, some of which are migrants and great depredators.

X. Baltimore (Baltimore Oriole). Upper part blackish, with a tawny band across the wings; under part tawny; greater coverts black, with white tips; first quills dull white, edged with brighter; tail feathers orange above and white on the under side, the two middle ones black, and the bill lead-coloured. The female is different: the head, neck, and back variegated with olive green and brown; coverts and quills margined with white, the tail greenish grey. The young resemble the female, but are paler in the colours.

These birds are migrant within North America, ranging as far northward as Canada in the summer, but moving to the south in the winter, but not so far as the shores of the Mexican Gulf. They are very elaborate nest-builders. The nest is finely interwoven of vegetable fibres, and perhaps closer than that of the first sub-genus; but it is not nearly so long, nor hung in quite so pendulous a manner. It is in the shape of a pear, not completely roofed at the top, and with a hole in the side. Vegetable fibres form the principal part of the structure, but hair and wool are also made use of. The eggs are mottled with reddish spots. The birds have a very peculiar way of jerking their wings and tails, and showing their different colours as they flit from branch to branch of the trees.

X. icterus (large Banana bird). General colour deep tawny yellow, with the head, throat, wings, and tail black, and two white lines across the wings. Length between nine and ten inches. This is a very handsomely formed bird; and though the colours are not gaudy they are rich and beautiful. It is a very active bird and destroys a great number of insects. It is also said to kill and eat smaller birds, but this part of its history is not very well established, and it is contrary to the general habits of the family.

This species is found both in North and South America, and it is abundant in many of the West India islands, especially in Jamaica but in North America it keeps to the warm grounds, and also to the more southerly parts of the country. It is a gregarious bird, and exceedingly active; but during certain seasons it is very apt to commit depredations in the fields of bananas, on which account it is called the banana bird. The nest is constructed at the end of a branch, and is of a cylindrical form. The bird is very easily tamed, much attached, fond of being caressed, and not without its domestic use in those low and humid parts of the country where the houses are much infested with insects, as it captures these very expertly, and in great numbers.

X. phœniceus (the scarlet-feathered Indian bird). This species, which is equally conspicuous on account of its numbers and the colours of its plumage, is found in the whole range of North America, from Mexico to Canada, and probably, at certain seasons, to the shores of Hudson's Bay, where insects are exceedingly abundant during the summer months. The vast production of insect life in those northern parts of America, which renders the swamps and uncleared parts of the forest so very annoying to Europeans, is a very important part in the natural history of the insectivorous and omnivorous birds of that part of the world. The great difference in temperature, and consequently of productiveness, between the summer and the winter in Canada, and the regions to the north and west, between the sterile rocks of Labrador and the Stony Mountains, renders the summer season one of great activity for every species of life, both animal and vegetable. The summer temperature is as high as that of the West Indies, and as the day is longer in proportion to the night than in these islands, the growth is correspondingly vigorous. The winter, too, does not nip and wither the vegetation, as in many other cold countries, as the snow falls early, and forms a complete mantle to the ground, which remains till the warm weather again sets in; and as much of the ground is flat, and tangled with bushes, the water produced by the melting snow soaks into the soil, and affords nourishment to the plants during the whole summer.

The same circumstances are peculiarly favourable to the breeding of all those insects which deposit their eggs in the water—gnats, musquitoes, and all the other pests which are equally annoying in the damp forests of polar and of tropical countries, with only this difference, that they are perpetual pests in the latter, and summer ones only in the former. The width of the uninhabited parts of these countries, and their remarkable productiveness, occasion a migration of birds quite unknown in any other part of the world; and many of them, and the species now under consideration, migrate in such numbers, especially on their return southward, that, if the facts were not well ascertained, they would not be credited.

This bird is about the size of a common starling, of a black colour, but with a patch of bright crimson margined with yellow on each shoulder. The female is brownish, with pale margins to the feathers, and the red is not nearly so distinct. The male is subject to considerable changes of colour, being sometimes black and white, so that they have sometimes been multiplied into two or three species. In winter they resort in vast numbers to the plains in the lower valley of the Mississippi, where sometimes as many as three hundred of them are captured at one haul of the net; and formerly when the red patches of feathers were used as ornaments to female attire, there were instances in which one person caught at least 20,000 birds in the course of one winter. These birds breed in the marshes, and suspend their nests between reeds in the most accessible parts of them. The nest is, like that of all the family, curiously constructed, but the materials are, of course, those which the marsh affords, the leaves of reeds and of coarse grasses. They sometimes use mud in the structure, and always line the nest carefully with the most delicate vegetable fibres that they can procure. They prefer reeds as a means of suspension, but in the absence of these they will suspend it to a bush, though always in marshy places. They are very prolific birds, having usually two broods in the season, and four or five in each brood. The eggs are greyish white with black spots. In the marshes of the middle latitudes of their range, they feed much upon the seeds of the Canadian rice (*Zizania aquatica*); but in the cultivated parts of the country they are great plunderers, especially of the fields of maize or Indian corn; and from the depredations which they commit upon that grain, they are popularly called "maize thieves."

They attack the fields at two seasons of the year, that is, when the seeds begin to germinate, at which time they have a sweetish taste, and again when the crop is nearly ripe, in which state it is also soft and sweetish. They are exceedingly bold birds, so that when they attack a field in numbers it is very difficult to drive them off; and though their temerity makes them easily killed by the gun, they are not worth powder and shot on their own account; for though sometimes eaten, they are far from being palatable. Destructive as they are, however, it is highly probable that they do the farmers upon the whole more good than harm, from the incalculable numbers of insects and larvæ which they destroy; and which but for the birds would render many parts of North America unproductive and uninhabitable.

They are remarkably good-tempered birds, living readily in confinement, and even, if at all attended to, running about the house without any restraint, and following those who feed them, with expressions of fond recognition and regard. Their song is not one of the finest, though tolerable, but they make up in quantity, and their manners are exceedingly lively and playful.

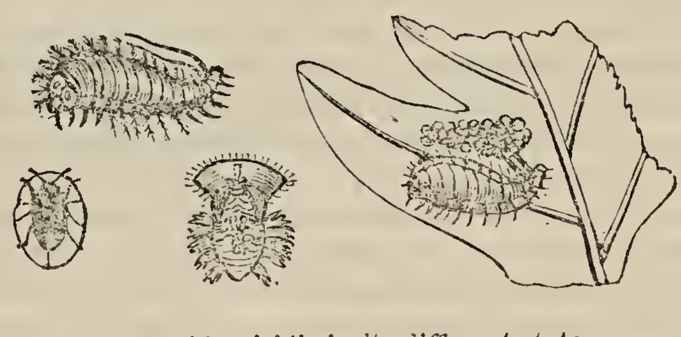
Oxyrhinchus. The distinguishing character of this sub-genus is, the bill quite straight, but much shorter than the head, whereas in the others it is as long or longer. There is but one known species, *Flamiceps*, which has a crest of long feathers mottled with red.

Dacnis. The birds of this sub-genus are very small; but in other respects they have the general characteristics of the family. The bill is conical and pointed. There are many species, but it will be sufficient to mention one as a specimen. They have sometimes been in part classed with the wagtails, and in greater part with the warblers but they do not belong to either. Their general colours are blue, black, and yellow. The best known species is, *De Cayana*, the Cayenne pit-pit, or Cayenne warbler. General colour blue, with the nape, scapulars, wings, and tail, black. Its colours, especially during the first two years, are, however, subject to much variation, and it has been multiplied into several species. The birds inhabit the forests, where they are gregarious, and perch in flocks on the tops of the highest trees. Most of the others are similar both in size and in habits; and it is not improbable that many of the described species are the same birds in different states of their plumage; and also that there are many others in the depths of the vast forests of Cayenne, Guiana, and similar parts of South America, which have not yet been discovered. To cross those forests is often no easy matter, to explore them properly is impossible, a thousand men occupied every day for a hundred years would still leave much to be found out in the highly interesting natural history of those most productive regions.

CASSIDA (Linnæus). The tortoise-beetles. A very extensive genus of coleopterous insects belonging to the section *Tetramera*, and sub-section *Cyclica*, and forming the type of the tribe *Cassidariæ* of Latreille, which is distinguished by having the antennæ inserted on the upper surface of the head, nearly together, straight, short, filiform, and cylindric, or somewhat thickened toward the tip; the mouth is placed entirely on the underside of the head, the various parts being very short, but the mandibles are broad and strong; the legs are short with the tarsi flattened, the third joint being deeply cleft, receiving between its lobes the terminal joint. The body being flat beneath, enables the insects, with the assistance of these flattened tarsi, to lay close to the leaves upon which they are found, and where they often remain immoveable; the form of the body is generally orbicular or oval, the head being often completely concealed beneath the thorax, the margins of which, as well as of the elytra, are greatly dilated, so as to give the insects the appearance of small tortoises, especially, as on being disturbed, they contract their antennæ and legs under the broad sides of the thorax and elytra, so as completely to conceal them. These insects are of very varied colours, which, especially in the larger exotic species, are elegantly disposed in spots, lines, bands, &c., upon grounds of different colours. They are entirely herbivorous in their habits. The genera are *Alurnus*, *Hispa*, *Chalepus*, *Imatidium*, and *Cassida*. In the first of these are contained the largest species of the tribe, being chiefly inhabitants of South America; they are of an oval form with the head uncovered.

The genus cassida is distinguished by its orbicular or nearly ovoid form, with thorax generally semicircular, covering and concealing the head and furnished, as well as the elytra, with a broad dilated margin extending far beyond the sides of the body, as may be seen in our figure of *Cassida viridis*, the under side of which is represented. The mandibles are short and strong with several teeth. Scarcely any of the species exceed one inch in length; but amongst the exotic species many very remarkable forms are to be observed: several Brazilian species are armed with two erect spines on the centre of the elytra, which meet together when these organs are closed, forming an acute and robust horn nearly half an inch long. Some of the species are highly metallic, amongst which are several British species; the latter, however, lose their beautiful colours when dead, but which may be reproduced by dipping them into hot water.

It is not, however, in the perfect state alone that nature has furnished these insects with a shield-like covering for their defence, since, in the earlier period of their existence, they are provided with the means of constructing a covering of the most singular nature. Reaumur has given us very ample details of their proceedings, and it is from his figures, corrected from our own specimens, that our illustrations of this genus have been derived.



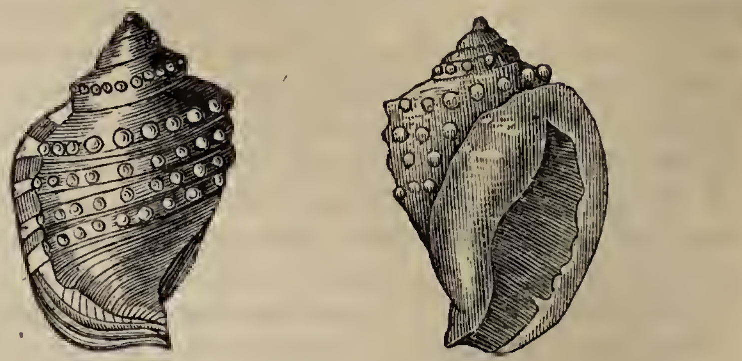
Cassida viridis in its different states.

The larva of the tortoise-beetles is rather broad, rather narrowed behind, and of a flattened form, with the sides of the body furnished with branched spines or setæ. The extremity of their bodies is also furnished with two long and slender scaly appendages terminating in a point, and which form a kind of fork, which is generally recurved upon the back of the larva; the anal aperture is placed at the base of this fork upon a fleshy tubercle, which the insect has the power to raise or depress at will; and the insect has the extraordinary instinct by the assistance of this apparatus to collect its excrement, which is pushed forward and upwards, sliding along the fork, when it has accumulated at its base, by means of the contractile motion of the abdominal rings; thus a roof is by degrees formed, the particles of which are glued together, so that at length a covering, or umbrella, sufficiently large to conceal the entire body of the tender larva is produced, it is of course subject to the motions of the fork by which it is supported, so that it is sometimes even carried perpendicularly. As, however, this parasol would in time become unwieldy, we find this inconvenience provided against by the casting of the entire skin, not only of the body, but also that of the various spines, as well as of the supporting fork. This takes place several times previous to the larvæ being transformed into pupæ. It is a difficult operation, and at the period of the last moulting, i. e. on becoming pupæ, the tails are completely lost. It is upon the same leaf that the larvæ has to undergo these moultings as well as to assume its quiescent form. To prepare itself for this, it ceases to hold the tail either in a raised or recumbent position upon the back, but, on the contrary, stretches it out behind in the same line as the body. It attaches itself to the leaf by the two segments which follow the last pair of legs; the skin then breaks behind the head, and by degrees is sloughed entirely off, having previously remained tranquil for two or three days. The exuviæ, however, remain for some time at the extremity of the body, which has caused incautious observers to state that the pupa is furnished with two prongs as well as the larva. The pupa is flat, nearly oval, with the head concealed beneath the thorax, which is very large, and of a semi-lunar shape in front, being bordered with spines. This portion of the body has been incorrectly figured by Reaumur as divided by a slit down the middle, it is, however entire: the abdominal portion is also bordered by large leaf-like appendages of a flat shape, and pointed at the sides and tip. The pupa is green, and in the underside of the body are clearly to be observed the antennæ, legs, and other parts of the perfect insect, which makes its appearance at the end of fifteen or twenty days after the larva sheds its last skin.

The females lay their eggs upon the leaves of various plants, as thistles, burdock, &c., arranging them side by side, and forming them into patches often covered with excrement.

The genus cassida is the only indigenous group belonging to this tribe, there being nearly twenty species, most of which are, however, rare. The *Cassida equestria* of Fabricius is one of the largest and most common example.

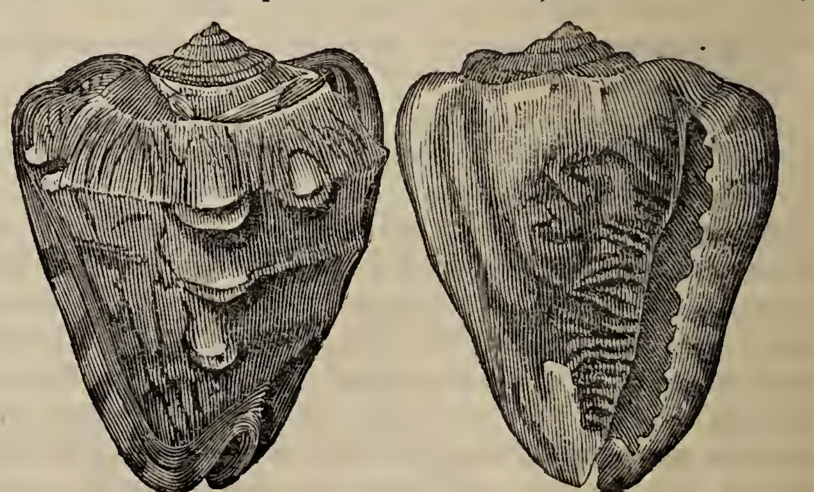
CASSIDARIA (Lamarck). This genus of molluscs must certainly be considered very nearly allied to the genus *Cassis;* a separation is however necessary, from some manifest differences of character. The shell is generally more inflated and rounder than those of the *Cassis,* and a very marked distinction is observable in the canal which terminates the lower part of the aperture. This, in the *Cassidaria,* is ascendent, and very little arched (while in the *Cassis* that part is *abruptly recurved* towards the back of the shell); the spire is short, conoid, composed of convex whorls, without any thickened bands; the left margin apparent and affixed to the columella, which is most generally covered with small rough, oblong, transverse tubercles; right lip plaited or thickened; exterior tranversely grooved, and the upper part of the whorls, in some species, regularly dotted with round tubercles. They have a horny operculum, and are found in the seas of warm latitudes; seven or eight species are known; that figured here is the *C. echinophora,* and strongly defines the peculiarities



Cassidaria echinóphora.

of the genus. They are thus subdivided:—1st, The oval sub-globular species, with the canal sub-ascendant; and 2nd, The oblong sub-cylindrical species, with a very short straight canal, forming Sowerby's genus *Oniscia.* De Blainville places this mollusc in his second class *Paracephalophora;* first order, *Siphonobranchiata;* second family *Entomostomata.* The animal, according to Adanson, is the same as that of the *Purpura* and its congeners. Several fossil species are known.

CASSIS (Lamarck). A genus of molluscs necessarily separated from the Linnæan genus *Buccinum,* in which the notch at the base is but slightly defined, compared with the canal at the base of shells of this genus, which is lengthened and abruptly turned towards the back; the form of the aperture is also very distinct, being longitudinal, straight, and nearly always dentated on the right side, the flattened side of the columella lip forming a very considerable angle, the spire seldom much elevated, frequently interrupted by thickened bands, or varies obliquely, having formed so many terminations or lips of the previous stages of growth, and constituting the discriminating character of the first section of the genus; the second not possessing these bands, the general form of these shells is inflated, the columella plaited or wrinkled transversely, the exterior smooth or nodulous, and the spire with bands or nodules only. They sometimes attain a great size; and in one species the columella lip projects above the spire, giving a flat ovate-angular appearance to the lower surface of the shell. They have a horny operculum, and are marine shells, inhabiting principally the Indian seas: nearly thirty species are known; two or three of which are however found in the Mediterranean. Several fossil species are described; that figured here is the *C. tuberosa,* internal portions of which, as well as of the



Cassis tuberosa.

other species, are exquisitely sculptured by Italian artists in imitation of antique cameo gems, the different strata of colouring matter resembling those of the onyx and other precious stones. Of these, a great variety of ornaments are made; of late years a considerable trade has been carried on in them particularly on the continent. The name of this mollusc is derived from a helmet or casque. This genus is of the same class, &c., as CASSIDARIA; which see.

CASSOWARY—*Casuarius*. A genus of birds belonging to the *Struthionidæ*, or Ostrich family, or to Cuvier's order of stilt birds, division *brevipennes*, or short wings.

The characters of the genus are: the bill straight, short, compressed at the base, rounded near the point, furnished with a ridge on the culmen, and the basal part extending backwards on the head, on the summit of which it forms a large, rounded, and elevated horny crest; the lower mandible of the bill soft, flexible, and angular near the tip; the nostrils pierced laterally in the bill, near its point, rounded, and opening in the front; the legs strong and muscular, with three toes all directed forward, the inner ones short, and armed with a very long and strong claw; the tarsi almost entirely feathered; the wings not at all adapted for flight, or even for balancing the bird when it runs swiftly, as is the case with the wings of the ostrich. This genus also differs from the ostrich in its internal anatomy, so as to indicate a different quality of food. It is still a gizzard bird, and therefore, in part, a vegetable feeder, but the walls of the gizzard are not nearly so strong and muscular as those of the ostrich, and the intermediate stomach between the craw and the gizzard is altogether wanting. The intestinal canal is also considerably shorter, and the cæca are very small.

There is only a single species, *C. galeatus*, the helmeted or crested Cassowary. It is the largest of birds with the exception of the ostrich. The general colour is black, but apt to fade into a dark sooty brown. The head and upper part of the neck are bare of feathers, of a blue colour, with flame-coloured reflections in the breeding season, or when the bird is in high condition. The helmet, or horny protuberance on the head, extends from the base of the bill to the middle of the crown; it is about three inches high, black on the fore part and yellow behind; on the sides of the neck, immediately under the ears, there are wattles, one on each side, something resembling those of the turkey-cock, and changing the colours in a similar manner, and from similar causes. The prevailing colour is purplish red, which deepens when the bird is excited, and becomes pale when it is exhausted. There is also a bare spot on the breast, covered with a callous or indurated skin, and the bird rests its weight upon this when it squats upon the ground. The rest of the body is pretty uniformly covered with blackish brown feathers, the webs of which are loose and flocculent, and have more the appearance of long loose wool than of feathers; but none of them are produced like the ornamental feathers of the ostrich. Some of them are, however, of considerable length; those on the rump are not less than fourteen inches, and they are pendulous, and form a sort of substitute for a tail. The wings, which indeed hardly deserve the name, are not feathered; but, in place of quills, they have five naked shafts in each, bearing some resemblance to the quills of the porcupine; and it is said that the male birds use those spinous shafts in their combats with each other, and also for a defence against enemies.

The body of this bird is as large as that of the ostrich; its neck is considerably shorter, and its bearing is not so majestic, so that it does not look nearly so formidable. The eggs are of smaller diameter, and rather longer than those of the ostrich.

Their ground colour is a delicate greenish grey, very beautifully marked with spots of grass-green, which are raised as if they were bits of enamel fixed on the shell. Towards the smaller end they have some white markings. These eggs are deposited in the sand without any formal nest, and the heat of that substance is often sufficient to hatch them without any assistance from the parent bird; but it is not true that these birds desert their eggs any more than the same is true of the ostrich, though it has pretty generally formed part of the description of both birds. When the temperature or state of the weather renders it necessary, these birds sit on their eggs as carefully as any other members of the class; and when the circumstances come round which enable them to dispense with sitting, they bring along with them a necessity on the part of the bird to spend the greater portion of its time in searching for its own food.

Here we cannot help remarking, that a very beautiful provision of nature for the preservation of those wingless birds of the wilderness has been most unphilosophically turned into a ground of accusation against the birds; and among romancers, the ostrich has, time out of mind, been used as the emblem for those unnatural parents of the human race who desert their offspring in its helpless years. Now, if it is borne in mind, that in those countries which birds of this family inhabit, there are many months without a shower, and with the hot sun beating on the naked surface all day long, at such times the food of the bird is of course scanty, and so scattered, that to procure one bill-full a journey must be undertaken; under such circumstances, one bird could not feed another, as the males of many of our birds feed the females, when they do not take turn with them in sitting. Hence it is necessary that, in this hot and dry weather, the female bird should have free range during the day, in order to maintain her own life; but when there is rain, food is much more abundant, and then the females of those birds do sit on their eggs. Even in the hot weather, when dews fall heavily, and they are frequently both heavy and chilly, the birds also sit; and when not sitting, they watch their eggs with most maternal solicitude. Thus, instead of the apparent abandonment of the eggs in dry weather being any evidence on the part of the birds, it is a proof of how very, beautifully the instincts of the bird are adapted to the circumstances of its native place. For the bird to sit, during the heat of the sun, upon the hot sand, would be injurious, and it would be perfectly useless, as the heat of the sun and sand alone is quite sufficient for the purpose; and were the bird to sit then, it would hinder rather than promote the hatching of the eggs; but whenever circumstances render it necessary, the bird is as true to her instinct as any other of the children of nature; and though she is in the desert, she is as completely preserved and protected there as the animal which dwells in the fullest pasture.

The cassowary is found only in the south-eastern parts of Asia, and nowhere without the tropics. The Molucca islands, and Banda, Java, Sumatra, and especially the forests of the southern part of the island of Ceram, are their principal localities; but they are rare birds everywhere. Their food is chiefly vegetable matter, but the succulent kinds, and not those which are hard and dry. They are fierce and powerful birds, striking severely with their bills, and kicking with great power with their feet. They are easily tamed, and will bear the climate of this country without injury; but they are objects of curiosity, and not of use, as their flesh is black, tough, dry, and tasteless.

CASSUVIEÆ, or ANACARDIACEÆ (the Cashew Family). A natural order of dicotyledonous plants, containing thirteen genera and nearly one hundred and twenty species, described by Jussieu Decandolle, and some other botanists. This order, as well as *Spondiaceæ*, *Burseraceæ*, *Amysideæ*, and *Connaraceæ*, are considered as divisions of *Terebinthaceæ*. All these orders bear strong affinities to each other, but still they have essential characters sufficiently well marked to induce Brown and Künth to separate them into distinct families.

The Cashew tribe is thus characterised: flowers generally unisexual; calyx small and persistent, with five or seven divisions; petals equal in number to the segments of the calyx, perigynous; stamens usually equal in number to the petals, and alternate with them; petals and stamens inserted upon the calyx or calycine disk; ovary single, one-celled, with one ovule; styles one to three; fruit indehiscent, most commonly drupaceous; seed without albumen; cotyledons thick, folded upon the radicle.

The plants of this order are trees or shrubs, with alternate, simple, or ternate leaves, and terminal or axillary flowers, provided with bracteas. They grow chiefly in the tropical regions of India, Africa, and America. Some species inhabit the south of Europe, and other countries without the limits of the tropics, such as the northern parts of America. They are propagated by cuttings, layers, and seeds.

The *Cassuvieæ* abound in an oily resinous juice, which occasionally possesses acrid and poisonous qualities, and which is applied to a variety of uses in the arts.

The order has been divided into two sections: first, *Anacardieæ*, including the genera *Anacardium*. *Holigarna*, *Mangifera*, *Buchanania*, *Pistachia*, *Comocladia*, &c., in which the cotyledons are thick and folded back upon the radicle; and second, *Sumachineæ*, including the genera *Rhus*, *Schinus*, and *Duvana*, in which the cotyledons are leafy, and the radicles bent back upon their line of union.

The genus *Anacardium* may be considered as the representative of the order *Anacardium occidentale*, which furnishes the well-known Cashew or Acajou nut. There are two varieties of the plant, one found in the West, and another in the East Indies. It is an elegant tree, bearing panicled corymbs of sweet-smelling rose-coloured flowers, and an edible fruit of a yellow or red colour. The fruit or apple has a somewhat acid flavour, and a considerable degree of astringency, and its juice, when fermented, yields an agreeable vinous liquor. The nut grows in a singular manner, supported on the enlarged fleshy and pyriform peduncle. The kernels form a delicious article of food, and are used in the West Indies as a dessert.

Cashew nut.

When ground with cacao, they form excellent chocolate; and when roasted, they are mixed with Madeira to improve its flavour. From the nuts an oily fluid is procured, which turns black and thick by exposure to the air, and is used in India to make varnishes. The fumes which arise from the nuts, during the process of roasting, are very acrid, and are apt to produce inflammation. An aromatic substance is procured from the tree, which was formerly used in medicine. For a drawing of the tree, and a full account of its properties, see article on ANACARDIUM.

Semicarpus Anacardium, or *Cassuvium*, yields a nut, the juice of which is used for marking table-linen and articles of dress; hence the tree has received the name of the *marking-nut tree*. If linen is placed on the nuts, and pricked through, an indelible stain is produced in consequence of the exudation of the juice from the nuts. The nuts of this plant, and the berries of *Holigarna longifolia*, another plant of this family, after being steeped for a long time in water, furnish by expression a juice which, by a particular mode of preparation, forms the varnish of Sylhet, in Bengal. The wood of the plant is soft, and contains acid juice. The fleshy receptacles, when roasted, are edible, and have the flavour of apples. The green fruit, pounded into a pulp, makes good birdlime. When ripe, the juice is used by the Telinga physicians in various disorders.

The varnishes which are yielded by several plants of this order, such as the *Cashew*, *Semicarpus*, *Melanorrhœa*, *Usitatissima*, *Stagmaria verniciflora*, and several species of *Rhus*, to be presently noticed, are very deleterious in their effects on the human body. They are highly acrid, and, when applied externally, produce inflammation and swelling to such a degree as sometimes to endanger life.

Several species of *Schinus* are filled with a resinous juice, which is easily expelled, in some cases by simple emersion in water. The oily fluid is said to be thrown out in such a way from the leaves of some of these plants, when thrown on water, as to make them move in a circle. *Schinus acroeria*, probably from the spontaneous exudation of an acrid fluid, is said to excite inflammation and swelling in those who sit or sleep under its shade. A similar remark is made in regard to *Stagmaria verniciflora*. The fresh bark of *Schinus molle*, Peruvian mastic tree, is employed to give a coating to ropes, which prevents their ready decay. A substance like mastic exudes from the tree, which is used in Peru as a dentifrice. The berries have a beautiful rose-colour, and the acid juice which they yield is used as vinegar in India. The inhabitants of Peru prepare a vinous liquor from them.

Stagmaria verniciflora, a native of the East India islands and Sumatra, furnishes an acrid resin which causes excoriations and blisters, and which is an ingredient in a varnish similar to Japan lacquer.

Rhus, or *Sumach*, is another genus of the order, containing many important species, several of which yield a milky juice possessing poisonous qualities. *Rhus coriacea*, elm-leaved *sumach*, from its astringency, is used in place of oak-bark in tanning. Leather in Turkey is chiefly tanned with this plant. The seeds are used at Aleppo to increase the appetite, and both the leaves and seeds are employed medicinally as astringents and styptics. The ancients used this plant, instead of salt, for seasoning meat. The plant grows abundantly in Spain. The bark of *Rhus glabra* is used as a mordant for red colours, and acts as a febrifuge. The leaves of the plant dye red, and the branches, boiled with the berries, give a black ink-like fluid. *Rhus vernix*, or *venenata*, affords the true Japan varnish. This substance oozes out from incisions made in the tree, and becomes black and thick by exposure to the air. With it the Japanese varnish the posts of their doors, their windows, and all their articles of furniture. The whole plant is acrid and poisonous. When applied to the skin, it produces inflammation, and a copious pustular eruption. *Rhus pumila*, and *radicans*, also possess poisonous qualities. *Rhus toxicodendron*, poison-oak, is another species of this genus, found native in North America. The juice of the plant is white, but turns black by exposure, and is used as a varnish. A volatile matter arises from the living plant, which inflames and blisters the skin. This noxious exhalation is said to take place chiefly during the night. The plant possesses both acrid and narcotic qualities. The leaves, in small doses of a quarter or half a grain, act as a powerful stimulant, and appear to exert a particular influence on the skin. They have been employed successfully in some obstinate cutaneous eruptions, in chronic rheumatism, and in palsy. They are said to excite a feeling of heat and pricking in paralysed limbs, which have sometimes been succeeded by the happiest results. It is a dangerous medicine, and always requires to be administered with the greatest caution. *Rhus cotinus*, Venice sumach, or wild olive, is cultivated for the purpose of tanning leather near Balcimara, in the Apennines. The wood is used by the modern Athenians for dyeing wool of a rich yellow colour. Several species of *rhus* are cultivated in gardens. The expressed oil of some of them acquires the consistence of suet, and serves for making candles.

Pistacia is another genus of the order which deserves to be noticed. *Pistacia vera*, or *officinarum*, Pistachia tree, is a native of Syria, and the countries near the Mediterranean, and is extensively cultivated in Sicily on account of its nuts, which are an article of commerce. The nut is fully the size of a filbert, and encloses a kernel of a pale greenish colour, having a sweetish unctuous taste, and yielding a quantity of oil.

Pistacia lentiscus, and *Atlantica*, both of which are natives of the south of Europe and the northern parts of Africa, furnish the resin called mastic. The former of these plants is a tree ten or twelve feet high, which flowers in May, and ripens its fruit in August. It does not thrive well in Britain, although it appears to have been cultivated in this country so early as the year 1664. Mastic is got from these trees by incisions in the bark, which are generally made in the month of August. A yellow resinous juice exudes, which gradually concretes. The Turkish and American women chew it, in order to make their breath agreeable, as well as for the purpose of whitening their teeth and strengthening their gums. It is also used to fill cavities in carious teeth. The tree is burned in order to furnish an agreeable fumigation. Mastic, as a medicine, is tonic and astringent, and is given in cases of debility, spitting of blood, and diarrhœa. The wood of the tree receives the name of *lignum lentischinum*, and was formerly supposed to possess medicinal virtues. It is now chiefly used in Portugal to form tooth-picks. *Pistacia terebinthus*, a native of Barbary and the south of Europe, and which has been cultivated for more than sixty years in Britain, yields the Chian, or Cyprus turpentine. It is the most esteemed of all the turpentines on account of its pleasant odour and its taste, which is neither bitter nor acrid. The turpentine is got by wounding the bark in the month of July. The resinous juice which exudes becomes thick by exposure to the air, and is easily collected. The quantity got is very inconsiderable, from large trees sixty years old, only yielding two pounds nine ounces and six drachms. In consequence of this, the price of the article is high, and it is very apt to be adulterated. The best Chian turpentine is like honey, having a clear transparent whitish colour, and a fragrant smell. Its taste is warm, not at all acrid.

Mangifera Indica, the famous Mango tree, is a large spreading tree, with leaves seven or eight inches long, and two or more broad, sending forth loose bunches of flowers, which grow at the end of the branches. The wood is brittle, and of a brown colour. It is used in India for burning bodies and for making coffins. The fruit is a kidney-shaped berried drupe, the size of a large plum, and of an orange tawny colour, with a tinge of red. The flesh round the nut is soft, pulpy, and luscious. The fruit is juicy and wholesome, and is much esteemed in

India. It is very high flavoured, and so fragrant as to perfume the air a considerable way around it. The plant has been cultivated in Britain with the view of producing fruit, but the attempt has scarcely as yet been crowned with success. The unripe fruit is pickled in the milk of the cocoa nut, after it has become sour, along with salt, capsicum, and garlic, and in this state it is brought to Europe. It is also eaten preserved in sugar. From the juice of the fruit a kind of wine is prepared, and the kernels, when reduced to powder, form an excellent flour, used in the preparation of bread. There are as many varieties of Mango as there are of apples and pears.

Comocladia integrifolia is a handsome tree, which produces a deep red edible fruit. *Comocladia dentata* is said to be injurious to those who sleep under its shade.

The Chilian genus, *Duvana*, resembles the myrtle tribe.

CASTALIA (Lamarck). A genus of molluscs, thus described by Lamarck. The shell equivalve, inequilateral, sub-triangular; apices eroded, and curved towards the posterior side; hinge with two lamellar teeth, transversely striated, one of them posterior, distant, shortened, and sub-trilamellar, the other anterior, lengthened and lateral; ligament exterior; the substance of the shell is thick and pearly; the valves with longitudinal flat ribs, transversely striated, but not extending to the upper margin, and covered with a brown epidermis. It is said to resemble the genus *Trigonia*, but the number and position of the teeth are more like those of the *Unid*, of which genus De Blainville has made it a species, and consequently places it in the third class, *Acephalophora;* third order, *Lamellibranchiata;* sixth family, *Submytilaceæ.* It is a fresh-water bivalve, and the animal probably resembles that of the genus *Anodon.*

CASTNIA (Fabricius). A remarkable genus of South American lepidopterous insects, the situation of which appears to be very doubtful, the insects partaking of the characters both of the moths and butterflies; the wings are broad, the antennæ are thickened towards the tips, terminating in a style, the palpi are short, thick, and cylindric. The species are, for the most part, of beautiful colours, and of a large size. Madame Merian has given figures of the transformations of one of the species; but lepidopterists have considered these representations as inaccurate.

CAT—*Felis* or *Felinæ*, THE CAT TRIBE. A very numerous genus of carnivorous animals—the most numerous, indeed, as well as the most powerful, and the most exclusively carnivorous, of all the mammalia. They are also the most generally distributed over the globe, being found, in one or other of the species in every latitude, and in all parts of the world, with the exception of Australia and the Polynesian islands, in which none have hitherto been discovered. They are the animals to which especially the name of "wild beasts" or "beasts of prey" is applied; and each of those names is far more descriptive than many of the popular names given to other races of animals. They are, strictly speaking, wild beasts; inasmuch as the generality of them belong to wild nature only, and disappear before the progress of population and culture. One species, the domestic cat is, indeed, a remarkable exception to this; for it is found in a domestic state only, in endless varieties of colour; and neither the original place of its habitation, nor the original race in a state of nature is at all known. It is indeed sometimes said that the wild cat, which is found in brakes and unfrequented places of Britain, and generally in similar places throughout Europe, is the parent stock of the domesticated species; but there appears to be little truth in this statement; as it is ascertained that in very remote times, when the country was not so well inhabited as it is now, and when in consequence wild cats were so abundant as to be troublesome, tame ones brought a far higher price than they do now. Indeed, at present, they have no marketable value except an ideal one from favouritism, which is of itself a strong proof that they have belonged to civilisation, and to civilisation only, not only from its first establishment, but that they have accompanied its march, like the ox and other domestic animals, from the time of its commencement. The real use of the domesticated cat has always been as a mouser; and it is natural to suppose that mankind no sooner began to accumulate stocks of provisions to serve them during those times when the earth is unproductive, than the small animals accumulated in their dwellings; and as most of the original houses, in temperate parts of the world, were in part at least constructed with mud, they afforded more easy lodgment for these little animals, than modern houses, which are constructed of brick or stone, and thus the service of cats became of more value.

Besides the common domesticated cat, there are some of the more mild-dispositioned of the others which are trained, in some parts of the world, for hunting; not that they follow the game by the scent, or even by speed through a long chase, like the dog family; for they must be carried till they are within sight of the game, and at no great distance from it; and they make their capture by springing upon it at one bound. The more powerful ones are known only in the wild state, or as kept in dens at menageries for the purposes of exhibition. But it must not thence be inferred that they are untameable, any more than even the mildest animals with which we are acquainted; for though none have been absolutely tamed in modern times, and though we may doubt the accounts of the generous forbearance of lions recorded by ancient writers, yet there is no question, that, if it were worth the trouble, the most naturally ferocious of them could be domesticated. The only question as to the taming of any animal is, whether its use when tamed would justify the trouble and expense; and the powerful animals of this genus use their strength so much by fits and starts, and are so indolent, except when excited by hunger, that it is not very easy to see to what use they could be applied.

If, however, a use for them could be found out, there cannot be the least doubt that, though they might perhaps require a little more careful management, in proportion as they are irritable in a state of nature, all animals whatever might be reduced into a state of perfect obedience to man; the purchase of that obedience being the constant and timely supply of their natural wants, and by this means the prevention of those excitements which are absolutely necessary for their preservation, so long as they have to depend upon themselves for subsistence.

It is in the study of those more powerful, and as we are accustomed to say, more savage animals, which live upon the flesh of other warm-blooded animals, that we have the best means of correcting those erroneous notions of the animal kingdom, which we are so apt to derive from judging of its members as we judge of mankind. Men proceed, both in passion and in action, by the judgment of experience, that experience never amounts to an absolute certainty, and in very many, perhaps the greater number of instances, it is weak and erroneous. Hence, human beings are often excited to foolish or unnecessary passion, and stimulated to erroneous, useless, or improper action. Men are therefore often cruel, deceitful, injudicious, and the whole list of the results of mistaken judgment, that can arise either from ignorance, improper habits, or uncontrolled passions. But in these respects man stands singly in the world, the only being in it capable of moral good and moral evil,—the only being that can decide by his own judgment; and therefore the only being which can in any instance be said to do wrong. But we are apt to overlook this distinction, and impute something resembling virtue and vice to animals, in the same way that we are disposed to attribute to them a certain inferior degree or species of reason.

This is a much more serious error than those who do not reflect carefully upon it are apt to suppose; and the mischief of it operates in two ways;—it leads us to treat beasts as though they were men, and also to treat men as though they were beasts; and although we do not take the trouble of tracing this root of evil in every or almost in any case, yet there is not the smallest doubt that to it are owing many of those crimes, follies, and sufferings, which so chequer the annals of the human race.

Among animals, as among plants, there is nothing which can, in any rational sense of the word, be considered as evil. The creature, whatever may be the nature of its food, and however it may destroy other creatures in the obtaining of that food, has no bad passion to gratify, no purpose of any kind to serve—that is, no purpose planned by itself; for, how artful soever it may appear to us to be in the capture of its prey, or even in the construction of snares to assist in that capture, stlll we can refer its operations to nothing save general obedience to the grand law of nature, of which its actions form a part, so long as that action is necessary for maintaining the proper balance of the system—that is, the greatest good of the whole; and when this necessity for it ceases, when circumstances, sometimes open to our observation and sometimes concealed, come round and render it less necessary, its members fall off; and when the necessity for it ceases altogether, its bones are only found in the earth as memorials of a former and different state of things, and they no doubt remain there, in part at least, to stimulate us to inquiry into a longer acquaintance with the earth's history than we can obtain from those events which we see taking place around us. The most powerful animals of the genus under consideration are met with only in those parts of the world where the powers of life are remarkably active, subject to much seasonal change, and liable to be overrun by wild plants of lofty growth, and wild animals of various kinds, if man, in consequence of war, or any of those other vicissitudes by which places become depopulated, suspend his cultivation even for a few years, and therefore the fossil bones are not so numerous as those of some other places; but still there are bones of those animals, of much larger species than any now met with alive to be found in caves, and other accumulations of animal remains, both in the middle latitude of the continent and Great Britain. But still it is as living animals that this genus belongs to popular natural history.

It is worthy of remark, that as birds of prey form the best defined natural group of the feathered tribes, so the genus *felis*, which to them, in as far as there can be a correspondence between birds and mammalia, in being the best defined natural group in the whole class. There is this further in common that, though many of the species are readily enough distinguished from each other, yet there are many in which no specific distinction can be clearly established, just in the same manner, and nearly to the same extent, as this difficulty occurs in the birds of prey. There is never the smallest difficulty in deciding whether an animal does or does not belong to the cat family; but there are many instances in which it is not easy to refer to the proper branch of the family to which the individual belongs. This confusion of species seems to be inseparably connected with that well-defined general character which marks the genus or the group; and though at first sight this may appear to be a difficulty in the study of those animals, it is a difficulty only to the systematist; for to the popular naturalist, who seeks a knowledge of the animals themselves, and not of the mere arrangement of them, it a great advantage to be able to include a number in one general description; and with the exception of size and colour, this can be readily done in the genus *felis*.

The generic characters are: six incisive teeth in each jaw; two strong canines in each, conical, slightly bent, very sharp pointed, those in the upper jaw the largest, and locking behind and partly outside those in the under. Three cheek teeth in the upper jaw arranged in a row, with trenchant carnivorous edges; three similar ones in each side of the lower jaw; and in the upper jaw, within side the cheek teeth, a tooth standing cross-wise with a flat or blunt top against which the point of the carnivorous tooth of the lower jaw acts much in the same manner as a butcher's cleaver acts in dividing flesh on his block. The tongue is beset with bony prickles, reflected backwards in the form of hooks, so that in drawing backwards across a substance, and pressing it at the same time, it abrades like a file.

Such are the general characters of the mouth in all the animals of this genus, and here we have another remarkable coincidence between them and the birds of prey. This mouth is not a proper instrument of prehension, as neither is the beak of rapacious birds. Each group is furnished with other instruments of prehension; and though the cats generally seize with the mouth at the same time that they seize with the claws or strike down by the blow of the paws; yet their mouth is a tearing instrument; and they do not snap with it, even at the smallest prey, as is the case with most carnivorous animals which have not prehensile claws. The mouth is, however, very powerful as an instrument of adhesion; and the structure both of the teeth and tongue is calculated to produce very destructive and painful laceration in every animal upon which they can fasten, if the skin is not tough and hard enough to resist their bite. This latter is the case with some of the *Pachydermata*, such as the elephant, the rhinoceros, and the hippotamus, especially the two latter, and even with some of the buffalo tribe, which are consequently not attacked by any but the largest and most powerful of the *felinæ*, and only by them in cases of extremity.

The shape of the head accords with this general action of the mouth. The head is round, generally flattened; the jaws short; the ears placed high on the head, and a large space left on the cheek for the insertion of those large and powerful muscles which move the lower jaw. This form of head is not calculated for giving so effective a snapping bite as can be given by those animals in which the jaws are long, because the long jaw acquires a momentum, and cuts by impulsive action, while the short jaws of this genus cut more by pressure, like a knife. Thus the same muscular action does not produce the same sharpness of bite; but it holds on much better, and this, together with the tearing action is that which accords best with the other structures, and with the habits of the animal. We have an instance of this difference of the action of long jaws and short ones in the hound and bull dog. The deep mouthed hound gives a powerful bite, but cannot retain his hold; the bull dog on the other hand does not bite so sharply in proportion to his strength, but he is much more staunch in keeping his hold.

The paws and their armature are remarkably well adapted for the offices which they perform. There are five toes on each of the fore-feet, and four on the hind, all of which are armed with very sharp crooked claws, which have their inner or convex edges with two trenchants or cutting ridges, like those of the more formidable birds of prey. The fore paws are the really efficient instruments in the capture of the prey; and for this purpose they are furnished with very strong bones,—bones which in the largest and more powerful species, are heavier in proportion, and also stiffer and less liable to be broken, than the bones of any other animals. By this means the paw becomes a very formidable striking instrument; and the stroke of it fells a small animal to the ground as if it were struck by a sledge hammer. It is, however, in the clutch of the paw, and not in the stroke of it, that the chief use of this formidable weapon exists. When the animal is in a state of repose, or when it is prowling about in search of its prey the claws are not visible; they are drawn back into sheaths on the insides of the toes, so that their points or their trenchant edges are never blunted by contact with the ground. This retraction of the claws is not produced by any muscular effect on the part of the animal, but it is the result of the mere elasticity of a ligament which is attached to the last phalanx of the toe—that which carries the claw. This phalanx is very short, its length being considerably less than its height; and when the flexor muscles are not in action, the ligament turns its back more than a third of its circumference. Except the retraction and repose which it receives from the elasticity of this ligament, the claw, the phalanx to which it is attached, and the muscles by which it is moved, when occasion requires, do not come into play in the common walking motions of the animal. The paw is thus, if the expression may be admitted, a double instrument, or perhaps even a triple one: it is a walking foot, it is a clutching foot, and it is a striking foot; for when the animal merely hits a blow, the claws are not protruded. The flexor muscles are, however, very powerful ones when they do come into action; and as they are never fatigued by the common motions of the animal, they are always fresh and ready for the attack.

Besides the advantage to the action of the claws themselves, which results from this structure, there is another advantage in the general economy of the animals. They are all prowlers, and liers in wait, seizing their prey by stratagem; and as the soft part only of their feet comes in contact with the ground, they move much more silently than any other animals; and as they keep their eye fixed upon the prey while they are endeavouring to approach so near it as that it may be secured, they walk with great circumspection; and, as all their joints, though fit for very energetic momentary action, are supple and elastic, they plant their feet as if they were let down upon both springs and cushions contrived with the greatest delicacy. There is, indeed, no part of their history more curious than the contrast which the extreme softness of their foot-fall upon ordinary occasions makes to the firmness and force with which they strike, when the flexors of the last phalanges are brought into action, and the claws all projected in order to take effect. This part of their action, never takes place, however, till they work themselves to the utmost degree of excitement, which, in the powerful ones is attended, and in all probability heightened, by a very harsh, and by no means a pleasant roar. It has been said that the object of this roar is to confound and stupify the prey, so that it shall not be able to escape; but the spring follows so instantaneously, that the prey is under both the claws and the teeth before this note of terror is heard; and if the animal is difficult to be overcome, the preyer often finds it necessary to excite his energy by fresh roars, and these are always attended with a new wrench with the head, a new clutch with the claws, and a violent convulsive action of the whole body.

In the more formidable species, which prey upon large animals, and prey comparatively seldom, those exhibitions are grand, though they are not either very pleasant or very safe for near observers, and therefore not very often seen. Those of the less powerful ones, which prey upon birds and small quadrupeds, are more of every day matters, and they take place oftener, and generally speaking, they take place comparatively in silence; and when they growl over their prey, it seems rather to be from fear of losing it than from any other cause.

As compared with the power which these animals evince in their proper manner of preying, they are feeble animals on their march. That looseness or flexibility of all the joints which enables them to steal so softly through the brakes and bushes, and come so unexpectedly upon their prey, and which also enables them to concentrate the action of their whole bodies into the spring which they take, and into those bounding leaps by which they endeavour to escape from danger, is not well calculated for steady walking, or long continued running. The more powerful the animals are, the joints of the legs, and especially those of the spine, are the more free in their articulations; and hence, when a lion, a tiger, or any of the more formidable species, is seen moving about in his prison house at the menagerie, his body may be observed twining about in all directions, something like that of a serpent. Indeed, though the animals belong to different classes, there is more analogy between the genus *Felis* and serpents, than one would at first be apt to suppose. They are both carnivorous; they are both awkward in their progressive motion, and they both dart or spring upon their prey with the whole accumulated energy of their bodies; and though the serpent swallows its prey entire, while the *Felinæ* rend theirs to pieces, and even file and grind the bones with their prickly tongues and formidable teeth, there is still a considerable resemblance in their methods of capture.

There is reason to believe that the sense of hearing in these animals is very acute, both from the very perfect development of their ears, and from their habits. Many of them prey only in the woods, and all of them lurk in brakes and thickets, and therefore very quick hearing is essential both to their discovering their prey, and preventing that prey from discovering them. It is also a well-known law in the economy of animals, that those which walk softly in proportion to their weight are always very quick in the ear. This extends even to human beings, among whom it is found that those who walk lightly have quick ears, while a dull ear and a heavy step are always associated together.

What is called the sense of touch appears to be very acute, at least in certain parts of the skin of these animals. The skin of the upper lip, from which the long bristly hairs, called whiskers, grow, is so very sentient as to feel the least bending or touch of any one of those hairs; and by this means they become important instruments in keeping the animal free from contact with obstacles while it is advancing with its eyes intently fixed on its prey. The inside of the ears appears also to be lined with skin of great sensibility, because it is impossible to touch the hairs on these parts so lightly as not to attract the attention of the animal. On the other hand the sense of taste is supposed to be rather weak, because of the particular manner in which the tongue is covered, and also the small supply of nerves with which that organ is provided. It is possible, however, that these suppositions are not very well founded, for these animals show very considerable discrimination, and even daintiness in the choice of their food; and though the callous papillæ on the tongue may diminish the sense of taste in that organ, yet it is certain that the general covering of the interior of the mouth is exceedingly sensitive, as is seen by administering a very small quantity of mustard, pepper, or any other pungent substance to a domestic cat.

There is no question, however, that the grand organ of perception in this genus of animals is the eye. In all of them it is large, prominent, and brilliant, and capable of considerable variations of lustre, and even of colour, in different states of excitement. Some of them have the pupil contracting to a point, and others to a line, though in all it is circular when distended to the utmost size to which it admits. Upon this form, to which the pupil of the eye contracts, it has sometimes been attempted to establish a division of the genus into diurnal and nocturnal preyers. But it does not appear that this is a very legitimate ground of distinction, nor is it easy to see for what reason it should be one. The form of the pupil has really nothing to do with the acuteness of vision, or the quantity of light, which may be necessary for enabling the animal to find its prey. The sensibility of the eye, the small quantity of sight which is sufficient for exciting the retina, is the ground upon which vision in twilight more immediately depends; and a superior degree of sensibility in the retina is in all cases, which are open to observation, attended by a similar sensibility of the iris, and probably also of the whole structure of the eye. It is not because the eyes of nocturnal birds have the iris contracted to a particular form, neither is it because their eyes are weaker than those of diurnal birds, that they see with difficulty in the bright light of the day. On the other hand, it is to the perfection of their eyes that they owe this apparent weakness. The eye, the iris especially, is so powerfully excited by strong light, the tendency of which is always to contract the pupil in the exact ratio of its sensibility, that the eye of the nocturnal bird becomes absolutely closed in bright light, not by the action of the eyelids, but by that of the iris. The same law, of course, regulates the vision of nocturnal mammalia; and, as in the other case, their vision must be supposed to be acute in proportion as they are able to see in a fainter light. The form to which the pupil contracts—a circle, a vertical oval, or a horizontal one, for it has these three forms in different animals, the first tending to close in a point, and the others in lines in the direction of the transverse axis of the oval, has reference not to the necessary intensity of vision, but to the direction of the plane in which the animal has most occasion for a greater range of it. The round pupil contracting to a point is found in animals which have occasion to use the eyes with nearly equal readiness and effect in all directions, vertical, horizontal, or oblique; the eye with the vertical axis is found in those which have most occasion to use their eyes in the vertical plane, especially above them; and the eye with the horizontal axis is found in those which have most occasion to use them in the horizontal plane. Thus in the dog, which ranges the wide field for its subsistence, the pupil is round; in the cat, which, in a state of nature, feeds in the copses, either upon small quadrupeds on the ground under it, or on birds in the branches above, has the greatest power of the eyes in the vertical direction, that is, when they contract they contract laterally, and preserve their vertical range; and in the hare, which has most occasion for view in the lateral direction only, the pupil contracts to a horizontal line. These contractions have, however, nothing to do with the quantity of light which is necessary for enabling the eye to see with the greatest perfection, only a powerful contraction of the iris is never given, except when the eye is a very important organ in the economy of the animal; and, therefore, it is only in such eyes that those differences in the form of the pupil can be perceived. Hence, though some species of the genus *Felis* have circular pupils and others elongated ones, no conclusion can be drawn from these differences with regard to the time at which the animals seek their prey; though there will be found a considerable accordance between the form of the eye and the usual or natural haunt. Thus the lion, which, though he lurks in bushes and thickets, generally preys upon animals which are in the open places, and also has his haunt in places so bare as that he can see what is going on around him, has the pupil round. The tiger, on the other hand, which frequents the grassy bottoms and jungles of much richer places, where the vegetation interrupts the lateral view, has the pupil elongated in the vertical direction.

We shall see afterwards that the structure of the tiger, as well as this formation of the eye, adapts him for those bottoms of tall grasses and reeds in which he is usually found, while that of the lion fits him better for more arid places. In all the genus the pupil of the eye is as susceptible of expansion as it is of contraction; and in all cases when distended to the full stretch it is round.

There is another peculiarity in the eyes of animals of this genus which is but little found in those of most others, that is, the glaring or glistening of the eyes, as if they were really radiant, or shot forth a portion of self-produced light, and also the change of colour which they undergo when the animal is excited, or even when the natural light is faint, and the pupil is consequently much distended. This glistening or glaring colour of the eyes is not peculiar to animals of this genus. It is found very conspicuously in those of night or twilight in other carnivorous genera, more especially in the hyænas, and perhaps there is no animal in which it does not appear to some extent, when the animal is sufficiently excited; but there are none in which it is so remarkable as in the cat tribe, and in them this inward light, so to speak, is so conspicuous, that the name of *cat's eye* has been given to a stone which appears to glisten with an inward light, as though it had a positive luminous power in itself, independently of the light which falls on it.

There have been various speculations about the means by which this remarkable phenomenon in those animals is brought about; and it has sometimes been supposed that their eyes have a power in producing light; and that in searching for their prey in the dim twilight, their own eyes serve them as a sort of lanterns. There is of course no truth in this; and the light which appears to beam from the eye, is reflected from the choroid tissue, which in them has a sort of metallic lustre, which reflects, something in the manner of a concave mirror, a portion of the light which enters at the widely distended pupil. This glaring light is generally different in colour from the light in the eye in the unexcited animal; and as that is in these animals, generally of a yellowish or brownish colour, the glaring light becomes bluish, greenish, or purplish. This change of colour tends in a great degree to explain the way in which the additional reflection of light is produced.

It never takes place except in dim light, and when the animal is excited, and its intensity and change of colour are very nearly in the same proportion as the excitement. Now, in the cameleon and other animals which change their apparent colours in various states of extension of the skin, without any particular reference to changes in the direction of the light incident upon them, it is always found that the change of colour from the natural whitish or brownish yellow to deeper tints, is invariably accompanied, or rather preceded, by an accumulated quantity of blood in the small vessels of the skin. It will be found in like manner, that the strong excitement which causes the glaring in the eyes of the cat family, is always attended by an additional flow of blood towards these organs; and that the difference of colour in the reflected light is always what might be expected from an additional quantity of blood in the choroid membrane of the eye, and deeper in proportion as this quantity may be supposed to be greater. In the eyes of all animals we have the different passions by which they are affected displayed in a manner something similar to this, they all glisten more or less when the animals are enraged; and there are several in which they become absolutely red: of these some of the most remarkable are to be found among ruminating animals, of whose eyes there can of course be no carnivorous lighting up.

It has sometimes been supposed that animals of this genus having eyes with the pupils differently formed, have still the same habits with each other; but it does not appear that this is the fact, though there are instances of species with round pupils, and other species with elliptical ones, being found in the same locality; and in all the other races which contain species having eyes of each of these forms, we find that those with a circular pupil seek their prey upon the ground only, while those which have it contracting to a vertical ellipse seek their prey at least on the lower branches of trees, or on shrubs nearer the ground. The foxes, for instance, which are nightly prowlers, and search for the low-roosting gallinidæ on their perches have the eyes with the pupil elongated vertically; and so far as has been observed, there is no carnivorous animal which has the range of the pupil placed horizontally; though ruminating animals, some of the pachydermata, and even the whales have them constructed in that manner.

We shall only make one other general observation with regard to this very interesting genus of animals, and that is, the comparatively little injury which they receive from falls, blows, and bruises, which would be very serious, if not altogether fatal to almost any other race of animals. "That a cat has nine lives," is a proverbial expression, and, as is the case with all popular proverbs that have come into general use, the foundation of it is true; and it is worth while to ascertain to what it is owing. There is also another peculiarity in which these animals differ from most others, which is, that however they may fall, or in whatever way, they generally alight on their feet, and seldom break their bones, or sustain any other very serious injury.

Now, both of those means of escape from injury, are to be attributed mainly to the freedom or litheness of the joints of the animals, of which notice has been already taken. Whatever part of them is struck, or made to strike against any obstacle always gives way like a spring; and thus the concussion of the blow or the fall is not communicated to any considerable part of them as a direct thrust, but is speedily dissipated and lost among their supple and flexible joints. This suppleness also gives them a command of their bodies in the air, which animals with more rigid skeletons, and especially more rigid spines, do not possess. It is thus that they are enabled in so far to right themselves, even when flung through the air; and the weight of the bones of their fore paws partly conduces to bring them to the ground always with their feet undermost.

That peculiar flexibility of the limbs, to which their twining gait when they walk is owing and the fact of their placing the yielding ball of the foot upon the ground, and not the points of the toes, farther help to let them down easily; and their weight, instead of being all received on one part, is, from the flexibility of the joints, distributed over many. It must not, however, be supposed that there is any weakness or laxity in the muscles of these animals; for their muscles are not only very well developed and energetic, but the freedom of the joints and the large processes of the bones, enables the muscles to act with the very maximum of effect.

Attempts have sometimes been made to divide the genus *felis* into several subordinate groups or sections, founded on the variations in size and colour, and sometimes on mere difference of locality; but these convey but little information which can be of real value, as it appears that all the species are subjeet to very considerable variations of a climatal nature, in the very respeets upon whieh it is attempted to found these groups. There is certainly less variety in the organic structure than in almost any genus whieh is as widely distributed; but if we take the eommon domestie cat as an instance, there is an almost endless variety of eolour, and no ineonsiderable one in size. We shall not, therefore, attempt to define the groups whieh have been formed by different authors, but shall confine ourselves to notiees, and very short notices, of the more remarkable species.

The Lion (*Felis leo*). This is the most famed, and generally described as the most formidable of all the speeies,—the "king of beasts," of whose brave, noble, and generous charaeter, so much is said in the writings of poets and romancing naturalists. But the truth is, that, though there is eertainly physieal power and physieal grandeur in the action of this "animal monareh," there is not any moral good or moral evil. He is a powerful beast, certainly, but still he is only a beast, aeting his part in the physical economy of nature without merit or demerit, and perishing like the humblest of those beasts of which faney has made him the sovereign, when the days of his years of alternate indolence and slaughter are numbered. It is the nature of the lion, as well as of all the other members of the genus that are strong enough for killing large prey, to feed heartily when he does feed, and to fast long in the intervals: so mueh is this the case, that those animals of similar habits at the gardens of the zoological society which had only one meal in the day were found to thrive much better than those whieh had the same quantity of food divided into two meals. The life which such an animal leads is naturally an indolent one; and by far the greater part of it is spent in lolling and repose, at which time there can be but little waste of the system, as the waste in the system of all animals is in proportion to the activity. In prowling for his prey, the labour of the lion eannot be very severe; and although the capture of it is attended with very great exeitement and energy, the time of its continuanee is but short. The lion is thus upon the whole an indolent animal, and when let alone it is comparatively a peaeeable one.

In those places where lions are most abundant, they are seldom seen during the day; and even when seen, if they are not hungry, or attacked, or otherwise annoyed, they do not exhibit any pugnacious disposition, but rather remain in their squatting places, or even slink out of the way. He is not indeed, in any sense of the word, a fighting animal, whieh uses his powers, great as they are, for the purpose of showing off.

Those animals whieh, as one would say, fight for fighting's sake, are seldom carnivorous; and the ones whieh are most so, and have a pugnaeious habit, are probably dogs. And even they, though they worry each other in a state of domestieation, for reasons whieh are not very easily explained upon any animal prineiple, probably fight no battles, save battles of gallantry, when they are in a state of nature. We do not know mueh about them in that state; but it is probable that they are, to a very considerable extent, gregarious; and that, as is the case with most, if not all, gregarious mammalia, the males, are polygamous or rather indiscriminate and temporary in their attachments. All animals which have these habits are more or less pugnacious during the pairing time; and this pugnacity appears to be not wholly without its use in keeping up the eharaeter of the speeies. It is a remarkable fact that, among all sueh animals, the female gives a very deeided preferenee to the stronger males; and the combats of gallantry are obviously eondueive to the same purpose.

Several species of the cat family are also, to a eonsiderable extent, polygamous, or at least indiserimi-nate; and of eourse battles take plaee among the males of them; and it is worthy of being borne in mind, that where such is the case, the male seldom pays any attention to the young, and in many instances is apt to attack and destroy them. Lions are monogamous, always found in pairs, which are attaehed to eaeh other, not merely during the season of intereourse, but for life: and though the greater part of the labour of feeding and proteeting the young, during the comparatively long period which they require to arrive at maturity, falls upon the female, it does not appear that the male treats the young with any positive hostility. How often they breed in a state of nature is of course not known; because the acquaintanee whieh man forms with lions in a state of nature, is neither very long nor very intimate. It is probable, however, that owing to the length of time whieh the eubs require before they come to maturity that the breeding is not every year, or even every second year; and it is probable, though not proved, that when the young are able to provide for themselves the old ones may drive them from their haunts, in the same manner as is done by eagles; for lions are seldom met with in more than a single pair in one plaee, unless when there is a lioness and her cubs.

The lioness goes about four months with young, and the eubs when dropped are of a very small size, and without any indication of the mane or the terminal brush on the tail of the males. They are not born blind; but their ears are soft and partially dependent, and they are without eanine teeth or retractile claws, the arms upon whieh they ehiefly depend for their subsistence when full grown. There are also certain markings of colour in the cubs which show that there is some natural affinity between lions, at least in their young state, and the striped and even the spotted members of the genus. The young lions have a blaek line down the baek, and transverse bars alternating with spots along the sides. These stripes and spots are obscure, and they are gradually obliterated; but they are general, and belong equally to both sexes, while young. At the age of about twelve months, the canine teeth of the eubs make their appearance; and judging from what happen from lions in a state of confinement, it is supposed that the cutting of those formidable teeth is a very trying time with them. In about a year and a half, the elaws acquire their retractile eharacter; and soon after the cubs begin to play the lion on a small scale; but the mane and brush do not appear till the end of the third year, nor do they arrive at full maturity till the end of the fifth. When full grown, the lion measures about eight feet from the point of the muzzle to the insertion of the tail, and the tail is about half that length, and generally ends in a small spine or claw on the middle of the brush; but this spine is attached to the skin only, and not to the terminal vertebræ of the tail; thus it is easily worn off, but whether in such cases it is again reproduced, has not been ascertained.

Some general notion of the form and bearing of the lion, when standing at gaze, or not excited, may be derived from the figure at the top of the plate "CATS;" but no figure or description can adequately represent the excited animal in full nature.

The general colour of the lion is tawny yellow, with the mane and the brush a little darker, and more inclining to sooty black, and there is generally some trace of the dorsal line remaining. The naked skin about the muzzle, and the pads on the paws are dark coloured, but not a deep or entire black. It is not very easy, however, to describe lions by colour, for they are subject to considerable variations in different places, and perhaps also in different individuals of the same locality. Thus, in Southern Africa there are lions with the mane nearly black, and very shaggy, while those which are found in India are all over of a uniform yellow colour, and have comparatively little mane.

The range of the lion, as at present found, may be described as extending from the secondary hills on the south of the Himalaya to the southern extremity of Africa, though it is not very probable that they are met with to the north or east of the great Asiatic chain of mountains. In the earlier periods of history we have evidence that they were plentiful in all the more thinly-peopled districts of Asia, to the south of the great central ridge; and that they were both frequent and dangerous visitants in some of the more inhabited places. In those times, that part of the world was much more fertile than it is at present; and that though many parts of it were much more thickly peopled than they are now, the intermediate places between the different kingdoms and states, which were comparatively small, and at very frequent hostility with each other, were of a very different character from the deserts which are now to be met with. We have evidence that there was much more cover for lions, and, which is more to the purpose, more food for antelopes, wild asses, and those other animals of comparatively warm and dry, but not absolutely barren places upon which lions chiefly subsist. There are accounts by the ancients of lions being numerous in Syria, and even in Asia Minor; and it is possible that they existed in the middle ages, and may still exist in many places of that country where they have not been observed. The name of the lion is a familiar one in all the languages of the nations throughout the whole extent which we have mentioned as forming their range; and the case of India is one which should make us pause before we decide, that there are no lions in the wild places of those countries where there is cover and food for them. In the days of the glory of the Indian empire, when the country was very generally peopled and cultivated, lions had long ceased to be met with, and they were described as being wholly extinct. But it appears that the remains of them had been only banished into the most inaccessible and least known parts of the country. For no sooner had the internal wars, by which India was so long disturbed and distracted, depopulated large tracts of the interior, and allowed them to revert to a state of jungle, than the lions made their appearance, and afforded a complete proof that, though reduced, they never had been exterminated. But they keep more in the wilds than tigers, and are neither so bold nor so active, though their spring is more terrible, and their teeth and claws more powerful; and thus they were not seen while people were but too familiar with the ravages committed by their congeners.

All the power of the lion, great as it is, is concentrated in the fore part; and though the stroke or the clutch of the paw, at close quarters, is rather a serious matter, the lion in free nature is, like the birds of prey with their stoop, truly formidable only in his spring.

The roar of the lion, for the production of which there is a very peculiar organisation of the throat, is very terrific,—deep, solemn, and heard afar, and startling to all the animals of the wild. It is not uttered during the day, at least till the sun is set, or nearly so; and it is said to be given most powerfully when the evening sky is murky, and the clouds threaten a storm during the night. These are favourite times for the grazing animals which form the lion's prey, and it is said that he betakes himself to an eminence, and sounds his terrific battle charge, in order to startle those animals, and enable him to find out the place where they are by the sound of their feet while they attempt to trot off to places of safety. But after the roar has given him the necessary information, the lion steals softly and silently upon the sound, crawling upon his belly from bush to bush, or from thicket to thicket; and the unsuspecting herd are not aware of their danger till the yell is given, and contemporaneously with that, the spring is taken, and the victim secured.

Unless when wounded, irritated, or pinched by the extreme of hunger, the lion does not attack parties and caravans with the same boldness and determination as the tiger. But he will follow, stealing and prowling for a much longer distance, and the nature of his haunts require it, as they do not abound so much in cover as those of the tiger.

There are numerous instances mentioned of the courage, the kindness, the docility, and many other qualities of the lion in a state of confinement; but all these are of little value in the natural history of the animal; and therefore, though space admitted, we should hardly force them upon the notice of our readers. They of course do not in any way alter the character of the lion; though they may be received as additional proofs of the otherwise well-established and indeed self-evident proposition, that the powers of the lion are never brought into play unless there is a sufficient exciting cause; and the same may be said of every other land animal with which we are acquainted.

The majority of those animals which civilised man can domesticate with advantage, must, however, always be those which feed upon vegetable matter, whether their labour or their flesh be the object for which they are domesticated. This follows as a necessary consequence of the cultivation of the ground always being the chief means to which civilised nations must have recourse for their support. In this respect, the vegetable-feeding animals and man work well together—because the refuse of human food answers in part for the food of those animals; they supply manure better adapted than any other for increasing and preserving the fertility of the fields; and those plants which are more exclusively used for food to such animals, instead of exhausting the land, improve its condition, and render it more productive of human food than it otherwise would be.

Carnivorous animals, on the other hand, are of no use in these respects; and therefore the different varieties of the dog, and the domestic cat, are probably all that can be bred in a domestic state with any advantage; and though it may be necessary to keep a few individuals of all the other species for the purpose of promoting the knowledge of nature, yet the number of these must always be limited; and, as even this limited number cannot be considered as part of the domestic creation, it is only a very limited portion of their history, and that portion, far from the most interesting part of it, which can be obtained from them in that state. If we would see them in their true characters, in whatsoever of grandeur or of any other striking attribute they may possess, we must seek them in their native haunts; and the more powerful that they are, the farther are they removed from the habitations of man.

This is peculiarly the case with the lion. Africa may be regarded as the wildest portion of the eastern continent; and therefore it is in Africa that we can see the lion in all his majesty, and have a proper conception of the physical powers which this animal possesses. In many parts of that continent his dimensions considerably exceed those which have been mentioned as the average in the preceding part of this notice, the length being sometimes more than nine feet, and the height nearly five. The lioness is generally about three-fourths the size of the male in lineal dimensions, and being without the mane, she does not look nearly so formidable. The mane of the lion is not confined to the upper part of the neck, but surrounds it on the sides, and even on the chest below. It is very closely set; and the hair of which it is composed is, in the largest specimens, more than two feet in length. This formidable clothing is with difficulty penetrated with any ordinary weapon. When the animal is prowling or using only his common powers of locomotion, in the use of which he is generally slow and majestic, this mane lies a considerable way over the back, hangs down over the shoulders, and thus protects the powerful muscles which put his destructive arms in motion from all changes in temperature, so that they are never stiffened by cold or relaxed by heat, even when he finds it necessary to prowl in the open deserts, either during the night or during the day. There is a beautiful adaptation of nature in this particular part of the covering of the lion. On the African deserts, the heat, even far without the tropics, is excessive during the day; but during the night the cold is often much greater than would readily be supposed. This is in great part owing to the excessive heat of the day and the dryness of the surface. The reflection of the ground makes the lowest stratum of the air as hot as an oven; and as the capacity of the air for moisture increases more rapidly than even the temperature, its thirstiness during the day is greater even than during the heat; but after sunset the air becomes cold, and its tendency to part with the moisture which it holds in solution increases faster than the cold, so that dew forms in the air itself, and instead of being produced on the surface of the ground, as it is in colder latitudes, it is actually evaporated by the ground, and this evaporation, where the ground is negative of vegetation, produces in the night air a degree of chilliness, by which travellers in the desert often feel themselves much more benumbed than if they were abroad in the night during a Lapland winter. On nights of this description, the male lion is often on the prowl, and the prey hovering in the neighbourhood of the caravans, which usually have their camels ranged in a circle round them, or in quest of the antelopes and other animals which are couched on the desert for the night. When he watches the caravan he prowls in silence, and never betrays his presence by a roar, or even by the sound of a foot fall, until he is sufficiently near for taking his spring; and then the yell and the capture of the victim are instantaneous, and he has gone, prey and all, before resistance can be offered. But when he ranges for the wild animals of the desert during the night, his conduct is different. He then roars; and in doing so he brings his mouth very near to the surface of the ground, by which means the roar is heard to a greater distance, and he is better enabled to hear the sound of the alarmed animals, when that terrible war note is sounded. Even the lightest antelope, being a hoofed animal, and with its hoofs hard, makes a considerable pattering on the sand, especially when it bounds in terror at the voice of the lion; and thus the quick ear of that animal is not only enabled to ascertain the direction, but how far the animals run, and where they halt, and thus he can come with his silent and stealthy pace, till he is within that distance at which the capture of them is certain. During the night, those animals do not, and cannot run very far, because they are in so far benumbed with the cold, and that cold exhausts them on their march, as cold is observed to do with horses during a keen frost. The lion, however, protected he is by the mane, is subject to no such calamity. The muscles which he uses in his prowling march are strong, and they are so slowly used as not be in the least heated or fatigued, when those which he has to use with greater effort while he springs, are secured by the thick covering of matted hair, which invests the neck, shoulders, and chest. The lioness, in general, prowls less in the open desert than the lion, and therefore the same kind of protection is not so necessary in her case. She is chiefly in the thicket, at or near the den; and it is understood that till the young are able to find the greater part of their own food, the plunder which the male makes during the night is carried thither as a common meal to the whole family; and the strength of the lion is such, that he can carry off not only one of the largest antelopes, but a wild ass, or even a buffalo, when he has torn out the entrails of the latter, upon which he usually feeds before carrying the carcass to the den.

It is not, however, when prowling in these deserts by night, and during the dry season, that the action of the lion is upon the grandest scale. He is more majestic in the majesty of scenes, and also in the majesty of the elements. The lion is not in all probability much of a migrant; and though he shifts his ground according as prey is for him to be found, it is not probable that he follows the great herds of migrant animals of Southern Africa throughout the range of their whole migration. When the plains are so completely burnt as to afford no pasture, and all the water has disappeared from the smaller streams, lions cease to frequent the thickets on the margins of the pastures, or those by the sides of the usual watering places of the migrant animals while the plains remain fertile; but on those occasions they betake themselves to the neighbourhood of perennial rivers, or to the forests of acacias and other trees, where there are still food and browsing animals. In the former places the larger antelopes and buffaloes are to be met with; and in the latter the giraffe, an animal which subsists chiefly upon the leaves of trees. The antelope is an easy prey; because the spring of the lion is sufficient at once to dislocate the spine of that animal, or to fell it to the ground; but the buffalo and the giraffe are a prey which require more art in the capture. It is true that several species of the antelope will attack the lion boldly, and transfix him with their horns if they find him in the open plain; but if he can spring upon them they are incapable of resistance.

The buffalo and the giraffe must also yield if the spring is rightly taken; but they are much stronger animals, and unless the lion can grapple at once with the muzzle of the buffalo, the skin of that animal is so firm, and its muscular powers so great, that it is able to shake off the lion, and turn and toss him with its horns, and trample and kneel him to death, before he can make his escape. He therefore springs upon it so that he can retain his hold on the shoulders with the hind feet, and grasping the muzzle and chin with his paws, wrench the neck aside till it is dislocated, or till his weight, acting on the lever power thus obtained, throws the animal down and enables him to despatch it by tearing the throat. This mode of attack requires the spring to be taken with more certainty, and also rather at a shorter distance than is necessary in the weaker animals; and consequently it requires more lying in wait. Buffaloes are also animals of very keen scent, and hence it is probably necessary that the lion should "take the wind" of them. They are also strongly excited by the sight of blood; and thus they are never in such repose near where the marks of former slaughter are to be found as that the lion can with certainty attack them. Thus, buffalo hunting is one of the hardest occupations of the lion, and consequently one to which he never resorts, while any other can be carried on.

The giraffe is not so formidable at close quarters as the buffalo, but still there are difficulties attending its capture. Its feeding grounds are not the most tangled parts of the forests, but rather those in which the surface of the ground is comparatively clear, and the trees on whose foliage the animal feeds at some distance from each other. He cannot steal upon the giraffe so as to spring at it in front, because, in that case, he would merely catch the tree, and the animal would escape beyond his reach before he had so far recovered himself as to be in a condition to spring a second time. There are also difficulties in an attack on their rear. From the position of its eyes the giraffe commands the view behind it much better than that before, especially when it is feeding, with its long neck extended upward to the branches. There is also a very powerful weapon, as well as a watchful eye, in the rear of this animal; for its hind leg, though much shorter than the fore one, is yet so long, and it can strike out with so much rapidity, that a single blow taking effect, would fell the lion to the ground, or even fracture his scull. This animal has therefore to be taken by stratagem, more so perhaps than even the buffalo; and it is chiefly when it resorts to the water, and is in the act of drinking, that it becomes the prey of the lion. Long as its neck is, it has to place the fore feet at a considerable distance from each other in order that it may reach the water, and the position of its head when so doing prevents the use of the eyes and the ear. Thus it is incapable of observing the approach of its enemy, and it is not in a good attitude for striking with the hind foot, although it could see him.

The places where water is found in the dry season, which is the chief time at which the lion preys on the giraffe, are, generally speaking, rather favourable for the attack of the lion. African rains fall so fast, and flood the water-courses so suddenly and to such an extent, that these are deeply worn, and in many places present rocks and hummocks high above the surface of the water in the dry season. On these the lion takes his post at the usual time when the giraffe comes to drink; and thus he is enabled to fling himself on the body of the animal, and tear its flesh with both claws and teeth, while it darts off at its swiftest pace. But it has no means of shaking off the spoiler; and thus, as the giraffe is not a very swift animal, the fatigue of the flight, the weight of the lion, and the agony produced by the action of all his lacerating instruments, speedily bring it to the ground, where it is soon in pieces. It is impossible to know experimentally what is the degree of pain occasioned by a lion riding on an animal and rending it all the time; because no one can feel that terrible infliction and survive to give any account of it. But if we may judge from casual wounds given by the clutch of one paw, or even of a single claw, we can easily perceive that it must be among the most terrible tortures to which the living body of an animal can be subjected, in consequence of mechanical laceration; and it is *possible* that, as the breath of the lion is peculiarly offensive, that there may be some quality in that, or the saliva, which may increase the irritation and agony of the wounding. The mechanical action is, however, of itself sufficient to produce great pain, by all the instruments which are at work for the destruction of the victim. The claws and the great canine teeth have all, to a certain extent, angular or tearing ridges, sharp enough to wound, but not so much so as to make a clean wound, while the tearing teeth, both by the form, and the double motion of gnashing them against each other, and writhing the bite, must much increase the pain to the animal; and it is possible that the abrasion produced by the tongue, with its thickly set and sharply pointed hooks, may not, after the skin has been divided to a considerable extent, be among the most painful parts of the process. There is this advantage, however, that not the most powerful animal can live long under the claws and teeth of the lion.

It is, however, when the elements are in all their grandeur, that the lion appears to be most in his glory and in his element. It has been already mentioned, the favourite times for the roaring of the lion are about sun-set, or a little after, upon those nights of lurid and portending skies, where there is every probability that the resistance of the lower atmosphere will give way, and the storm break about the turn of the night. We find that the portending storm, after long drought, produces an unusual stir among the animated tribes, even among those of our peaceful climate; and it will readily be understood, that where things are on so much grander a scale as they are in Southern Africa, the excitement must be proportionally great. The fresh activity thus displayed is, on the part of the animals, a grateful though instinctive anticipation of the plenty which is to be the consequence of the storm, and we must suppose, that as the lion is part of the system, he is affected in common with the rest, Indeed his share comes first, and in this respect at least he deserves his common title of king of the beasts; but this enjoyment is death to the rest; and as they are thrown off their guard by the excitement of the time, he is enabled to commit far more havoc than usual; and, as if he loved the sport, he, on these occasions, is said to kill far more than he is able to eat.

The first part of the storm consists of lightning and thunder, the former very vivid and the latter correspondingly loud; and both are so incessant, that the eye of the excited lion would glare, and his voice roar, in vain, either for the alarm of any animal or for the warning of its danger. The wondering animals crowd into masses and stand exposed in the open places, betrayed to the eye of their murderer by the incessant gleaming of the lightning; this continues after the clouds have given way, and while the wind blows in hurricanes and the rain falls in floods.

It is but seldom that men have the opportunity of beholding these sublime displays of natural power; but sometimes the lions get so excited and emboldened upon those occasions, that they attack the domestic animals close by the habitations of remoter colonists, and carry their war into the heart of the villages of the native Africans, to make reprisals for the injury done to them by the poisoned arrow and the assagay in more peaceful times. Thus it is in the midst of the mightier commotions of nature, when man must keep within his shelter, when all appears going to wreck, and when much is actually so going, that the power of the lion is fully displayed.

We shall close our notice of this much, long, and not unjustly celebrated animal, with only a few short observations. There is this resemblance between the lion, which, when he has the advantage of his spring, is unquestionably the most powerful beast of prey, and the eagle, which, when she has the advantage of her stoop, is as unquestionably the most powerful of predatory birds, that in all cases where the stroke, or the clutch of the claws, is sufficient to occasion the death of the prey, that prey is never touched with the mouth until life is extinct; whereas in the less powerful animals of both classes, the mouth is called in to assist the other weapons from the very beginning of the attack. Farther, the lion's whelps, before they have their tusks or their protractile claws, are exceedingly playful; and they are suckled for about twelve months. The lioness is naturally much weaker and also milder of disposition than the lion, and does not hunt so large prey for the supply of her own appetite; neither does she prowl so much by night in the bare and dry deserts, or play so bold a part during the breaking of the storms. But her attachment to her young is very strong, and in defence of them, or in quest of food for them when they are hungry, she is quite as ferocious and even more indifferent to personal danger than the lion himself. When lions are young and vigorous, they seldom appear without the brakes and forests; but when they grow old, and are incapable of so constant or so powerful motions, they venture nearer to human habitations, and prey more upon domestic animals, which are less fleet and also less fearful than wild ones. When the male lion is not excited, he is not dangerous to man nor any animal; and when a traveller comes upon him, either couching in a thicket or pacing slowly and carelessly along, if, after his eye has caught the traveller, his mane and tail remain motionless, he will do no harm unless irritated; but, if his mane begins to stand on end, and his tail to be erected, and especially to lash against his sides, these are sure signs that he is working himself up for mischief. The age of the lion, in a state of nature, is not exactly known. In confinement, it has been ascertained that some individuals have lived to the age of seventy years; and it is at least probable that, when free from restraint, he may live considerably longer. The number of young in a litter is not very well ascertained; but there have been instances of as many as nine in a state of confinement, and it is reasonable to suppose that the broods should be more numerous, rather than fewer, in a state of free nature.

Though the lion has probably more powerful muscles than any other of the mammalia, those muscles have not the same firm and rigid character as those of the eagle. The reason of this is, as it should seem, that their powerful action is much more momentary.

The flesh of the lion is certainly not so delicate as that of less energetic animals, as the coarseness of the muscular fasciculi is generally in proportion to the power of action in animals; but the toughness is more in proportion to the constancy and continuity of their action. In Africa, the Negroes occasionally eat the flesh of the lion, and some Europeans have pretended to like it—but the general report is that it is rank and disagreeable. The skin does not come under the usual denomination of fur, as the hair is short and rather coarse; but it is tough and durable. The ancients were fond of it on account of the fabled heroic account of its owner, and they made it a robe of distinction for their heroes; but the heroes of modern times prefer the skins of the more showy members of the genus, and these they use, not as ornaments for their own bodies, but as caparison for their war horses. The natives of Africa use it indiscriminately as a mantle and as a covering for their beds, and in both cases it is very durable.

THE TIGER (*Felis Tigris.*) Next to the lion, the tiger is the most formidable of this genus; and as it is a much more generally active animal than the lion, and consequently a much more frequent feeder, it is more destructive and also more dangerous. The danger is increased by the nature of the places which the tiger frequents. It is not, like its congener, an inhabitant of the desert, but of the rich jungles, where prey is to be found at all seasons; and as these are more in the vicinity of human habitations than the favourite localities of the lion, many more human beings fall victims to the rapacity of the tiger.

A very spirited figure of the tiger, in form, in markings, and in attitude, is given in the plate "CATS." This figure is not in the attitude from which the tiger takes its spring, but in that of advancing in a low and crouching attitude in order to gain the distance at which he shall take it; and this is perhaps the best for displaying both the litheness and the symmetry of the animal. It will be seen in the figure, which is equally faithful and spirited, that the tiger is a much more symmetrical animal than the lion; that, though the fore paws are still stronger and more firm in their texture than the hind ones, yet, that the strength of the tiger is more uniformly distributed over the whole length of his body than that of the lion; and consequently, that he is much more an animal of chase.

The name *Tiger*, in the Armenian language, means an arrow or javelin, and the Hindoo word *Tippoo*, which is the general name of the tiger in the East Indies, has much the same signification, as it imports "that which rushes impetuously and irresistibly." The river Tigris is so called from the swift and arrow-like rush of its current; and it is not uncommon in India to give the name of Tippoo to bold and relentless warriors, of which Tippoo Sahib was an instance; and it is worthy of remark, that while Tippoo, or the Tiger, is the name for a great warrior or a powerful chief in the southern parts of India, Singh, or the Lion, is the name for the same sort of personage in the northern parts. This difference of name is important, as pointing out the geography of the animals; the epithet Singh being used only to the north of the central height and the Nerbudda, and the epithet Tippoo only to the southward; thus marking the tiger as a more southerly and easterly inhabitant than the lion, and also the inhabitant of more fertile districts, though tigers are occasionally met with in the country of the lions, and lions, though more rarely, in the country of the tiger.

The length of the tiger is rather more in proportion to the whole size of the animal than that of the lion, and the tail is also rather longer; the length of the body sometimes exceeds nine feet, and the tail is about five feet in length; the legs are rather shorter, and the animal bends them more, and has more of the snake-like flexure of the spine when he walks. The head is less square than that of the lion, the features are not so grim and formidable to appearance; the cheeks appear much more rounded, which is in part owing to the thick fur with which they are covered, and the absence of the eyebrows and the mane cause the animal to look less ferocious than the lion, though, in reality, he is equally so, if not more. The absence of the eyebrows and mane indicate a difference of habit in the animal, and this difference is farther pointed out by a difference in the structure and appearance of the eyes themselves. The shaggy mane of the lion defends him, as already observed, from the great changes of temperature to which the nature of his haunts exposes him; and as, during the dry season, even the bushes among which he resides afford him but little shade from the rays of the perpendicular sun, the projecting brow makes up the deficiency. The richer vegetation and more expanded foliage in the haunts of the tiger, render those protections unnecessary in his case; and thus, as nature is never redundant any more than she is defective, the tiger is not furnished with these. The pupil of the lion, which, when he ranges in the strong light, which he seldom does in exposed situations, contracts to a circle even in its greatest contractions; but that of the tiger, though round when distended, and even when moderately open, closes to an oval and almost to a short line in very strong light. This form of the eye enables the tiger to see above him when he springs upward, and below as he descends when he is bounding through the tall grass of the jungles, and thus his whole muscular exertion is, on these occasions, left to the general movement of his body. In consequence of this consent of the whole body to the one species of action, the tiger is, according to a very general law in animal mechanics, enabled to bound through the jungle a long time without being fatigued, though the character of its vegetation requires that each bound should be taken very high, and for a distance proportionally long. The flexibility of the joints, and the readiness with which the spinal column arches and extends itself in accompaniment to the legs, tend greatly to lessen the labour of the tiger's march in these places, and thus the tiger can keep in motion for miles, in situations where the lion, notwithstanding all its strength, would be exhausted by a march of a single furlong.

The ground colour of the upper part of the tiger is straw yellow, of much richer tint than that of the lion, and passing into pure white on the under part; the whole is beautifully marked with cross bars of black, of a spindle shape, or broader in the middle than at the ends; and, where they run to considerable breadth, the middle of them is often relieved by a narrow streak of paler tint, sometimes approaching to the yellow of the ground colour. These markings vary considerably both in number and in size in different specimens, but they always contract very strikingly both with the yellow and the white. The ground colour of the tail is intermediate between the deepest yellow and the purest white of the body, and finely, and in general very regularly annulated with black. The interior of the ears, a space round the eyes, the cheeks, the throat, and the muzzle, are also white, and there is a white soft and thick fur projecting forward on the under part of the chin. The eyes, when the animal is in a state of repose, are more yellowish in the tint than those of the lion, and when it is excited, and they glare, they have more of a greenish cast. The absence of brows and the rounded form of the head, make the eyes stand out more than in the lion; they are also more restless, and when the animal is incensed they are probably more terrific.

As the male tiger has no additional furnishing of hair, excepting perhaps that on the cheeks, and the chin is a little more produced than in the female, there is much less difference of appearance, and also of strength and of habits in the sexes, than there is in lions. But still the tigress is, upon the whole, a milder animal than the tiger, unless when she has cubs, at which times she is perfectly ferocious in their defence. The period of gestation in the tigress is not ascertained with perfect accuracy, neither is it known whether the duration of it may not be, in part at least, modified by circumstances, though such modifications can of course take place only to a very limited extent. It is generally understood to last between three and four months. As predatory animals are much less dependent on seasonal supplies of food than those which live upon vegetable matter, their breeding times are not so strictly confined to definite periods of the year; and as, in the richer parts of tropical countries, the difference of seasons are very slight, even the birds are quite miscellaneous as to the periods when they build their nests. This being the case, we may naturally suppose that tigers, which invariably inhabit rich places, breed indiscriminately at all times of the year. We have a very striking instance of this difference of breeding in the case of herbivorous and carnivorous animals, and also in the differences of different genera of the former in our common domestic animals. The horse is pretty constant as to breeding time, and so are sheep and cattle when they are left exposed to the weather the greater part of the year; but dogs and cats have no fixed season, but produce young indiscriminately, summer or winter, spring or autumn. In the case of the horse it does not appear that difference of treatment very much changes the period of breeding, though in proportion as the climate is warmer, and they are better fed, they upon the whole breed earlier. Cattle and sheep, especially the former, are much more obedient to circumstances. The natural period for sheep to bring forth is in the spring, earlier than that of cattle, but by management the time may be carried forward into the winter; and thus we have house lamb fit for the table, a month or two before the time ewes, left exposed to the weather, drop their young. In the case of cattle again, this period may, by management, be extended over the greater part of the year, so that if there is a demand and a price for it, veal may be had for the market at all seasons. It is natural to suppose, however, that these young animals, bred out of the natural times, are neither so racy nor so wholesome as those which are produced at the natural period, just in the same manner that animals of which the fattening is forced by indolence and cramming, are never so wholesome and so savoury as those which have the free range of good pasture.

In those circumstances, simple as they may appear, there is a good deal to be learnt respecting the geography of the animals; and this, when we can get any satisfactory clue to it, is always a very important matter, as affording more insight into the general history and economy of nature than we can obtain by any other means. It will readily be understood and admitted, that no domestication or artificial treatment can wholly change the nature of any animal any more than it can change the organisation; though it may so far obscure the original character, as that it may escape the notice of ordinary observers.

In devoting one short paragraph to this important point, which we can better do here, where it has arisen naturally, than if we had written a separate article on the subject, the technical name of which might have prevented those for whose benefit it is intended from reading it;—in devoting a single paragraph to this point, we shall put carnivorous animals altogether out of the question. When we do so, we find that the others point very plainly, if not to their original latitudes, at least to the kind of surface upon which we might expect to find them in the wild state. The horse, as the least obedient to cultivation in this respect, evidently points out a native locality in those dry plains in the middle latitudes, which have the alternate seasons of fertility and barrenness strongly marked; and these are exactly the places in which analogous races of animals are still to be met with in the wild state—the plains of central Asia for instance, northward of the line of the Hindoo Kosh. The sheep, which are a little less seasonal, or are more easily diverted from the proper season by artificial means, point out a native locality where the succession of the seasons is less uniform; and there is some reason to believe that the parent stock of our domestic breeds is the moufflon of the mountainous parts of the south of Europe, and especially of the islands in the Mediterranean. As in so far corroborative of this fact, it has recently been ascertained, by experiment in Malta, that the moufflon will breed with domestic sheep. The ox again, which in this respect is the most obedient to art, points exactly to those places where animals of the genus are still met with abundantly in a wild state,—the humid plains of the middle latitudes, where vegetation is nearly or altogether perennial.

Tigers are, as we have said, more independent of this seasonal influence than almost any others even of the carnivorous animals. They not only inhabit the warmest latitudes, but they inhabit the most fertile places of those latitudes; the regions, in short, where the vegetation is in continual growth, and where, in consequence, those animals upon which tigers prey find plenty of food at all times, and are in consequence very numerous. It does not appear that the tigress is so productive at a single litter as the lioness, but it is probable that she breeds oftener. Four or five is the usual number; and when they are produced they bear a very considerable resemblance to young lions, though it is probable they come rather sooner to maturity, and are perhaps not quite so long lived. The life of animals is very generally, though not invariably, in the inverse ratio of their activity; and, upon the whole, the tiger is a much more active animal than the lion. Savage as those animals are when they are hungry, or when alarmed or irritated, there is no animal more attached to her young than the female tiger. The determination with which she will fight in their defence, and the dangers which she will encounter to prevent them from being taken, or to recover them after they are taken, are truly wonderful. On such occasions she will enter a city, or encounter a whole army; and when she does not succeed in recovering her offspring, her cries are the most piercing, and also the most piteous that can well be imagined.

The cry of the tiger, even upon ordinary occasions, is much more appalling and even horrid than the lion. There is grandeur in the deep and full tones of the latter animal; but there is neither majesty nor music in the voice of the tiger. It begins with deep, slow, and melancholy growlings; these gradually become more acute and hurried, till they terminate in a piercing cry, of which no description can be given, and this cry finishes with a convulsive jarring, as if the rocks around were shaking to pieces. This voice is very loud, and when it is uttered in the forests, it is so repeated in echoes, that the roaring of one tiger is heard as though the place were surrounded by numbers of them. These cries are generally uttered during the night; and, blended as they are with the yelpings of jackalls and hyænas, and the alarmed cries of all those beasts and birds which are terrified at the sound, they render night in the tropical forests any thing but a season of repose. Nor fares it much otherwise in the early part of the morning; for no sooner have the beasts of prey become silent, than the larger quadrumana begin their howling; and when they cease, the chatter of the monkeys, and the screaming of the tree birds, keeps the forest alive all the remainder of the day.

The countries around the Bay of Bengal, with the larger islands of the Malay peninsula, are the principal habitations of these formidable animals; and they appear to be large in size and powerful in action, in proportion as the ground which they inhabit is fertile.

There is, perhaps, no river in the world which has made so extensive deposits in the lower parts of its valley, or where the portions near the sea are so closely tangled with vegetation, or so thickly stocked with animals, as the Ganges. The Sunderbunds, or islands formed between the different mouths of the

Ganges, and the name of which signifies a forest of rapidly-growing trees, form altogether a triangle, each side of which is nearly two hundred miles in length, or altogether it is not much less than England. This may be considered as *par excellence,* the demesne or park of *Tippoo,* in which he reigns in splendid but ferocious majesty. It is true that he has some subjects who do not very much regard his sway upon ordinary occasions, but these are not exceedingly numerous. The elephant and rhinoceros are both met with in this singularly blended scene of life and death ; but the ground is rather soft for their heavy tread, and they are consequently but rare. The gavial, or crocodile of the Ganges, is however exceedingly numerous, and very large ; and though but a slow and sluggish animal upon land, it often makes prize of the tigers when they come to the waters to drink. But, with the exception of the three species now mentioned, the tiger lords it over all the animals of this wide region, and very often issues from it to invade the plantations and even the villages which are in its vicinity. Swamps and jungles of smaller dimensions are formed by the back water of all the greater rivers of India, and indeed in every place where the water stagnates ; and where such jungles are formed, tigers are always to be met with. The greater number of them keep within their jungle, because the woody jungles are generally interspersed with grassy ones, in which deer, antelopes, and other animals pasture ; and the woods themselves afford an ample supply of wild hogs, monkeys, and other animals, of all of which the tigers make prey. Sometimes, however, they issue from their fastnesses ; and as when they do so they are generally in a state of great excitement, they commit terrible ravages, and are generally destroyed by the people rising *en masse* to hunt them, and those hunts, as well as the hunting of the tiger for sport, are attended with no inconsiderable danger. When they make these inroads into the habitations of men, or of tame animals, they kill much more than they eat ; and it has thence been concluded that tigers are endowed by nature with a love of slaughter unknown to any other animal. It does not appear, however, that this is the case ; for though the tiger comes more into the settled and peopled grounds than the lion, yet he is not exactly in his native element there, but is excited, and generally also alarmed, and therefore he does not rest to eat what he kills, but goes on attacking and killing indiscriminately. In his native jungles, there is no reason to believe that he commits murder for the sake of murder, but simply that he seeks his food according to the general law observed by all animals ; and that, when fed, he is in repose, and quite harmless, as well as the rest. Tigers are much more numerous in those jungles than perhaps any other beast of prey is in any part of the world ; and as the individuals are all very like each other, it is possible that this character may have arisen from one tiger getting credit for having done that work which was really the performance of a dozen or more.

Many of the islands and muddy banks in the tiger's country are held as sacred by the superstitious Hindoos, and as such, they are resorted to by devotees. These devotees very often fall a prey to the tigers ; but as not a few of them go to such places for the express purpose of seeking death, it is possible that death by a tiger, by being more brief, is attended with less real suffering than starving to death in a region where the atmosphere is pestilence. When the water is high, and boats can pass near the trees which cover these islands, such approaches are highly dangerous, because a tiger will spring for a very considerable distance from the jungle upon a boat full of armed men, and make off with one of them before the rest have time to offer any resistance. Even when parties of mounted soldiers ride too close to the tiger jungles, the tiger will sometimes spring, seize a horseman, and be off with him almost before the others are aware of it.

In places which are not so humid as the jungles of the Sunderbunds, tigers do not attain the same size, but they are more active, and on this account more dangerous to the inhabitants. In the larger islands, Sumatra and Java especially (we know less of the interior of Borneo), these animals are highly destructive. They not only intercept the people in journeys through the woods,—and, from the nature of the climate, the greater part of the surface is either wood or cultivated fields,—they also carry them off not only from their field labour, but when they are busy at the doors of their houses, and even when they are inside. They will sometimes descend or issue from the woods in a troop upon a village, and destroy the whole inhabitants ; and there are many places of those islands where, from a sort of foolish superstition, the people take no pains to thin their numbers. The general superstition is, that if they make a wanton aggression upon the tiger, he will wage a war of extermination against their family ; but, on the other hand, if the tiger is the aggressor, they conceive themselves entitled, in as far as they are able, to wage a war of extermination against him. There is no doubt some show of iniquity in this tacit code, but the misfortune is, that only one of the parties can be made to understand and obey it, and that thus it induces the people to spare those animals to the destruction of many of their own lives ; the more so that, from the nature of the country, there is cover for tigers in the close vicinity of almost every village. The people are not, however, without dexterity in the capture or destruction of tigers, when once they can be induced to undertake that operation. Sumatra and Java are, generally speaking, too tangled with woods for admitting of tiger hunting, even with the assistance of elephants ; and therefore the people have recourse to traps, pit-falls, and gins, in the formation of which they display no inconsiderable ingenuity.

Though the tigers of these islands are not so heavy as those which are found in the jungles of Bengal, they are exceedingly strong, as well as active. It is reported that they can break the leg of a horse or a buffalo, not by the force of the spring, but by the mere stroke of the paw, while the bite is sufficient to hamstring and cripple an elephant, and they are said to aim at that part of the animal. But the elephant, in a wild state, is seldom to be taken unawares in this way ; and if it must receive the spring of the tiger on the hinder part (and the tiger will not attack an elephant in front, unless by surprise), it crouches, and receives him on the upper part, where the skin is so tough, that the tiger can make but little impression upon it, and capable of so much motion, that the elephant shakes him off, and falls upon him, or stamps him to death ; nor does it quit the carcass till it has reduced the whole to a soft mass. Other animals, even the heaviest, are carried off to the woods with the greatest ease; and when he is thus enraged, he cares but little for musket-shot, if they do not hit him in a vital part. In his ordinary haunts, and when he is neither hungry nor exasperated, the tiger is, like all wild animals, afraid of fire, and in such cases a lantern is sufficient protection for those who have occasion to be in the woods at night; but when hungry or excited, fire does not deter him from making his attacks. Sharp shrill sounds annoy the tiger a good deal; and in some places where they are abundant, the people contrive to keep them at a distance by blowing a sort of horn which has an acute and piercing sound. But, formidable as the tiger is in these islands, he cannot be considered so absolute a monarch as he is in the jungles of the Sunderbunds. In these last, there is no animal to attack the tiger, save the gavial, and he is only in the water or on its margin; but in the islands, the great python, *ular-sawa* of the Javese, usually called a boa constrictor, though it is not a boa, except in manners, which are very much alike in all crushing serpents, occasionally makes prize of the tiger, and even lies in wait for him, and, strongly as he is built, and little as he cares for common wounds, the folds of this powerful serpent very speedily break his bones.

From his greater activity and daring, or rather, perhaps, from his frequenting more fertile places, the tiger carries off human beings much more frequently than the lion; but there does not appear to be much truth in the common saying, that he gives human flesh the preference. Beasts of prey, from the nature of their organs of taste, cannot be very dainty in their choice; and the probability is, that of prey equally within his power, the tiger takes that which is the largest. There is not more truth in the allegation of the older naturalists, that the whiskers of the tiger are poisonous. The breath of the animal is offensive, and both the bite and the tear occasion ugly and festering wounds, but that is the case with the whole genus. As was remarked of the lion, the saliva of the tiger may not be a very wholesome application to a wound; but there is no reason to suppose that any of the genus is furnished with a direct poison, as they are sufficiently armed without it, and nature, though she always does enough, never does too much.

The tiger has many more points of resemblance to the domestic cat, both in form and in manners, than the lion has; and in the few instances which we have of tame tigers, they are represented as playful animals. They are not, of course, very safe play-fellows, as if they are irritated, they become quite unmanageable; but still there have been instances in India, of full grown tigers being led about in chains, though, as is usually done with bears so led, they have been kept muzzled. The muzzling is, in the case of both animals, more an apparent means of safety than a real one, as the most formidable weapons of both are the paws; and these led tigers have, upon occasion, been unmuzzled, in order that they might show how a tiger deals with his prey, which cannot be so well or so safely observed in wild nature.

Now, nearly the same action may be seen by any one, who has the opportunity of seeing a wild cat kill a hare or a rabbit, and part of it is displayed by the domestic cat when in play. If you tumble the cat on her back, and tease her to an affected biting at your hand, she will embrace the lower part of your arm with her paws, and keep working away with the claws of the hind feet on the upper part, as if she were attempting to tear that part in length, and the wild cat, when she has sprung upon a hare or rabbit, and beat it down, seizes it by the throat with her teeth, and round the shoulders with her paws. Then she turns on her back, and by the action of the claws of her hind feet tears open the stomach. Even bears have a similar habit, and often tear open before they bite; the hugging and tearing jointly being with them the means of putting animals to death. When the led tiger was unmuzzled, and a sheep fastened to a stake by a rope offered to it as prey, it advanced crawling and cat-wise, till within the proper distance. Then it sprung, beat the animal to the ground, seized it by the throat, clasped it around the shoulders, and, turning on its back, tore open the abdomen with the claws of the hind feet.

It is probable that this mode of preparing for the feast is common to all the genus *Felis*, at least when their prey is of any considerable size; and, indeed, it is not easy to see how they could, in any other way, rip open the belly of an animal, without completely mangling the carcase; and it is well known to be the habit of beasts of prey to open their victims and devour the viscera before they proceed to eat, and, in the case of the weighter victims, before they carry off the body. There are some of the other carnivorous genera which first break open the skull and eat the brains of their prey, but that does not appear to be done by any of the *Felinæ*. They certainly do open the abdomen, and probably the chest, of their prey; and if they do not effect this by means of their claws, it is not easy to see in what manner they can accomplish it. We have an analogous case in animals of another class;—birds of prey, or, at all events, the golden eagle. When a rabbit or cat is thrown into the cage of that powerful bird, if the cage is large enough for allowing the bird to display even her habit at close quarters, the animal is, with the rapidity of lightning, struck down by the pounce, and the eagle is instantly seen over it with one foot clutching the throat, and the other the lower part of the abdomen. It is held in this fashion with the wings of the eagle shivering, as they generally are when she kills; and when the victim ceases to throb, which is very speedily, the Eagle, with one sweep of her beak, and in all probability with that trenchant hook on the tip of the upper mandible which projects over the under one, which other than this appears not to have much use, rips open the integuments of the belly as neatly as if it were done by the knife of a butcher. The claw of the carnivorous mammalia (at least of the Felinæ) appears to be used in the same manner, and thus they get at the viscera without mangling the carcase, which they could not possibly do by means of the teeth only.

It is very generally stated, in the books which profess to give accounts of this genus of animals, and particularly in descriptions of the tiger, that the first thing which they do is to gorge themselves by drinking the blood of the animal from the vessels, and that it is for this purpose that they plunge their heads into the cavity of the body. Now, it would be a very good rule in natural history, and one would think far from a harsh or unreasonable one, to make it binding on every one who asserts that an animal does any thing, to show that it is capable of doing that thing. How it does it would be desirable; but the other and simpler matter should be indispensable.

Well, upon this principle, we would bid any one look at the mouth of any of the *Felinæ*, after they have ceased to suck their mothers, and have got their teeth, and say what sort of sucking apparatus he thinks it would make. Then we would bid him look at the manner in which a cat laps milk, and consider whether she could extract blood from the vessels of an animal. But all the genus lap when they drink; and they lap not with the tongue bent upwards at the tip and edges till it forms a sort of scoop or spoon, as is the case with the dog, they lap with the tongue bent downward at the tip, and thus they lap slowly; and the plunging of the head into the body of the animal is not done so much in order to drink the blood, as to eat the viscera.

At the same time, we do not mean to deny that all, or that any of the animals of this genus do not lap blood as well as tear and eat flesh; only their organisation is expressly formed for the one operation and not for the other; and though there is a good deal of range in every organisation, we must either allow the purpose for which it appears to be especially adapted to predominate, or there is an end of all rational knowledge of animals. We are aware that many of the *authorities* describe some of the *Felinæ* as sucking the blood of their victims before they tear the flesh; but there was a time when the *authorities* generally—and some of the *ancient* authorities still adhere to the belief—accused tom cats of "sucking the breath" of infants while asleep. Animals which suck blood always make a punctured wound, as is done by the weasel tribe, and not a lacerated one, such as is always made by the cats.

We have extended our observations on these two, the most powerful and famed species of the genus, to some length, both on account of their interest and in order to bring into one description, and thereby shorten the general account of, animals which have so many corresponding characters as the whole race of the cats, great and small, possess; and having done so, we shall be enabled to dismiss the others very briefly.

Tigers are not only subject to considerable variety in size and in the markings and tints of the colours, but there are sometimes albinos met with, which have been considered different varieties, and described

under the name of WHITE TIGERS. We give a figure of one, from which it will be seen that these albinos are feebler and less handsome than the animals which have the usual colour.

Animals of this colour are not, we believe, met with anywhere, as a variety, in pairs and producing broods of their own colour; and there is a reddish tinge in the eyes of the few solitary individuals that are met with, which tends to establish the fact that they are not a separate race, but are merely defective in the colouring matter. They have transverse bands, the same as the others, only these bands appear to consist more in the different texture of the hair than in any real difference in the colour. The hair which answers to the yellow ground has the silvery gloss and semitransparent appearance of the hair of albinos of other races; but that which marks the stripes is chalky and without lustre, so that in some lights it appears whiter than the rest of the skin, in others it appears darker, and in others still the whole colour seems to be uniform.

THE CLOUDED TIGER (*Felis macrocelis*). There is little doubt of this one being a distinct species, and according to the best accounts we have of it, it seems to be a tiger-cat rather than a tiger. The following figure will afford some idea both of its form and its

markings. It is a native of the eastern Archipelago, and perhaps also of some of the south-eastern parts of continental Asia. The ground colour of its skin is white, pure and bright on the belly, but much duller on the back, where there are stripes of rich velvet black, and the intermediate places have a greyish appearance from the mixture of black hairs and whitish ones. The markings on the sides are ill-defined blotches of a variety of shapes. The body is much more clumsy than that of the tiger, the legs are shorter and apparently thicker, but the apparent thickness is in fact owing to the thicker fur with which they are covered. The tail is longer, thicker, and much more furry, having no inconsiderable resemblance to that of some of the common cats. The eyes are not so large in proportion as those of the tiger; they are more inclining to grey in the irides; and though the animal is rather fierce for its size, they have not the same glare as tiger's eyes.

According to the descriptions, this is a comparatively small animal, not exceeding in size the largest specimen of the wild cat found in this country; and from their diminutive stature, and consequently inferior strength, they never, in their natural economy, attack man, or any other of the larger animals. It is to be borne in mind that animals of this genus always hunt singly, and that, therefore, they never can master any animal which is above the strength and arts of the individual. The genus *Canis*, on the other hand, generally make their attacks in packs or parties, even when they are in a state of nature; and thus they can vanquish much more powerful prey, as compared with the strength of the individual, than the genus under consideration. The present animal is not merely a woodland species, but it is an inhabitant of trees, lying there in wait for its prey so habitually, that the substantive part of its name, in the language of Sumatra, is *Dahau*, which means the fork of a tree. Its usual prey consists of birds and the smaller species of deer, some of which, in that country, are not larger than rabbits, if so large. It has, indeed, all the characters of that division of the genus which, from their resemblance to the domestic variety, are more peculiarly called cats. From all the accounts which we have, it appears that this animal could be domesticated with the greatest ease; and that if fed, it is good tempered and playful, and courts fondling with as much solicitude as a pet cat; but its proneness to climbing and bird catching are so strong, that there is no keeping it out of the woods. This fondness for trees and birds is no argument against a considerable similarity of disposition with the common domestic cat; for in all countries, cats are very partial to climbing and bird catching; and, in British Guiana, where the settlements are near the woods. and the woods not only swarming with birds, but have the stems of the different trees so festooned and interlaced with twining and climbing plants, that cats can mount to the very tops with as much facility as sailors mount the shrouds of vessels, the colonists are obliged to crop the ears of their cats close to the head, in order to prevent them from going to the woods.

The extreme sensibility of the interior of the ear renders any substance very annoying to them in that part, and more especially moisture. Cats thus cropt, cannot therefore go into the open air at all during the rains; and even in the dry season they cannot pursue their feathered prey in the woods at night, which is their favourite hunting time, because even then the leaves are generally covered with heavy dew, which the progress of the cat causes them to twitch into the exposed openings of the ears; and thus the cat is obliged to stay at home and pursue her mouse and rat catching, which are no sinecures at a sugar work.

The Leopard (*Felis leopardus*). The name leopard is a fabulous one in its original application, and it has occasioned no small embarrassment in the history of all the larger spotted cats of the eastern continent; nor is the difficulty yet over, for though a tolerably clear distinction is supposed to be drawn between the leopard and those other species to which it has the nearest resemblance, and which, having indiscriminately been called leopards and panthers in many instances, the distinction is more of a geographical nature than of any other. The name is composed of the two words, *leo* (lion) and *pardus* (panther), and the fable was, that the leopard was a mule or hybrid between these two species, partaking of course of the fabled generosity of the one and the savage disposition of the other. This of course was purely imaginary, and even ridiculous, as being an attempt to form distinctions of animals upon mental qualities, qualities which, in the very nature of things, animals do not and cannot possess. The exhibitors of animals, who have generally made matters worse, by investing every beast in the show with all the marvellous qualities which they could hear of or invent, and representing it as coming from the most terrible spot upon earth, and perpetrating the most sanguinary deeds,—these have increased the confusion, and popular describers have done little to diminish it. So that the true distinction between the leopard and the panther remains as much a mystery as ever; and as the only difference between them is in size and marking, and perhaps in that more active and playful but milder disposition, which seems to be connected with smallness of size in this genus of animals, it is possible that the animals may be only climatal varieties of the same original species.

The circumstances of development in size, and sullenness and ferocity of disposition, always going hand in hand in animals of the cat tribe, is a very important point, though it is one which has not much, if at all, attracted the attention of naturalists. It strongly points out the value of a doctrine which is yet but in its infancy, and which the ignorant and the prejudiced are up in arms against, in the same way in which they have been in arms against every scientific discovery so long as that discovery was new, and those bigots had the majority of mankind on their side. The doctrine to which we allude is that of a perfect type in the different natural families of animals, to which all the individuals of the family have a tendency to approximate, but which counteracting circumstances never suffer them exactly to reach. They however come nearer to the type in proportion as the circumstances in which they are placed are more favourable to the typical development, and they also stop farther short of it in proportion as the circumstances in which they are placed are less favourable. This doctrine has been, by the persons above alluded to, stigmatised as having a tendency towards materialism, and even to a denial of the existence of God; and they who have made those allegations have, like small curs which are unable to fight, exhibited their nature by snarling.

Now, we have only to bear in mind how powerfully these physical discoveries, of which the illustrious Galileo may be said to have been the founder, have conduced both to the natural proof of the existence of the Creator, and to those sublime and striking views of his power and wisdom, as displayed in creation, and bear in mind that Galileo was constrained to abjure the truth for a time, in order to escape martyrdom at the hands of an ignorant and bigotted church, as one who was subverting religion, and we can learn how to estimate those small calumnies of the ignorant of modern times.

It is true that this doctrine of types is one which calls for the very nicest investigation, and one in which conjecture cannot advance a single step, and in this it agrees exactly with the physical doctrine above alluded to. It was because that doctrine demanded of men that they should advance no opinion for which they could not show cause, that physical philosophy, in all its departments, has become matter of certainty and demonstration; and until we can carry a similar principle into the philosophy of living nature, we can never hope to find in that any thing better than a conflict of opinions fiercely opposed to each other, and all substantially wrong; just as we find in the physical systems of the ancients, and before mankind learned to form their opinions according to nature, instead of attempting to form nature according to their opinions.

This is not the place to go into any extensive investigation either of the nature or the usefulness of the system of types, and the subject is yet too much in its infancy for being made very instructive in a popular point of view; but it is necessary that even those who take the most casual and cursory view of any one living production of nature in its natural state, should know that there are specific principles in nature, well grounded in reason and philosophy, according to which the structures and the functions of animals may be studied as parts of one general and beautiful system, and not as detached individuals, which have nothing to tell but what is apparent to the senses of the most ignorant and most unreflecting observer. The latter is so contrary to what we meet with upon every other subject, that it cannot possibly be true; for it would be the most glaring inconsistency if there were not in that subject, which is calculated, above all others, to draw the attention of mankind, the same reward to that attention as there is in subjects of a humbler, and in many respects less useful character. Nor can we doubt that very much of the uncertainty, contradiction, and absurdity, which is to be met with in very many of the descriptions of natural objects, is owing to the want of established typical characters which shall form the foundation of a system at once natural, philosophical, and of easy application.

We feel the want of such a system every where throughout living nature, but no where more forcibly than in the genus *Felis*, and especially in those species or varieties of it which have led to these remarks. This is therefore the proper place to hint at the general nature of what is wanted; and we do this the more readily that, being a matter acquireable by common observation, and not by the help of any technical science, it strictly belongs to the popular view of natural history, in the best sense of the term, and may be promoted by every one who will examine those productions of nature which come within the sphere of his own observation.

It is not easy to say to what number of animals one type should in every instance be extended. The action of the animals—the part which they appear perfected to perform in nature—is unquestionably the foundation; and we must regard the whole system of animated nature as being, as every thing in nature is, sustained by the balance of certain actions and reactions. Thus, for instance, the foundation, or, if you will, the design of the genus *Felis*, is to keep down the numbers of other animals,—of other mammalia in the cases of the larger species,—so that those animals may not multiply to excess, and derange the system. The genus *Felis* is, in this respect, the ultimate genus, as it were, for the more powerful ones are not subduable, so as to have their numbers restrained, by any other race of animals in wild nature, whatever they may be by man. But we are not on this account to suppose that they are set in lawless dominion over the rest of the animated tribes; for even man, if he is to profit by the cultivation of nature, must profit not by breaking the laws of nature, but by obeying them; and in like manner we may be sure that though the more powerful species of the feline race are absolved from animal control, they are no more out of the government of nature, that is, of the Author of nature, than the weakest animal of which the least powerful of them makes prey.

Thus, we are to consider that the typical law in the animal, that is, in all the varieties or species which observation can fairly bring within the type, tends to the evolution of a certain organic structure; and that the tendency of the reacting circumstances is to make the individual stop short of its type, sooner or later, according to the strength of those circumstances. Thus we have all the feline race harmless and playful, and without their more formidable weapons—their canine teeth and retractile claws—when they are in a young state. Farther, when they are in that state, we have them all with markings of colours; and it is not a little remarkable, that different as the lion and the tiger are when they grow to maturity, the cubs, when very young, might very readily be taken for each other. We find too that the lion in Asia, in which the characteristics of the lion, the muscular appearance, and the thick shaggy mane, and also the stature, are not so much developed as they are in Africa, is a much less formidable animal than in the latter country. When we take the two animals which are considered as the leopard and the panther, and consider them in similar localities, we find a similar difference of development, although they are still as like each other in general appearance, as the lion in Asia and the lion in Africa; and thence we are, perhaps, warranted in concluding that the two are nothing but climatal varieties of one original species of animal, for whose typical development the climate of Asia is not so favourable as that of Africa.

We have a corroboration of this in the case of two other animals, the one an Asiatic, and the other an African. These are what are usually called the hunting leopards, of which the Asiatic is a smaller and much more docile animal than the African; and when we compare these two with the lion as found in the two continents, we discover an analogous change in the lion, and in these hunting leopards. The most striking difference in the appearance of the Asiatic lion is the paucity of his mane, as compared with the formidable bush which surrounds the neck, shoulders, and breast of him of Africa; and it is worthy of remark, as establishing the analogy, that the hunting leopard of Africa has a mane, though of course a small one in comparison with the mane of the lion, while the hunting leopard of India has none. These remarks are of course not conclusive, because nothing in natural history can be conclusive which does not rest upon observation at every step; but still they point out the way to a proper conclusion in a part of the subject which is at present involved in the obscurity of ignorance, and consequent uncertainty.

The usual distinctions of these animals have been the general colours of the skin and the markings; but these are not to be depended on; for though we describe or figure a specimen ever so accurately, it is not *the* leopard, or *the* panther, in the general sense, but merely *a* leopard, or *a* panther. The ground colour is generally of some yellowish shade, but that varies much in depth; in some it is pale straw colour, or even dirty white; in others it inclines to black; and there are all the shades intermediate between these: the spots are in general black, well defined, and regularly distributed; but they vary much in number and intensity, and often run into each other. Thus there can be no distinction made of the animals which can be entitled to the name of scientific ; and perhaps two may be found, one geographically a leopard, and the other a panther, which more nearly resemble each other than the other two do which come from the same part of the globe, and are geographically called by the same name. There is, however, nothing to guide us but the geographical distinction ; and so, in the present state of our knowledge, we have no alternative.

We may, however, mention the probability that the leopard of the ancients was not the leopard of modern times ; for that animal is obtained chiefly or exclusively from the Eastern Archipelago, with which the ancients had little or no intercourse, *Taprobane*, or Ceylon, being the south-eastern limit of even their conjectural geography ; and Ophir, being in Africa, where gold is still found for exportation, and not in India, where there are not, and never were, any mines of that metal.

The ancient name leads us at once and clearly to the leopard of the ancients. It was the maned hunting leopard (*Felis jubata*) of the systems, which has the spots of the panther, and, rudimentally at least, the mane of the lion ; and it is still to be found in those countries with which the ancients were acquainted, as are also the lion and the panther, or pard, between which it was supposed to be a hybrid ; and though the fact of its originally being so is purely hypothetical, it is not impossible.

A figure of a Leopard is given in the plate, "Cats," from which the character and markings will be more readily understood than from verbal description. The spots are generally pretty uniform, rather small and close, and the skin is beautiful. The animal is remarkably lithe and flexible in all its motions, and as it is considerably less than either the lion or the tiger, it is much more feeble and more mild in its expression ; but, as it lives upon smaller prey, it is more frequently on the hunt, and perhaps kills a greater number of animals than its more powerful congeners. It is said to be found only, or chiefly, in the larger islands of the Oriental Archipelago, and probably in the Eastern Peninsula. It is a very symmetrical animal, and as its expression partakes as much of wildness as of fierceness, it is among the most handsome in the whole genus. It is described as being subject to very considerable variations, both in the ground colour and in the spots, being sometimes bright yellow with the spots well defined, and at other times nearly black. The larger spots on the flanks and sides are often slightly ocellated, or have the middle paler, but they never have so much of that character, neither are they so large as the spots on the jaguar of South America, which has sometimes been shown and even described both as a leopard and as a panther.

The Panther (*Felis Pardalis.*) From what has been already said, it would be occupying space to very little purpose to enter into any detailed account of this animal as a species.

It is rather larger in size, and more ferocious in manner, than the leopard of the Eastern Isles; but, like that, it is subject to very considerable varieties of colour. It is found in central and northern Africa, and also in the south-west of Asia.

The spots upon the panther are described as being larger than those upon the leopard, and as being more regularly arranged in lines ; and if this be the case, it would lead us to infer, that in proportion as the animals of this genus approach nearer to that great strength, which must be considered as the perfection of the type, their colours have a greater tendency to be uniform. The young lion has rudimental markings of the stripes of the tiger; the panther has the spots in rows, as if they were interrupted stripes, only they are longitudinal ; and the leopard of the east has them alternating, so that they do not range in rows either way, and they are much smaller and more numerous.

The changes of colour which we trace in these animals, as modified by differences of climate, and of character thereby produced in their several localities, agree perfectly well with what we may observe in those animals which have been longest under a state of domestication by man, and which we may therefore consider as being most diverted from their natural type by artificial treatment. In them, as in the others, the most perceptible external deviation from the uniformity of nature, is the departure from the original colour ; and where wild animals are placed in climates so different from each other as the Oriental Archipelago and Northern Africa, we may naturally look for considerable differences of colour among them.

Both the leopard and the panther have the pupil of the eye contracting to a circle, as in the lion, and not to an ovular one, as in the tiger. This points them out as being more inhabitants of dry, if not open places, than of the damp and close jungles. They are both long animals in proportion to their height. The length of the full-grown panther is about three feet and a half, of which the head occupies about eight inches. The tail is about two feet and a half in length. The height of the shoulder is about one foot ten. It is only particular specimens, however, which reach these dimensions. The spots on the body of the panther are not circular, or ocellated, but formed into a sort of cinquefoils, as if five spots ran into each other ; while those upon the leopard, when they appear to be confluent, have more a quatrefoil appearance, and are usually less or more pale in the centre. The upper part of the tail in the panther is black, annulated with white ; the under parts of the body, and the insides of the thighs are white, with black markings. Among furriers, by whom the skin is much valued, the panther is sometimes called the African tiger. It is probable that, like the lion, this animal was much more generally distributed in ancient times than it is now, and was found in all the west of Asia, as far to the north as the mountains of Armenia, and their continuation eastward ; and that it even reached to the confines of those places which are now inhabited by the leopard of the moderns, if indeed the two are not the same identical species, a portion of which is left at each end of its former locality, while it has become extinct, or so much rarer, as to be but seldom seen in the intermediate part.

If we could implicitly depend upon the accounts which we have of the relative abundance of these animals at different periods of history, which, from what has taken place in modern times, cannot, we fear, be the case, we should be in possession of a most important element in the progressive natural history of the globe. Thus much at least we can infer, and it is highly important that, if man for a long succession of years so cultivates the earth as to change it very much from what it was in a state of nature, and then abandons it, owing to any cause, it does not return to the natural exuberance of its fertility, but passes into the condition of a desert, from which the art of man cannot again fully reclaim it. We have abundant evidence of this in those countries which were the first habitats of civilised man, which have now become too unproductive even for the panther. There is a beautiful and valuable moral in this, but we must leave both the inference and the application of that to the reader.

THE HUNTING LEOPARD (*Felis jubata*). This animal, which, though the point is one of no very great importance, we must consider as most probably the leopard of the ancients, is much lighter in its make, more swift in running, and much more docile in its manners, than any of the species already noticed. It is found principally in Africa, though it also occurs in the south-western parts of Asia, and there may be remnants of it in the intermediate regions of that part of the world until we come to the *chetah*, which appears to supply its place in India, and which, according to the accounts, is still more lightly made and more docile.

This species is about three feet long from the muzzle to the insertion of the tail; the head is about half a foot long, the tail about two feet, and the height is also about two feet. The head is shorter, and also more slender in proportion to the size of the animal, than in almost any other of the genus. The legs and tail are also longer in proportion, and the whole body is lighter, and formed for more prolonged exertion. Even the paws differ in some respects from the more typical cats; the toes are longer, and they come to the ground with more firmness, as the last phalanx is more produced, and also better supported by the claws. The claws are crooked and sharp pointed, as in the others, and the points of them do not come exactly to the ground when the animal walks, but they are only demi-retractile, and therefore they are not so efficient tearing claws as those of many of the genus. The feet of this animal are, in fact, in some respects intermediate between those of the typical cats and the dogs; and it is worthy of remark, that there is some sort of intermediate character, both in the action of the animal and in its disposition. It does not lie in wait, and crouch, and spring so exclusively as the others, neither does it use its paws to such an extent in the capture of its prey. It cannot follow on a long chase in the same manner as the swifter of the dogs; and, therefore, it is said that the hunters, when they do employ it, carry it on a pad attached to the saddle, till they are within sight of the game; and that when the game is shown to it, it reaches it by repeated bounds, and uses the teeth more than the paws in the capture. The chetah has those habits so nearly alike that it will not be necessary to again allude to them in the notice of that animal. The ground colour of the hunting leopard is usually a bright clear yellow on the upper part; and white on the under part and the chin. The yellow is marked with small round black spots at nearly equal distances; and the white part with larger spots further apart from each other. The last half of the tail is marked with about a dozen rings, alternately of black and white, the last one, or tip of the tail, being white. It is said that this species is easily tamed, very docile in the domestic state, and not disposed to quarrel with the dogs or other domestic animals which are its usual associates. It is called the *maned* hunting leopard, because the hair on the upper part of the neck is much longer than that on any other part of the body excepting the cheeks; on which, as well as on the neck, it stands out, and has a woolly or somewhat frizzled appearance.

THE CHETAH (*Felis venatica*). This is the Indian variety of the former species; or, if a species, it differs very little from the one just described. It is a very handsome and graceful animal, as mild in its expression as the common domestic cat, and very agile and active in its motions. It is generally, though not always, paler in the colour than the former; and though there is an indication of longer hair on the cheeks and upper part of the neck than the rest of the body, it is only an

Felis venatica.

indication. The above figure will give a general notion of the appearance of this animal.

THE JAGUAR (*Felis onca*). This is the largest, most powerful, and most ferocious of the feline tribe which are natives of the American continent. It is often called the American tiger; and in manners it bears no inconsiderable resemblance to that formidable animal, and even its size and strength are not much less. In some of the accounts, however, it has been confounded with the larger spotted cats of the eastern continent, from which it is readily distinguished, both by the peculiarities of its markings, and by its form and manners, which are more to be depended on, though the markings are fully as striking. The greater number of the spots, at least upon the flanks and sides of the jaguar, are regular ocelli, or eye spots; that is, they consist of an external circle of black, with a spot of the same in the middle, and the intermediate space of the same colour as the rest of the ground on which the spots are placed. The spots upon the cats of the east have sometimes a paler portion within the black, but we believe no specimen has occurred in them with a black spot in the centre; and, though jaguars are subject to considerable variety in colour, and also in the form and intensity of the spots, we believe no specimen of them has been found entirely destitute of spots consisting of a black circumference and a black centre. The spots, more especially those on the haunches and shoulders, sometimes have the external circle broken, so that they appear, five or six in number, ranged at equal distances round a central one. Those on the ridge of the back are in general almost confluent, while along the sides they arrange in four nearly longitudinal rows. They are often, however, mixed with transverse bars of a paler colour, having some resemblance to the stripes on the tiger. The upper part of the animal is in general of a rich yellow colour, and the spots of an intense black. The under part is white, marked with regular spots and transverse bars of black. The skin of this animal is indeed one of the most beautiful of the whole race, though there is probably less uniformity in the markings than in those of any of the others. No two individuals are marked exactly in the same manner, and generally the two sides of the same individual are differently marked. Different individuals vary much in their colour, and some are found with the spots obliterated, except a small ring at the circumference, and a little dot in the centre; on the other hand, some have been found very dark coloured, approaching to black. The following figure expresses very accurately the character of this animal.

Jaguar.

From this figure, it will be seen that, but for the markings, the jaguar has a very tiger-like appearance, only it is lower on the legs, and the tail shorter and thicker. The tail is very frequently borne with the tip trailing on the ground, though, like the tails of all the genus, it is capable of very considerable motion. There are one or two varieties of the jaguar mentioned by writers on the zoology of South America, but there seems to be no difference between them, excepting in size and in colour, and, as is the case with the tiger in the East, the larger specimens are met with in the richest places. They are chiefly found in the thick forests, near the banks of the great rivers, and seldom, if ever, to the southward of Paraguay. They are solitary animals, or, at all events, they are found only in pairs; but it is not ascertained whether their pairing is constant, like that of the lion, or only temporary, as is the case with the tiger. Analogy would, however, lead us to suppose that, as they agree most with the tiger in appearance and in locality, they also agree most with it in all their habits.

As the jaguar is not quite so powerful an animal as the tiger, and not nearly so active, even in proportion to its strength, it is not in any situation so formidable to human beings during the daylight; but, after nightfal, it is a dangerous animal, whether met with in its native forests, or when, as it sometimes does, it makes an inroad upon the remote settlements. Generally speaking, a fire or a light will keep it at a distance; but when it is very hungry, or otherwise greatly excited, it is said to bid the same defiance to these as the tiger does.

Its usual time for preying is during the night, or at least when the sun is down, and it lies in wait to attack, and springs upon the back of its prey. As the largest native mammalia of that continent are but of inconsiderable size, the jaguar finds them a very easy conquest; and since the introduction of cattle and horses by Europeans, and the great multiplication especially of the former, in a wild state, the jaguar gets nobler game than peccaries, and game more obedient to his claws than armadilloes. The full-grown bulls are as formidable to him as the buffaloes are to the lion in southern Africa; but the cows and the young he readily masters; and even the horse is said to be a favourite prey with him. His method is to lie in wait, and to spring, uttering a yell which, though not very agreeable, is not so horrible as that of the tiger, alighting on the shoulders of the larger animals; then, holding on with the hind feet, he advances his fore paws, and, grasping across the nostrils with the one, and the chin with the other, closes the nose and mouth, and, straining his body together at the same time, at once suffocates the animal, and dislocates its neck. Though the march of the jaguar is not very swift, and he is unable to carry such a load, either in the teeth or across the shoulder, as the tiger, yet he can drag the carcass of a horse for a considerable distance, and even swim with it across a river.

The strength and the predatory disposition of the jaguar make him a subject of great dislike in a country where wild cattle form a considerable portion of the wealth of the inhabitants, and therefore, among the settlers in the vicinity of his haunts, the hunting of him becomes an object of advantage, as well as of glory. This is usually done by dogs—not that they can master this powerful animal, or are very fond of going in upon him to make the attempt; but he is not so staunch as the lion, and especially the tiger, for the dogs put him to flight, from which he does not rally so as to act an offensive part. He is not habitually a climber; but if there be a sloping tree within reach, he mounts into that, and is despatched by spears or musket-shot, according as he is better situated for the one or the other. Some of the native tribes, too, are expert at despatching him with their arrows, prepared with *wourali* poison, and delivered from the bow or blown from the tube. When he takes refuge in a hole of the earth, he is either worked out, or the Indians tempt him with one hand wrapped in a skin, while they spear him with the other; but this is an exploit which requires great courage and presence of mind. As is the case with the lion in southern Africa, and the tiger in most parts of India, the jaguar is now nearly exterminated from all the settled parts of South America.

The Puma (*Felis concolor*). The puma is another South American species. It is of an uniform dun yellow colour when full grown, and has, on that account, been sometimes called the American lion, though it has few or none of the characters of the lion, any farther than that both belong to the same genus, are of a uniform colour when adult, though both have stripes when they are young.

The general form and expression of the puma are shown in the annexed figure, from which it will be seen that there is much more of the common cat than of the lion, especially in the head, neck, and tail of this animal.

Notwithstanding its cat-like aspect, the puma is an animal of considerable size, being sometimes four feet from the nose to the tail, and having the tail more than two feet long. Its height at the shoulder is a

Puma.

few inches more than two feet. Its frame is not nearly so compact or so muscular as that of the jaguar; and though, in the wild state, it displays nearly the same disposition as the other large species of the genus, it is greatly inferior in strength, courage, and activity, to many which are inferior in size. It is represented, however, as being rather a voracious animal, and keeping its food with great pertinacity after that food has been once obtained.

The puma is found both in South and in North America, probably with some varieties of colour; and if we are to credit some of the anecdotes which are related of it, we should be apt to consider it as a more formidable animal in the colder latitudes than in the warmer. This is certainly contrary to the natural analogies of the genus; and some of the anecdotes are, besides, such as cannot easily be brought within the range even of possibility. It has, for instance, been gravely said, that the puma has been known to carry the body of a man that it had killed up into a tree. Now, in the first place, it has not been very satisfactorily ascertained that the puma is a climber of trees, even when it is not loaded; in the second place, if this were ascertained, it would be an argument against the killing of the man, for the tree-cats are chiefly catchers of birds, squirrels, and monkeys; and, in the third place, notwithstanding all the marvels that have been told of lions and tigers, there is no feat at all comparable with this told of either of them. We have heard a similar story of a common brown bear carrying the body of a horse along a single tree which lay across a wide and deep ravine in the Scandinavian forests, but we never supposed that the tale was meant to be believed, and the feeling with regard to this feat of the puma is much of the same kind.

The more probable accounts represent the puma as attacking only the weaker animals, and as hoarding or burying its food; and pumas, when tamed, can be made to play with substances in the same way as young cats, only they are more indolent, and their motions not so graceful. It is well ascertained that the puma is very easily tamed, and that, if it is fed, it shows not the least disposition to attack any animal, but shows considerable affection for those who are attentive to it. Its general manners are more like those of the domestic cat than perhaps any others of the genus, more so even than the wild cat of Europe, which is often, though it would seem erroneously, considered as the parent stock of the domestic. The puma watches for birds in the same manner, and with the same action of the body, as the domestic cat, and, like that animal, it purrs when caressed.

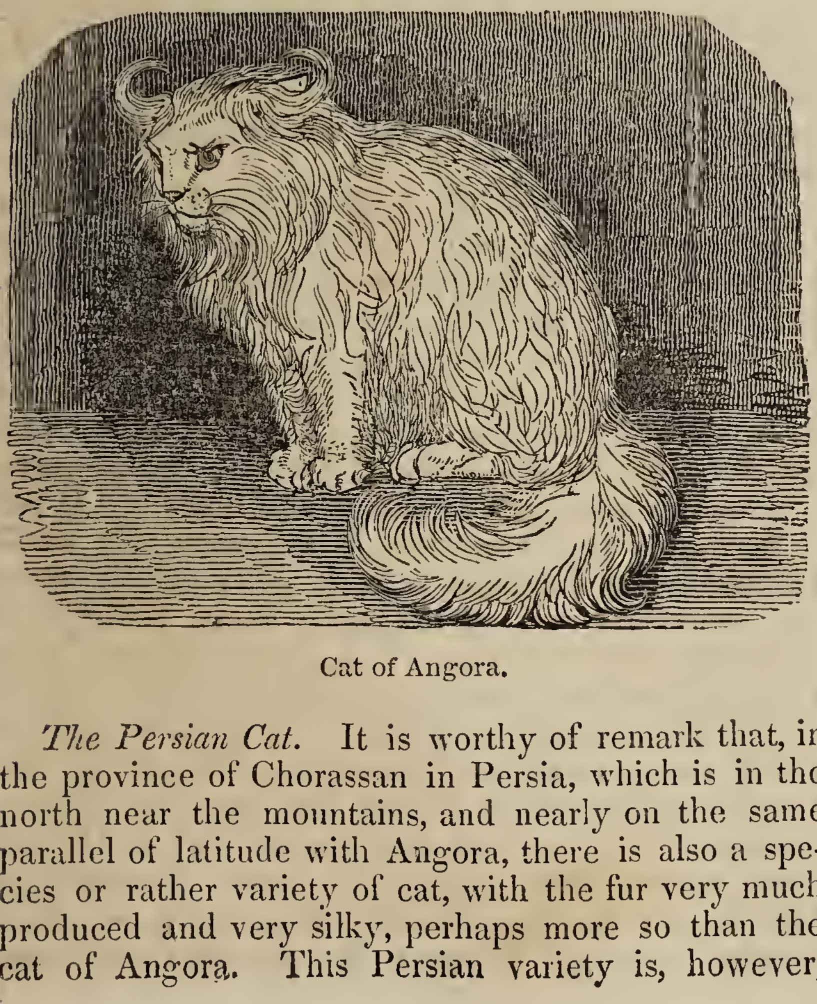
The Cat (*Felis catus*). Though we consider the specific difference between the wild cat and the domestic to be much better established than that of many others of the genus which are described as distinct species, yet we shall, for the sake of brevity, include both in a short notice. The following figure will show the character and expression of the wild cat.

Wild Cat.

This figure, which is a very faithful representation, will show that the wild cat is a much more ferocious and formidable animal than the tame one. The teeth and claws are more powerful, the ears are shorter and differently shaped, the eyes are more glaring, and the whole appearance of the animal is more ferocious. There are also some peculiarities of the internal structure which indicate an animal of more exclusively carnivorous disposition; the chief of which is that the intestines are shorter. This is a difference which could hardly be expected to arise from domestication, though that might be considered as, in part at least, occasioning the difference in the external appearance of the animals. We may perhaps add that the wild cat is a far more hardy animal, and braves the winter, exposed to the weather in even the coldest districts of Britain, in which it is in fact more at home, and attains a larger size than in warmer places. The domestic cat, on the other hand, from its fondness for basking in the sun or near the fire, indicates a more southerly origin, though it does not appear that there is any species now existing in the warm latitudes that can be considered as the parent stock. The one which comes nearest to it in manners is probably the puma; but to consider that as the parent race is out of the question. There is one consideration which should never be lost sight of when we speak of domesticated animals, and wild races as their probable parents: wild nature has undergone very great changes since man first began to domesticate animals, and as the places in which civilisation was begun are now, to a greater or less extent, exhausted and desolate, it is by no means improbable, that the parent races of those animals which have been preserved in a domestic state, have perished from wild nature as one of the effects of the change. On this point all, or nearly all, is of course hypothesis, but it is hypothesis which is necessary to a full understanding of the question.

It is altogether unnecessary to give any description of an animal so very generally known as the domestic cat; but we may mention one or two of the more remarkable varieties, observing that it is just as difficult, from their present appearance, to refer them all to one origin, as it is to believe that that origin is the wild cat now met with in this country; and we may add that though there are slight differences of disposition in these varieties, and that the most beautiful are in general also the most gentle in their dispositions, yet that there is much less difference in manners than in appearance, and that those which are best fed and most kindly treated are invariably the best natured and the most attached.

The Cat of Angora is a very beautiful variety, with silvery hair of fine silken texture, generally longest on the neck, but also long on the tail. Some are yellowish, and others olive, approaching to the colour of the lions; but they are all delicate creatures, and gentle in their dispositions. It is perhaps worthy of notice, that Buffon attributes the produced hair of this species to the fineness of the climate of Syria, whereas Angora is on the north side of the mountains of Taurus, at a considerable elevation, and exposed to the storms from the Black Sea; and therefore the variations of the climate appear to have more influence in the production or the long fur, if that be a climatal production, than the fine climate; but Buffon was no philosopher. The annexed figure represents the cat of Angora.



Cat of Angora.

The Persian Cat. It is worthy of remark that, in the province of Chorassan in Persia, which is in the north near the mountains, and nearly on the same parallel of latitude with Angora, there is also a species or rather variety of cat, with the fur very much produced and very silky, perhaps more so than the cat of Angora. This Persian variety is, however, differently coloured, being of a fine uniform grey on the upper part, with the texture of the fur as soft as silk, and the lustre as glossy; the colour fades off on the lower part of the sides, and passes into white, or nearly so, on the belly. This is probably one of the most beautiful varieties, and it is said to be exceedingly gentle in its manner.

The Chinese Cat is another variety with the fur beautifully glossed, but it is different from either of those which have been mentioned. It is variegated with black and yellow, and different from most of the race, it has the ears pendulous.

It would not be easy, at least upon rational grounds, even of analogy, to consider any of these varieties as descended from the wild cat; and, so far as we are aware, there is not, in all the wide extent of longitude over which they extend, any wild species at all resembling any of them. It is worthy of remark, however, that they all belong to a zone or latitude in which many of the other genera of mammalia that are exposed to the weather, have the hair much produced, and, whether coarser or finer in the staple, uniformly of a silky gloss; but the information which we possess respecting its natural history, either physical or animal, is neither full nor precise so far as it goes. It is enough to unsettle some of those theories which are stated with sufficient dogmatism, but not enough to substitute more rational ones in their stead.

The Tortoise-shell Cat is one of the most beautiful varieties of those which have the fur of moderate length, and without any particular silvery gloss. The colours are, very pure white, black and reddish orange; and, in this country at least, males thus marked are said to be very rare, though they are abundant in Egypt, and in some parts of the south of Europe. This variety has other qualities to recommend it besides the beauty of its colours. Tortoise-shell cats are very elegant, though delicate in their form; but they are at the same time very active, and among the most attached and grateful of the whole race. Cats generally, and it should seem those of this colour especially, are much more apt to form attachments to persons, and that not from selfish motives, than the world is disposed to give them credit for. A gentleman in the neighbourhood of London had a tortoise-shell cat which, though he never fed it, or paid much attention to it, formed an attachment for him equal to that of any dog. It knew his ring at the bell, and, at whatever time he came home, it was rubbing against his legs long before the servant came, saw him into the sitting room, and then walked off. It was a very active animal, and usually went bird-catching during the night, but when its master rose, which was generally early in the morning, the cat was always ready to receive him at the door of his room, and accompanied him in his morning walk in the garden, alternately skipping to the tops of the trees, and descending and gamboling about him. When he was in his study it used to pay him several visits in the day, always short ones, but it never retired till he had recognised it. If rubbing against his legs had not the desired effect, it would mount the writing table, nudge his shoulder, and, if that would not do, pat him on the cheek; but the moment that he had shaken it by the paw and given it a pat or two on the head, it walked off. When he was indisposed, it paid him several visits every day but never continued in the room; and although it was fond of society generally, and also of its food, it never obtruded its company during meals. Its attachment was thus quite disinterested, and no pains whatever had been taken to train it. These are but simple circumstances, yet they show the inaccuracy of the vulgar belief that "cats are attached only to places." All animals which are either necessary or desirable in a domestic state should have their due; but it has been too much the practice to elevate the character of the dog at the expense of that of the cat, though there is no question that a great deal of harmless amusement and some instruction might be derived from paying a little more attention to these, the most domestic of animals.

We would not, of course, propose any such ridiculous association and discipline of cats as that which, for a time at least, was practised by the late Lord Eldin the Scotch Judge. He had a numerous colony, to whose general accommodation he devoted a large apartment, and had them duly fed and attended, endeavouring to make them a happy as well as an orderly society. Civil wars were, however, constantly breaking out among them, to the disturbance of the neighbourhood; and at last they became so noisy, that, at a late hour one evening, he went in person to enforce the necessity of observing the king's peace, even on the part of his quadruped subjects. The Toms and Tabbies, for the whole colony were up in arms, paid not the least attention to the presence or admonition of the learned gentleman. He retired, sent for his clerk, and desired him to fetch the riot act from the library. This being obtained, the two proceeded to the territory of the conflicting cats, the clerk with the riot act, and the barrister (which Eldin then was) with a horsewhip. After proclamation duly made, the riot act was read with the necessary solemnity, and the cats warned of the consequences if they did not return to an orderly deportment before the expiry of the statutable time. That time passed without any abatement of the riot, upon which, the governor bolted the door, and bestowed on them a hearty discipline with the whip; but whether that tended to the restoration of tranquillity is not mentioned. The rest of the story, however, is strictly true.

There is some amusement in watching the conduct of a young cat with a looking glass. At first it paws at the image, but not being able to touch it, it peeps slily round the edge of the glass, as if to catch its companion on the other side. It returns disappointed, but again observing the image renews its attempt. It continues to do this for some time, and then it begins to extend its paws in a variety of directions, and to put its body in a number of attitudes, watching the corresponding motions of the image. After a while, it sits motionless, still studying the image, and retires when it is wearied. After this it is fond of taking a peep in the glass, but it does not attempt again to catch or play with the image.

The glistening of cats' eyes in the dark, or rather in dim light, is explainable upon the ordinary principles of reflection, the light being thrown back from the concave membrane, and does not, as has sometimes been said, arise from phosphoric light produced in the eyes themselves, which it is easy to see would effectually prevent the vision of the animal. It is only by the rays of light entering the eye that vision is produced, and it is easy to perceive, that if a stronger light than that which entered the eye came out of it, there could be no perception of external objects.

The high state of electricity to which the fur on the back of the cat can be excited, is a matter worthy of more consideration than it has hitherto received, because a careful examination of it would probably throw considerable light on the connexion between electricity and the heat, and, more especially, the excitability of these animals. It is probable that this property belongs to the fur of all the feline race, especially to all those which have what is called dry hair, that is, which have the fur so free from any oily substance, as to be readily injured by water. Hair of this kind is a very bad conductor of electricity, and as such, it can be made electric by friction; and it is well known that the electricity of the cat is much more easily excited in dry air than when the air is damp, and still more easily excited when the animal is placed on a stool with glass feet. Now, it will readily be understood, that this non-conducting power in the fur of the cat, must act as a barrier between what goes on internally in the animal, and, the external atmosphere,—that, if great energy is, by any means, excited, this property of the fur must prevent that energy from being dispersed in the air; consequently, that the animal must, with the same degree of original excitement, be capable of much greater exertion than if the fur were a conducting substance. We find, not only that cats are capable of being excited to more momentary efforts, than almost any animals of the same muscular strength; but that, when enraged, their passions are much more ungovernable then those of any other animals. A cat much irritated is, in fact, perfectly frantic, altogether disobedient to command, and altogether indifferent to danger. The connexion between this susceptibility of being worked up to frantic action and the non-conducting property of the fur, appears to be well worthy of investigation, as one means of establishing the identity of animal action, and the action of electricity,—or, rather, the identity of all material action, a truth, the full establishment of which would be the most important point ever gained in science; and there are many circumstances well established by experiments, performed by the most scientific and careful experimenters, that point strongly to its establishment in other cases. It cannot yet, however, be considered as legitimately within the province of popular natural history, but it is worthy of the most careful examination.

The wild cat (*F. catus ferus*) is well known in many parts of this country, and it is by no means rare on the continent of Europe and in some parts of Asia. It is much larger and stronger than the domestic cat; has the fur longer and more shaggy, the intestinal canal shorter, and the heart and stomach not quite so like those of the dog. It is a forest, at all events a coppice, animal, and disappears before the progress of population, though in agricultural countries it has a tendency to linger even in comparatively small plantations, as the small animals which collect about the neighbourhood of the corn fields, afford it a plentiful supply of food. It is, however, chiefly in the wild woods of the mountains and rocky places where it is chiefly met with in this country; and in these it occasionally attains a size which is truly formidable. Individuals of more than four feet from the nose to the tail are not uncommon, and some have been met with as much as five feet. Its principal food is the smaller mammalia, from the hare downwards, to which, however, it adds birds in great numbers; and in remote places it sometimes plunders poultry yards, but only during the night. In its native places, and especially about nightfal, it is a very bold animal, and not very apt to retire at the approach of man. On the other hand it stands in a menacing attitude, and with its eyes glaring in a very formidable manner. It does not attack; but if attacked and slightly wounded, it is apt to spring upon the assailant, and bite and scratch in a very serious manner. It may now be regarded as the most powerful of the wild mammalia of Britain.

The wild cat is never met with in bleak or exposed places, but always in brakes and copses, and in them rather than in the extensive forests of tall trees. Hunting in these is not very well adapted for them, as the birds, which would have to be the chief part of their food there, are rather too high for a wild cat's hunting: they lie in wait upon the ground, or only in the lower branches and sprays. During the greater part of the day they are in a state of repose, but they become very active about nightfal; and in places where they are abundant they keep up a very disagreeable yelling during the greater part of the night. They set up a loud cry when they are alarmed, but it is probable that the most offensive of their nocturnal music is, as is the case with the domestic cat, their love song. It is possible that, where their haunts are near houses, they may produce hybrids with the females of the domestic race; but they are said to attack the males with much determination. When hungry or irritated they are very bold in their attacks, though they always spring, and use their claws very effectively. In defence of their young, the females show the same boldness, and follow the captors of them with almost as much resolution, as the tigress herself.

Ocelot (*Felis ocelot*). This is the name of a numerous, but not very well defined, group of cats of middle size, that is to say, intermediate between the lions, tigers, and other large and formidable species already noticed, and the wild and domestic cats. There is one circumstance attending the gradations in size of these animals, which is worthy of notice: in proportion as they are smaller, the tail is larger and covered with longer fur. The group now under consideration (we call them a group only because their history is not well known) are all inhabitants of central America, but generally of more upland places than the jaguar and the puma. They are mountain cats, or rather hill cats, but still they are found in the woods, not in the open places,—the lion is perhaps more in the open wilds than any of the tribe, and even he generally crouches and lurks in thickets.

The animals now under notice may, perhaps, be considered as the American branch of an exceedingly numerous family, which are found in Africa and Southern Asia, as well as in America; but there are differences in the general appearance of those of each of the three localities. The American species, or ocelots as they are called, are the more handsome of the whole; they are "clean made" animals, light and well proportioned in all their parts; their legs are rather long, and their tails peculiarly handsome. They pace along with the same long step and majestic tread as the tiger; and though, from their comparatively thicker fur, the working of their muscles is not so well seen, yet, colour excepted, they bear no inconsiderable resemblance to tigers in miniature.

These animals are, in general, rust coloured and white in the ground of the fur, the former being chiefly on the head and along the shoulders and flanks, while the latter occupies all the under part, and a greater or smaller portion of the back. The markings consist of stripes and spots of black; the stripes are longitudinal, only, in general, inclining downwards a little towards the flanks. There are also longitudinal streaks of black on the top of the head, the cheeks behind the eyes, and the sides of the neck; but the fore-legs from the shoulder, the belly, the hind legs from the insertion of the tail, and the tail itself, are spotted with black. The stripes on the back are also interspersed with spots, and they very generally have oblong spots or darker down the margins and sometimes the middle of the stripes. Some of them have the tails annulated. There are, however, so many diversities of colour among them that a minute description, even of one, would be inconsistent with the nature of this work, and, indeed, of but little value in any work, because it is highly probable, that in animals which have their colour so much broken, no two individuals are alike. We shall mention one or two of the American ones which have been described as species or varieties.

Paraguay Ocelot. This is the *Chibi-gouazou* of D'Azzara; and though not probably confined to Paraguay, it is very plentiful there. It is two feet and a half long in the body, with the tail one foot three, and the height the same as the length of the tail; so that it is smaller than many specimens of our wild cat. It is, however, a much more handsome animal; walks more lithely, seems bolder, and has much more the air and the voice of the larger beasts of prey. It is a retired animal, living in the thick bushes, and not stirring out save during the night, at which time it is very ferocious in proportion to its size. These animals live generally in pairs. Perhaps this is the most beautifully marked of all the American tiger cats. The strokes are continuous along the sides and flanks, and finely interspersed and mottled with spots.

Mexican Ocelot. This is said to be smaller than the former, but to have even more of the tiger appearance. The colours are nearly the same, only there is a reddish ash instead of the rust colour. The stripes are shorter than in the former, and interrupted. It is found in Mexico, and on the whole of that part of America which lies to the west of the Carribbean Sea. There are said to be two varieties, one on the table land, and another on the *tierras calientes* by the sea; but as these are said to be similar varieties of that which has been described in Paraguay, it is probable that the whole form only a single species, which is broken down into many climatal varieties.

The linked Ocelot (so called because the stripes upon it are chain-like) is smaller than any of those already mentioned, and shorter on the legs. The upper part is dull yellowish, darker on the sides of the head; and the under part is white. There are irregular chain-stripes along the sides, which are continued in lines upon the legs. The tail is clouded rather than annulated. This variety or species is said to mew like a cat, but its habits are little known; and, as remarked in a former part of this article, domestic cats are apt to escape to the forests in the warmer parts of America. This fact, by the way, throws some light upon the disputed question of the original race of the domestic cat, and affords at least a strong presumption that it is not the wild cat of Europe; and when we take the structural difference into consideration, we have perhaps as strong a circumstantial proof as we can obtain in such a case. In Europe, domestic cats hunt in the woods, but they do not reside permanently there, or attempt to escape even in the mildest of our climates. If they had this disposition, they have so many opportunities of gratifying it, and they breed so freely that we should ere now have had every copse in the country completely stocked with domestic cats. There are, however, not any such; but in warmer countries they do betake themselves to the woods and remain there.

Now, in as far as analogy is evidence (and there are many parts of natural history in which if we are not satisfied with this evidence we must go without any), we find that, of the other domestic animals (mammalia at least), those of which we know the native haunts have a tendency to run wild in proportion as the country in which they are domesticated more nearly resembles that in which they are found native. Deer are natives of Britain, and we have in many parts of the country instances of them escaping from parks, and stocking the wooded hills all around. There is a remarkable instance of this in Forfarshire, where the stray deer from the extensive park of Lord Panmure have stocked many places to the annoyance of the cottagers near the plantings. The domestic dog, on the other hand, never goes into the wilds to breed there, but we believe the case is different in India. There is even a proof in birds. The common poultry, which are from the warm jungles of India, never quit their domestic habitats, or at least do so very temporarily, whereas the pheasants which are from climates comparatively temperate, and more resembling that of Britain, are more partial to the woods than to the vicinity of houses, so much so, that they must be confined in order to keep them in the latter places. There may be part of this owing to difference of habit and of power of flight in the birds, but much is unquestionably owing to climate. From this evidence, and much more might be adduced, we must conclude that the domestic cat is of a family originally inhabiting warm climates, but which is not now to be met with in a wild state in any part of the world. Perhaps there is one species of American cat about the size of those mentioned, which merits a separate notice.

The Margay. This species is chiefly found in the warmer parts of North America, though it is also met with in other places of that continent, and it is perhaps very generally distributed. The ground colour of this species is greyish-yellow on the upper part, and white on the under. It has four black stripes along the neck and shoulders, which are continued in spots along the back, the sides, and the flanks. The shoulders and thighs are spotted, but the feet, which are of a grey colour, are without any spots. The length of the body is about eighteen inches; the tail about a foot, and marked with about a dozen irregular blackish rings. It is probable that this species is known by different names in different parts of America, and also that it has been confounded with some of the others already mentioned, with which it agrees so nearly in manners that no further description is necessary. Indeed the habits of all the smaller cats of warm countries are so much alike, that when one is known all are known, with the exception of some differences of colour, and as the colours do not appear to be constant in almost any one they are matters of very minor importance.

There appears to be many varieties, if not species, of these animals in America; and it is by no means improbable that some of those which were seen and imperfectly described by the earlier writers may be now extinct. When America was first visited by Europeans the whole continent, with the exception of a portion of the table-land of Mexico, was entirely in a state of nature; and as, with the exception of the northern savannahs, no part of it was inhabited by vegetable feeding animals of any considerable size, it was peculiarly adapted for the middle sized cats. This was the case both in those places which were covered with thick forest and those which were bare. In the former the birds swarmed, and still swarm in numbers unknown in any other part of the world; and in the latter, different species of rodentia were, and in many places still are, exceedingly numerous. In order to keep down the superabundance of animal life in both those places, a number of cats was necessary; but as the prey consisted of only small animals, it was not necessary that these cats should have the same powers as the lions and tigers of the East.

The jaguar is no doubt a powerful animal, though much inferior to the great cats of the East; and the jaguar may be considered as the chief of those American species which lie in wait in thickets. The puma on the other hand is the typical species of those which inhabit the more open places, and prey upon small mammalia; and as the puma retains always a row of stripes or other markings on the sides, though in those places where it attains the largest size these are very faint, there is every probability that, in places differently favourable for its development, it differs much in colour as well as in size. The same may be said of the jaguar, and it is exceedingly probable that these two species will be found, upon more careful examination, to comprise many of those which have been described under different names—the forest varieties ranging with the jaguar, and the varieties of the open places with the puma.

Of these there seem to be some species found in that rich but partially explored country, the interior of Guiana, of one or two of which we shall quote a few notices from the very able and discriminating accounts of Hamilton Smith.

The Colocolo. "It does not appear certain," says Smith, "though it may be probable, that this is the animal Molina indicated as the colocolo, as he calls the marked spots, and not streaks, at least the word is so translated.

"This fierce animal was shot in the interior of Guiana by an officer of Lewenstein's riflemen, and by him stuffed and sent to England for his royal highness the Duke of York, but probably never reached its destination. A whimsical occurrence took place with it. The gentleman who had shot it placed it on the awning of the boat to air. As he was descending the river to Paramaribo, the boat often passed under the branches of large trees which overhung the river, and on which were the resting places of numerous monkeys, sometimes hanging to the extremest branches above the water. Although the vessel would, on other occasions, excite but little attention, no sooner was the stuffed specimen in sight than the whole community would troop off, with prodigious screams and howlings. It was of course surmised from the excessive terror of these animals, that this species of cat must be an active enemy to them.

"This animal was larger than the wild cat. The head was remarkably flat and broad; the ears large and round; the body slender; the tail just touched the ground when the animal was standing; the legs were very strong; the colour of the neck and back was whitish grey. The head, throat, shoulders, sides, belly, and inside of the limbs white. The back was marked with lengthened streaks of black, edged with tawny; and towards the shoulders and thighs with streaks of tawny. There was a black streak from the corner of the eyes to the jaws, and some bar like marks on the forehead. The outsides of the ears were dark grey, the insides pink and naked, as well as the nose. The tail was semi-annulated with black, having a black tip, and it exhibited a great peculiarity in the legs, which were all of them of a very dark grey colour up to the knees."

The Chati is another distinct American species, and the smallest of the whole. It is about eighteen inches long, the tail ten, and the height at the shoulder about eleven. The ground colour is brownish grey passing into white on the throat and belly, and the cheeks are also white. It is marked with black spots of very irregular figures, quite detached from each other, though traceable in a sort of lines along the back and upper parts of the sides. It is found in Brazil, but probably exists in several other parts of South America.

The Serval. This is the tiger cat of Africa, and an idea of its appearance and markings may be obtained from the annexed figure.

The Serval.

Africa appears to be the principal habitat of this species, though, it is probable, also found in the adjoining parts of Asia. In its general appearance and character it bears no inconsiderable resemblance to the last mentioned of the American species; and like them it is very probable that climatal varieties have been described as different species. It is the tiger-cat of the fur dealers, and brought under that name from Northern, Central, and Southern Africa, and, as the different parts of that continent differ very much in their physical characters, it might be supposed that there are corresponding differences in the same animal as inhabiting Barbary, Guinea, and the Cape The general colour is tawny, inclining to grey in some species, and yellow in others; but the insides of the legs, the lower part of the body and neck, are white. The produced hairs on the fore parts of the cheek are black, and from them double black lines extend to the throat. There are also black lines on the back of the neck, and the rest of the upper part of the body is spotted, the spots being continued as represented in the figure.

This is an animal of considerable size, though its size, like its colours, is subject to considerable variation. It is usually met with from two feet to two feet two inches in length, exclusive of the head and tail, the first of which measures four inches and a half, and the last twice as much. The height is about fifteen inches.

The serval is an exceedingly lively animal, found chiefly in the forests, in which birds and monkeys appear to be the principal part of its food; and from its size, the delicacy of its fur, and the beauty of its markings, it is much sought after by furriers. It is probable that this is the animal which has been described as the *Caracal*, or naked-eared lynx of northern Africa, and also that climatal varieties of it are the Cape cats, of some authors. It should seem that the colours of these animals vary considerably by age; and as the size also varies, not only in this, but in every species of the genus, which continue for a great part of their lives to grow in the bones, as well as to gather flesh, it becomes exceedingly difficult to ascertain whether the different sized and coloured specimens which are met with, be or be not different species. This is the grand difficulty which is met with in the systematic natural history of the genus *Felis*, and it is a difficulty of which there does not appear any means of getting the better. The wild habits of the animals, their retiring from view during the day, and their flitting before the progress of civilisation, render them puzzles to systematic describers. In their real natural history there is however no difficulty; for all the middle sized ones, with smooth ears, agree so closely in their habits, and perform parts so exactly alike, though in different quarters of the world, that there would be no great impropriety in regarding them all as one species, and including the wild cat of Europe among the rest.

As might be expected, animals of this description are very numerous in the south-east of Asia; and, as is the case in other parts of the world, their history there is a little perplexing; though the manners of all the varieties resemble each other so much that, in as far as utility is concerned, no serious inconvenience arises from the difficulty of determining the species. As is the case in the western world, some of them inhabit the banks of the rivers, and prey upon the small bank quadrupeds, and even upon fishes; but the greater number are found in the woods, with which all the richer parts of India and the oriental isles so much abound. We shall mention one or two of those which have been described as species :—

Java Cat (*Kuwuk* of the natives of that island) is of a greyish-brown colour above, with the throat, neck, and other parts, white; the ears are small, and placed at a considerable distance from the eyes; the body is small and handsomely made. This is a very active and also a very handsome animal, bearing a considerable resemblance to the domestic cat, in the general form and action of the body, but differing so much in the head, that it cannot be considered as the parent stock of that animal. The whole of the upper part is marked with distinct blackish spots, which form streaks on the head and neck, but gradually become rounder as they proceed toward the tail. The tail is annulated, though somewhat irregularly. The length varies; but the average, when full grown, is about two feet, and the length of the tail, and also the height of the animal, about nine inches. This species is entirely a forest animal, and very abundant, resembling in its habits our wild cat, as nearly as a tropical animal can be supposed to resemble one of temperate climates. It forms its den in hollow trees, where it remains inactive and silent during the day, but at night it is exceedingly active, committing extensive depredations among birds and the smaller mammalia. It seems, indeed, to be one of the most voracious feeders in the whole genus; and is not so delicate in its feeding as some of the others, as it eats carrion greedily when recent food cannot be obtained. It is a fierce animal, quite untameable, according to the accounts, and at the same time very bold and daring in its manners, invading the poultry yards of the natives with equal boldness and dexterity. Indeed, in its native woods, the perching gallinidæ form no inconsiderable portion of the prey of this animal; and they breed so fast as to afford it a very ample supply.

The Sumatra Cat. It does not appear that this species differs in any material degree from the former; only it is said that the ground colour on the upper part is yellower, the spots larger, blacker, and more irregular; and that the animal is found nearer to the water.

Diard's Java Cat. This species, if distinct species it be, was discovered in the forests of Java by the naturalist whose name it bears. It is described as being larger than the other, being about three feet long, exclusive of the tail, and standing a foot and a half high from the shoulder. It is greyish yellow on the upper part, with distinct black spots which form longitudinal rows; and on the flanks these spots are annulated, black, with grey centres. The tail is annulated, or perhaps rather clouded with grey and black. It is not so common as the species formerly mentioned.

There are some species or varieties of cats in the central mountains of Asia, to the northward of India, with whose appearance and manners we are little acquainted; and the few notices which have been given of them are so indefinite, as to render it unnecessary to refer to them here.

It must be borne in mind, that there are difficulties attending the natural history of this part of the world, which render it somewhat difficult to decide between what are really natural productions, and have remained in that state from the beginning, and what are productions once domesticated or cultivated, which have lapsed into a wild state, in the various changes and revolutions which that part of the world has undergone.

To the northward of these central mountains we may expect a change in the animals of this genus, corresponding to that which occurs in the general physical circumstances of the country. In consequence of the drought, the summer there is nearly as warm as in India, at least the more elevated and northerly parts; but the winter is very cold, colder indeed than in Europe under the same parallel of latitude. The coverings of animals undergo changes, adapting them to these extremes of temperature. It consists of two sorts of hair or fur; a close and woolly one, more or less frizzled according to the species of animal, and one consisting of longer and straighter hairs, which serve to throw off the snow, while the under fur protects the animal from the cold. There is only one well ascertained species of cat which inhabits this part of the world; and it is found in the mountains which skirt the southern boundary of Siberia, and eastward along Chinese Tartary. This species is

The Manul (*Felis manul* of Pallas). This species is in its covering, and several other of its characters, intermediate between the cats, properly so called, and the lynxes, but its tail is much longer than that of the lynx, and its ears are not pencillated, that is, they do not terminate in a pointed brush of hairs. There is one variety of the lynx, a red one, with very obscure spots, to which this animal bears no inconsiderable resemblance; but the tail of the manul is long and bushy like that of the fox, and marked with about nine rings of black. The general colour on the upper part is reddish-yellow, fading into whitish on the under part; this colour is nearly uniform and entire; but the forehead and top of the head are mottled with small black spots. The winter fur all over the body is nearly two inches in length, but it is cast as the warm weather sets in; and toward the latter end of summer, when the new fur is rather less than an inch in length; the skin is highly prized by the furriers. The muzzle is very short, and the animal is said to possess one tearing tooth fewer than the typical cats; but still it belongs to the genus *Felis*, and not to any other.

In its general habits it differs from all its congeners, being found in bleak and exposed places, generally among the rocks, where it seeks its food by chase rather than stratagem. That food consists chiefly of hares and other rodent animals, which abound very much in these wild places; but, true to the habit of the genus, it preys during the night, and most likely catches these animals when squatting on their forms. It does not climb trees or enter the forests; and, according to all the accounts which we have of it, it differs greatly from the rest of the genus. There are, however, many particulars to be ascertained before we can speak decidedly respecting either its natural history, or the natural history of the very peculiar district which it inhabits. We may, perhaps, at some future period, be able to establish this, and one or two animals of similar places, of which the indications are exceedingly vague, into a separate group or sub-genus; but at present the data which we possess are too scanty for this purpose, and we must therefore describe the manul as a cat, intermediate between the southern cats and the northern lynxes, but combining with the characters of these some at least of the habits of the fox.

LYNXES. These animals form a tolerably distinct group, of which the most remarkable characters are—the fur very long, the ears pencillated, and the tail short. They are bold and fierce animals, though without the savage character which marks the more powerful cats of warm climates.

Barbary Lynx, or caracal. This species is found in northern Africa, and south-western Asia, at least as far to the east as Persia. Its colour is uniform venous red; the ears are white within, but black on the outside, and they stand up conspicuously. It is on this account that it is called "caracal," which is the Turkish for black ear. Its length is—the head five inches, the body two feet, and the tail about six inches; and it stands about a foot and a half high at the shoulder. This is the species which borders most nearly on the manul, and the one with which that animal has sometimes been confounded; but the difference in the ears and the tail is sufficiently conspicuous to prevent any mistake with those who have seen both animals.

The Booted Lynx, or *Marsh Lynx*, is a smaller animal than the former, and its colours are not so entire. It inhabits the same regions of the world, only it frequents more humid places, and preys upon aquatic birds, indiscriminately with small mammalia. Its size is rather greater than that of the common wild cat, though that animal varies so much that it forms but an indefinite standard. Its tail is shorter than that of the caracal, but not quite so small in proportion. Its colour is yellowish-brown on the upper part, shaded deeper in some places, fading into lighter on the belly, and on the throat nearly white. The limbs and cheeks are yellowish, and so are the insides of the ears, but there are three black annuli on the tail, and the tips of the ears and hind parts of the paws are also black; from which last circumstance the name of booted lynx is given to it.

The Common Lynx. Some notion of the general appearance of this animal may be obtained from the following figure, but it is an animal which ranges over a great extent of longitude and also of latitude, and thus it is subject to great varieties of appearance.

The Common Lynx.

The common lynx was in former times very plentiful over all Europe and in the northern part of Asia, but its numbers have fallen off greatly, so that it is now entirely unknown in France, and rarely, if at all, in Germany. It is a forest animal, and is met with only in those places which are covered only with thick trees; and it appears that the cause of its becoming extinct in the more cultivated parts of Europe is the cutting down of the forests. It is still abundant in Sweden, in the forests of Russia, onward to Siberia, subject to considerable variations in size and in colour. There are considerable varieties even in the same country, and in Sweden the names of "cat lynx," "fox lynx," and "wolf lynx," are known to the country people. It does not appear, however, that there is any more reason for regarding these as different species than there is for so regarding the "hog badger" and "dog badger," of which mention is made by the country people of Britain; but the lynx, even in a single individual, has some claim to all the names bestowed on them by the Swedes. It is a cat certainly; it has at least some of the craft of the fox; and its howling at least resembles that of the wolf. It is said to be very long-lived, and subsists by hunting and pursuing its prey on the tops of the highest trees, feeding on ermines, weasels, squirrels, &c., which are unable to escape from it. The lynx watches the approach of the fallow deer, hare, and other beasts of the chace, and darts on them from the branches of trees, where it lies concealed, seizing them by the throat, and sucking their blood; after which it abandons them, and goes in quest of fresh game. Its sight is remarkably quick, and it eyes its prey at a great distance. When attacked by a dog, it lies down on its back, strikes desperately with its claws, and frequently compels its assailant to retreat. When urged by hunger, it has been known to prey on its own tribe. The female is gravid nine weeks, and brings from three to four young. As its manner of howling is similar to that of the wolf, and its skin is variegated with spots like those of a young stag, the lynx has been denominated *lupus cervarius* by some naturalists, and *loup cervier* by many of the French writers. In a state of captivity it is extremely ferocious, frequently expressing its malignity by a snarling scream, and refusing to be tamed. Its fur is held in considerable estimation on account of its softness and warmth, and it is exported in great quantities from America and the north of Europe. In general, the farther north that this article of commerce can be procured, the whiter it is, and the spots are more distinct. The skin of the male, too, is more spotted than that of the female.

It is unnecessary minutely to describe the colours of an animal which is subject to so much variety from age, season, and climate, as the lynx; but we may mention in general, that its prevailing colour is reddish brown, marked with small spots of darker brown, its ears long and pencillated, and its tail short, and black at the tip. The fur on the body is very long, especially in the winter months, and in the more northerly localities; and in these the colour in winter becomes much paler than it does in places farther to the south.

It is natural to suppose that an animal which is passing away, as the lynx appear to be doing in many parts of the eastern world, should change its characters in the individual along with the decrease of the numbers; and therefore, though we cannot perhaps give implicit confidence to the stories told by the ancients of the strength and craft of this animal, yet it is highly probable that lynxes were much more formidable, and also much more daring, when they inhabited the rich forests of central Europe, than they can be now that they are confined to the comparatively barren pastures of the extreme north. It is true that the centre of Europe was colder than than it is now; but it is also true that, with reference to wild nature, it was more productive.

We have evidence of a falling off in the character of the individuals, being an accompaniment of decrease in numbers in another animal of this genus—the lion himself. Upon turning back to the notice of that animal, it will be found that, in India, and partially also in Persia, where lions have reappeared after they were supposed to have been extinct even for centuries, they evinced very considerable deterioration of character, which clearly show that in their case there was a wasting of the race, as well as a lessening of the numbers, during the period of their decline.

Those which are now met with in India are smaller and lighter made, paler in the colour, and with their mane small and feeble as compared with the lions of Africa, where these maintain their position as lords of the wilderness. And if this has been the case with one animal, we may not only conclude that it must be the case with all other animals of the same genus, but with all animals whatever. A race of animals may be cut down in their strength, if a direct war of extermination is waged against them; but if they yield to the change of natural circumstances, they must yield gradually, and decline in strength and energy of character, generation after generation, for some time before they become extinct.

This is a most important branch of natural history—a curious law in the animal economy, from which man himself is not exempt; and any one who has an opportunity of examining, for a long period, the lists of men in any given locality, will find that it contains a curious succession of surnames, and consequently of races or families. We shall find, for instance, the predominance of some particular surname at almost whatever point of the record we may begin, and at the same time we shall find several other names less numerous.

After a time, some of these will increase in number, while others disappear from the record, and the increasing ones will grow till they become predominant, and again fall off. Of course the waxing, the waning, and the permanence, are not the same uniformly, neither are they the same even in one family. But still the progress of the law itself is exactly as has been now stated; and, were such records accurate, a philosophical examination of them would be of great value in studying the progressive history of human society.

Now, in all the rest of nature, and more especially in animated nature, we may fairly look for the same vicissitudes, and though these may take place sometimes at long periods, and sometimes at short ones, yet this is the only rational way which we have of connecting the state of the world as at present it exists with those former states, of which we have dumb evidences in the remains both of animals and of plants, and also for enabling us to grope our way to the future, in so far as that is practicable.

This is not the place for even giving an outline of what should be done on this highly interesting, but exceedingly difficult subject. We must content ourselves with throwing out the hint, and earnestly recommending it to the attention of our readers. At the same time, we may remark, that there are few animals whose progressive history is so important in this respect as the common lynx. We cannot say positively that the lynx follows the pine forests, but still, whether we look at the eastern continent or America, there appears to be more connexion between them than can be merely accidental.

Canada Lynx. This animal is much longer furred, and has fur of a much finer texture, than the common lynx, and on the sides of the head the fur is very much produced. The general colour is pale ash, yellowish on the upper part and whitish on the under, but without any spots or markings. The grey colour is produced by a mixture of the yellow basis and white tips of the fur; in the more northerly parts of Africa the colour is very pale and very entire; but farther to the southward lynxes are found with shorter fur of a reddish colour, and more or less spotted with brown; and in the mountains to the westward of the United States they are described as being different. It is possible, however, and indeed by no means unlikely, that there are local or climatal varieties of one species, or at most of two; and though their skins are obtained in great numbers by the fur-merchants, we are still without any good account about the animals themselves, and we must look to others than the hunters for better information, because those whose business it is to kill animals are very seldom good naturalists.

We must here close our notice of this most interesting genus of wild animals—a genus, the characters of which are imperfectly understood, and whose history is involved in much confusion; but there is so much to be done, and also to be undone, that we must content ourselves with the hints already given, until the animals shall be more carefully studied in their native dwellings.

CATABROSA (Beauvois). A curious aquatic perennial herb, indigenous to Britain. Linnæan class and order *Triandria Digynia.* Natural order, *Gramineæ.* The catabrosa aquatica was formerly called aira aquatica in English botany; and there is another species called viridula; but they are both small inconspicuous plants.

CATALPA (Tussac). A fine flowing ornamental tree, formerly called Bignonia catalpa. Linnæan class and order, *Decandria Digynia.* Natural order, *Bignoniaceæ.* Generic character: calyx in two parts; corolla bell-shaped, tube swollen, limb of four unequal lobes; stamens five, three of which are sterile; style bearing a double-plated stigma; capsule pod-shaped, two-valved; dissepiments opposite the valves; seeds many, their base and apex covered with membranaceous down. This tree has been in our shrubberies ever since 1726; and in old gardens, where collections of curious plants were cultivated, the trees have got to a considerable size, and are annually covered with flowers.

CATANANCHE (Linnæus). A genus of two species of ornamental herbs, one perennial, the other an annual, both natives of the south of Europe. Linnæan class and order, *Syngenesia Æqualis;* natural order, *Compositæ.* Generic character. anthodium imbricated, with broadish carious scales; receptacle bristly; pappus composed of five chaffy awns. These plants thrive well in the open borders, and are propagated by seed, or divisions of the root.

CATAPHRACTUS (Lacepede). A genus of soft-finned fishes with abdominal fins, belonging to the family of *Siluridæ* in Cuvier's arrangement. The characters are, the body almost entirely cased on the sides by four rows of scaly pieces, similar pieces on the upper part of the head, but the point of the muzzle and the lower part of the body are naked. There is only a single ray in the anterior margin of the last dorsal fin. The spine in the pectoral fins is very strong, but that in the first dorsal is short and feeble. The opening of the mouth is small, and the teeth are barely visible. The eyes are very small, and placed in the sides of the head.

They are all fresh water fishes, and found in the rivers of warm countries. Some of them have the pectoral spines smooth, though the greater part of them have them jagged or toothed. These spines, especially the jagged ones, are capable of inflicting very severe wounds; and they appear to form the natural weapons of the animals. They are bottom fishes, having the gill-openings very small; and they are very tenacious of life, and can crawl and wriggle about on the dry ground like eels.

CATARIA. The old trivial name, and now the specific name, of the *Nepeta*, or catmint of Britain.

CATESETUM (Richard). A curious family of South American epiphytes. Linnæan class and order, *Gynandria Monandria;* natural order, *Orchideæ.* Generic character: flowers ruspinate; sepals unequal, conniving, and hollow; labellum large, inflated, concave, and adhering to the column; column cylindrical, concave in front, dilated above; apex produced to a point; two filiform processes project downward from the column; pollen in two masses.

There are six species of these interesting plants already introduced into English collections, and no doubt many more will in time be found in the same quarter of the world. Their management in our hothouses is as yet but imperfectly understood; but great advances have been lately made in the culture of *Orchideæ*, and no doubt, if suitable houses are built for them, as has already been done by some spirited individuals, their culture will be as well understood as that of any other exotic plant whatever.

CATCHFLY. The English name of a numerous family of herbaceous, annual, biennial, and perennial European plants, called *Silene* by Linnæus and other botanists. Some of them are highly ornamental, many are pretty, and all of them curious. The strong-growing sorts thrive best in light rich soil, and they are all easily increased by cuttings or by seeds.

CATECHU. The specific name of a palm, called *Areca* by Linnæus, and by the English cabbage-tree. It also yields the medicine called catechu.

CATERPILLAR. A plant so called from the resemblance of its curious-twisted pods to the larva of butterflies. It is the *Scorpiurus* (scorpion's tail) of botanists, and consists of six species, all natives of the south of Europe. As objects of curiosity, the plants are raised in flower-gardens along with other hardy annuals. The flowers are nothing, but the pods are exceedingly curious.

CATERPILLAR. The common name by which the larvæ of lepidopterous insects are known. There is the greatest possible difference in the appearance of these insects in this stage of their existence, so that it is difficult to lay down any general observations upon them. They are for the most part of an elongated and cylindric form, and the body is fleshy, often entirely naked, but oftener clothed with hairs, spines, tubercles, or warts; they are composed of thirteen rings, of which the first represents the head, the second, third, fourth, the thorax, and the remainder the abdomen of the perfect moth or butterfly; moreover on each side of the body nine breathing spiracles are to be observed. The head is generally of a more scaly nature than the remainder of the body, and is furnished on each side with six minute shining tubercles which appear to be the rudimental eyes of the future insect, as well as with two short conical antennæ, and a mouth furnished with a pair of very robust jaws, two fleshy under jaws with their two palpi, and an under lip with its two palpi. The silken matter which is spun by these insects, and which in the silk worm (which is the caterpillar of *Bombyx mori*) constitutes one of the most valuable of insect productions, is elaborated in several long internal vessels, of which the extremities are narrowed and terminated in a tubular and conical tubercle, situated at the tip of the lower lip, which thus acts as a spinneret for the discharge of the silken threads. Caterpillars are also furnished with six short-jointed scaly legs attached in pairs to the second, third, and fourth segments, and representing the legs of the future insect; they moreover possess from four to ten fleshy legs armed at the extremity with a circular series of innumerable little bent hooks; the hind pair of these false legs, as they have been termed, are placed at the extremity of the body near the anus; and it is by the assistance of these fleshy legs that the insect in general retains its hold upon the substance upon which it is placed; thus we find the fore legs of the sphinx caterpillars seldom employed except in progression, the insect when at rest raising the fore part of its body into a curved position, whence the fanciful name of sphinx was given to this

Fig. 1, Caterpillar swallow-tailed moth (*Curapteryx Sambucaria*). Fig. 2, Caterpillar privet hawk-moth (*Sphinx ligustri*).

group of insects. In like manner many of the looper caterpillars when at rest erect themselves into an upright position, or at different angles with the branches, on which they are observed attaching themselves firmly by means of the hind pair of false legs alone, closely resembling in this situation small twigs, a resemblance greatly increased by the colour and warty appearance of many of these animals. These species have only ten or twelve legs including their six fore legs, and have obtained their name of loopers from the curious manner of their progression, seizing hold of the twig with the fore legs they elevate the intermediate rings of the body until it almost assumes the appearance of a ring by bringing the hind legs almost in contact with the fore ones, so as exactly to resemble the Greek letter Ω, as represented in the figure of *Abraxas grossulariata;* they then leave go with their fore legs, and extend the body in a straight line, retaining at the same time with their hind legs the hold of their advanced position, so as to enable them again to effect the same manœuvre. They are enabled to effect these motions as well as to retain their fixed and outstretched position for a great length of time, by means of the prodigious muscular power which they possess. In fact, according to Lyonnet, in the caterpillar of the goat-moth (*Cossus ligniperda*), there are more than four thousand muscles.

Thus we see that the hasty assertion contained in a work which has just been published, that the possession of a greater number of eyes than two, and of legs than six, leads us to refer an animal to some other division of animated nature than that of insects, is completely negatived, as well as the following statement, that "the propodeon* and following segments never bear limbs of any kind, whether wings or legs."—Newman's Grammar of Entomology, 1835, p. 100.

Caterpillars are, for the most part, vegetable feeders, some feeding upon leaves, often causing great destruction, as we have lately had occasion to mention under the article Bupalus; the cabbage caterpillars, and those of the brown-tail moths, may also be mentioned; others devour flowers, roots, buds, and seeds; whilst a few feed upon the ligneous particles of trees, boring, as in the case of the goat-moth, &c., through the stems, and sometimes even completely destroying them when in a young state; others, again, feed upon cloth, furs, &c., of which the caterpillar of the clothes-moth, one of our most destructive domestic enemies, is an example; whilst a few devour lard, wax, and other fatty matters, as in in the galleriæ; some species are confined to a single plant, whilst others, as the garden-tiger moth, will thrive upon many different sorts; some species, again, are found in a state of society, as is especially the case with the small ermine moths and the processionary caterpillars; these spin a common web, which serves to protect them during inclement weather. Others, again, take a similar precaution, although solitary in their habits, as is the case with many small *Tineæ*, *Psyche*, *Fumea*, and in the large exotic *Oiketicus*, all of which form portable mantles, or cases, in which the caterpillars reside, and in which they become pupæ. Many species of the minute and gilt *Tineæ* reside within the body of different leaves, feeding upon the parenchyma, and forming slender tortuous passages. Many caterpillars feed by night; the majority, however, are day insects.

These caterpillars, for the most part, shed their skins four different times previous to becoming chrysalides; they then generally spin a silken cocoon, in which they inclose themselves, and in which they undergo their transformations. Others, however, simply fasten together the neighbouring leaves, particles of earth, or of the substances upon which they have been feeding, so as to form a rougher kind of cocoon. The caterpillars of butterflies, however, as we have stated under the article Butterfly, very rarely indeed take any of these precautions.

The following extract from Mr. Peale's beautiful "Lepidoptera Americana" (of which the publication has recently been commenced in Philadelphia), will, we are sure, be read with interest, presenting as it does one of the most interesting manœuvres hitherto recorded relative to the insect race. It relates to the *Bombyx Promethea* (Linnæus), a very handsome large moth, very abundant in 1833 in the vicinity of Philadelphia, at least judging from the number of cocoons seen hanging from the branches of the sassafras (*Laurus sassafras*) and spice-wood (*L. benzoin*), and which, by an ordinary observer, would readily be mistaken for withered leaves which had withstood the blasts of winter, for such they were evidently intended by the little architect to represent whilst preparing its narrow cell. After the caterpillar has attained its full size, and lost "the voracious appetite which had hitherto been its predominant character, it begins its preparations for the great transformation it is to undergo, by selecting a perfect leaf, the upper surface of which it covers with a fine light yellowish brown silk, extending this coating with great skill and foresight over the footstalk of the leaf, and attaching it firmly to the branch, so as to secure the leaf from being separated by any accident. This preliminary operation having been accomplished, the caterpillar next draws the edges of the leaf together, thus forming a perfect external covering or mantle, in which it spins a fine strong and durable cocoon of fine silk. In this habitation our little architect passes the winter secure from birds and other enemies. As soon as the cocoon has been completed, the caterpillar again sheds its skin, and is transformed into a pupa or nymph. At first, the leaf enveloping the cocoon remains green, but soon changes to a red or brown, when it becomes brittle, and is gradually carried away by the winds and storms of winter, until, finally, nothing remains except the cocoon itself, which is firmly suspended by the silk which once covered the footstalk of the leaf." The instinct of the caterpillar in thus providing for the permanent attachment of its future

Caterpillar, leaf-cocoon, and chysali of the Prometheus moth.

habitation appears far to exceed that shown by any other caterpillars, if we except those of the pomegranate butterfly of the East Indies, of which an account was read at a meeting of the Entomological Society of London. The silk spun by the *Prometheus* moth, according to Mr. Peale, is as fine, and is produced in as great abundance, as that furnished by the *Bombyx mori*, or common silk-worm, but it is of a darker colour, and will, it is feared, always present difficulties in reeling, from the manner in which part of it is attached to the branch. We cannot conclude these observations without congratulating our readers upon that widely-extending spirit of observation into the wonders of the creation, of which Mr. Peale's work exhibits an example, trusting, at the same time, that this beautiful book will meet with that success which it so richly deserves. See also the articles Butterfly and Lepidoptera.

CATESBÆA (Gronovius). A genus of beautiful flowering shrubs, natives of the West Indies, and

* Under this name and those of podeon, metapodeon, octoon, ennaton, &c., this author has most absurdly, as far as simplifying the science is concerned, designated the abdominal segments of insects. The uselessness of such a nomenclature is equalled only by its bungling nature as contrasted with the Latin names of caput (head) and prothorax, which he has adopted, or the hybrid and incorrect names of metalæ, metapedes, &c., which he has proposed.

named in honour of Mark Catesby, Esq., author of the Natural History of Carolina. Linnæan class and order, *Tetrandria Monogynia;* natural order, *Rubiaceæ.* Generic character: calyx of four teeth or divisions, persisting; corolla tube very long, funnel-shaped, limb in four divisions; stamens, filaments inserted in the base of the corolla, long and exserted; style filiform; stigma with two teeth; berry crowned with the calyx, two-celled; seeds imbricated and scaly. These plants, from the amplitude and shape of their flowers, are called the lily-thorn, and no plant has a more splendid appearance when in flower. They are propagated by cuttings struck in sand under a glass in a hotbed.

CATHANTOCARPUS (Persoon). A genus of tropical trees, celebrated for their medicinal qualities. Linnæan class and order *Decandria Monogynia;* natural order *Leguminosæ.* Some species of this genus were formerly included in the extensive one, *Cassia*, their purgative qualities being similar. Some of them are free flowerers, and are propagated by cuttings planted in sand, in a little heat. A loamy soil is most suitable for established plants.

CATILLUS (Cuvier). A genus of molluscs, the animal of which is quite unknown; first established by Brongniart, from fossil species erroneously confounded with it.

CAT-MINT is the *Nepeta cataria* of Linnæus. It belongs to a very numerous family of perennial herbs, mostly indigenous to the south of Europe. The common cat-mint is a native of Britain, and frequently found by road sides and on waste ground.

CATOCALA (Schrank). A genus of lepidopterous insects, belonging to the family *Noctuidæ,* and comprising some of the largest and most beautiful species in the family. The body of these insects is less robust than in the majority of the group to which they belong, and the abdomen is gradually attenuated from the base, the spiral tongue is as long as the antennæ, and the latter are rather long, slender, and similar in both sexes; the wings, which are scalloped, are large and but slightly deflexed during repose, forming a broad triangle; the larvæ have sixteen legs, the two anterior abdominal ones being less perfect than the following. They do not go underground to perform their transformations, like the majority of the family, but inclose themselves in a cocoon, placed within rolled-up leaves, and covered with a fine purple bloom.

These insects exemplify, in a remarkable manner, the observations which we have in some degree noticed under the article *Calosoma;* the family *Noctuidæ* being composed, for the most part, of dingy and obscurely-coloured moths, would lead us to believe that they were formed for the dim and dusky twilight, and such is the case; but there are some insects in this family which are more gaily coloured, amongst which the gold and silver spangled moths (*Plusiæ*) are most conspicuous, and these, like their types the humming birds, are often to be seen hovering about the flowers in the hottest sunshine. In these, however, it is the upper wings which are alone ornamented, the lower ones, when at rest, being completely concealed by the upper pair, but the reverse of this takes place in the catocalæ; here too, indeed, we have even a more marked diversity between the colouring of the upper and lower wings, the former being generally grey or ashen colour, variegated with bands and markings of a darker hue, whilst the latter, which in this genus are of very large size, are nearly always of a rich crimson colour, with broad black bands. If therefore, as has been asserted, the catocalæ were twilight fliers, and "always to be observed only about six or seven in the morning, and never at any other time," the brilliant colouring of their under wings would escape notice, but such is not the case, as we have seen them repeatedly on the wing at mid-day; indeed, the author of this article has cause to remember an especial chace of one of the species amongst the willows, upon the banks of the Isis at this same period of the day. The caterpillars of these moths likewise, in their colouring, present two circumstances worthy of notice. We have seen (article CATERPILLAR) that some species closely resemble twigs, but in this genus the larvæ bear so much similarity to a stripe of brown lichen dotted with black, that they would be easily overlooked, the deception being increased by the sides of the caterpillar being flattened, fringed with short whitish hairs, and applied to the twigs; hence Lyonnet describes one of these larvæ in his recently published researches as a "grande chenille qu'on n'aperçoit pas aisément." The other circumstance which we would notice relates to the want of uniformity between the colours of the caterpillar and perfect insect; in this case the former is unsightly, whilst the latter is highly beautiful; but the reverse of this often takes place, whilst it not seldom happens that two larvæ which closely resemble each other, produce moths totally different in colouring; the habits of the caterpillar likewise are quite at variance with those of the perfect insect, for Lyonnet has observed, that none of his caterpillars fed during the day, but remained stationary in the branches from morning till evening, and it was not until after sunset that they quitted their stations to commence feeding. The same author has, with great care, represented the structure of the abdominal legs of the caterpillars, and has ascertained that there are about fifty minute doubled hooks on each foot, so that it may be said that this insect has not less than five hundred claws.

There are five or six British species, the large red under-wing moth (*Catocala nupta*) being the most common, as well as the typical species. It appears at the end of the summer; but the largest species is the Clifden nonpareil (*Catocala fraxini*) in which the under wings are of a fine pale blue, with dark bands. This is very rare, and is about four inches wide.

CAT'S-EAR is the *Hypochœris maculata* of Linnæus. There are about a dozen species belonging to the genus, all European plants. They are in the natural order *Compositæ,* and bear yellow flowers.

CAT'S-TAIL is the *Typha angustifolia* of Linnæus. There are three other species of cat's-tail, inhabitants of pools and ditches; being reed-looking plants, with their flowers and seed-vessels arranged in a cylindrical, brown head, near the top of the stems. This feature renders the typha particularly conspicuous among its aquatic intimates.

CAT'S-TAIL GRASS is the *Phleum pratense* of botanists. It belongs to the order *Gramineæ,* and consists of nine species, which are all (except two) perennials. Four of them are agricultural, and valuable as pasture and meadow grasses. They are all indigenous to Europe.

CATTLEYA (Lindley). A remarkable and beautiful genus of *epiphytes,* natives of South America. Linnæan class and order *Gynandria Monadelphia;* natural order *Orchideæ.* Generic character: flowers ruspinate; sepals spreading, nearly equal, edges undulating; labellum hollow, dilated at the point, edges waved or curled, surrounding, but not adhering to the column; column wingless, semi-cylindrical, concave in front, point obtuse, and three-toothed; pollen masses parallel. This is certainly one of the most splendid of all the *Orchideæ*, the flowers being large and richly coloured. They flower readily when properly treated; which is not by potting them in soil, but among moss in dry cocoa-nut husks, fastened to a dead stump of a tree having the bark on, set upright in the bark-bed. A moist atmosphere and a high temperature are necessary for this, and all the other South American *Orchideæ*. They are increased by dividing the root. This genus received its name in compliment to the gentleman who introduced, and was a successful cultivator of it, William Cattley, Esq.

CAUCALIS (Linnæus). A genus of annual herbs, natives of Europe, of no beauty, nor are they cultivated. Linnæan class and order *Pentandria Digynia;* natural order *Umbelliferæ*. Several of the species are found in England, and are called bur-parsley.

CAULIFLOWER. A favourite variety of the cabbage family, long cultivated in this and other countries of Europe. As the common cabbage is cultivated for its congregated head of leaves, so is the cauliflower for its large head of flowers. The flowers of almost all the Brassicæ are, on their first appearance, compactly united together, but those of the cauliflower and broccoli are much more so than any of the others. For this peculiarity of growth they are managed under prescribed rules of practice which experience has laid down.

It is not probable that the cauliflower was, when first noticed and used as a distinct culinary vegetable, so perfect as to compactness and size of head, as we now find it to be. Selecting the truest of the desired character from each succeeding crop, has been the means (by raising sub-varieties) of gaining the superior sort we now possess. And, indeed, even at this day, it requires no little share of attention to keep the best sort free from adulteration with other species of cabbage, and to prevent them running back to their original habit. The plants which produce the whitest, closest, and largest heads, are those which can only be depended on to produce their like; and, when reserved for seed, care must be taken that no inferior or different plant of the same genus be in flower at the same time near them.

This cauliflower being the most delicate of its tribe, much care is required to preserve young plants through the winter; but this is absolutely necessary, otherwise the flowers cannot be had so early for table as they are required in the spring. They, therefore, for the principal crop, require to be sown in the autumn, nursed through winter, and planted out when the spring is so far advanced as not to risk their well-doing.

The cauliflower is a biennial, that is, it requires parts of two years to arrive at full perfection. Sown in the autumn of the first year, it ripens seed in the summer of the second; and a rule must be observed as to the precise period of committing the seed to the ground; if sown too early, the flower comes forth prematurely; and if too late in the autumn, the flowers do not come into use soon enough in the following summer.

To provide against these exigencies, practical men have found that the best time for sowing the principal summer crop is any day between the *eighteenth* and *twenty-fifth* of August. It is well to make three small sowings between the first of these dates and the beginning of September, in order to have an extended season of the crop in the following year; for it is generally found that all the plants, from the same sowing, come in for use together, a circumstance to be avoided if possible. Some practitioners are of opinion, that the latest sowings in August, especially if not pricked out into nursery beds till November, are hardier, and stand the rigours of the winter better than the earlier sown and transplanted plants. There is some reason in this; because early pricked-out plants have taken root, and are in active growth when the frost sets in, and therefore more easily hurt; whereas, plants which have been pricked out into nursery beds in November, are stationary from the check of removal, and consequently less liable to suffer from frost. But whenever sown, it is the universal practice to transplant the seedlings, as soon as they have got three or four leaves, into nursery beds, either on warm sheltered borders, where they may be occasionally covered by hoops and mats in inclement weather, or into glazed frames, or under hand-glasses. In giving protection against frost, however, care must be taken not to give it unnecessarily; because the plants become so tender under coverings, that the least accidental exposure afterward kills them outright.

Protecting cauliflower plants under bell or hand-glasses, is one of the most common expedients in kitchen gardening, and is executed as follows, viz.:— A border, on the end or side of a compartment in the open garden, is prepared by having a good coat of rich dung deeply digged in. Thus prepared, it is divided into four feet wide beds, with two feet wide alleys between. Along the middle of the bed or beds a rank of hand-glasses is placed, by line, two feet apart from each other. Within the impressions made by the bottoms of the glasses, four or six of the best and healthiest plants are dibbed or let in with a trowel. Three or four of these plants are intended to perfect their heads on the spot; the supernumeraries to be transplanted to some other place in the spring. When the planting is finished, a little water may be given to each to settle the earth about their roots, especially if the weather or soil be dry, as sometimes happens in the month of October, the proper season for the performance of this work. The glasses are then put on for the winter, but, on the morning of every fine day, the south fronts of the glasses are raised on a brick-bat to admit fresh air, but shut down close again at nights.

This is the only protection and attention required by the plants throughout the winter, except perhaps taking the glasses entirely off in the middle of a mild day, stirring up the surface of the earth among the plants, and taking off dead or dying leaves, and replacing the glasses before night. Attention should also be given that no snails or slugs take up their winter quarters within the glasses, because these would assuredly injure the plants one way or other. If any enemy of the kind appear, a dusting of hot lime, or a sprinkling of lime water will kill or drive them away.

The plants, during March, will be advancing rapidly; and about the beginning of April will have filled the glasses with their leaves. When this takes place, the supernumeraries must be removed, and those that remain well earthed up, at the same time forming a kind of basin round the roots to hold water, copious supplies of which they will occasionally require if the season be dry. At this time also, the glasses are raised all round, by being set on three or four brick-bats to give head room, till about the beginning of May, when they may be taken off the plants entirely.

Cauliflower plants cultivated in this way are the first ready for table, and very often come in too much together for private use, too many hand-glasses, therefore, need not be employed; for those plants which have stood, perhaps, exposed to the open air all winter unscathed, will come into use very shortly after those in glasses. The progress of the plants depends greatly on the winter; if it has passed mildly, whether under protection or not, the plants are advanced accordingly; but, in severe and long continued frost, every exposed cauliflower plant is cut off.

In places where a high style of kitchen gardening is carried on, and where there are forcing-houses of different descriptions, another method of obtaining an early crop of this favourite vegetable is had recourse to, which is as follows:—As soon as the seedlings which are sown about the 25th of August are fit, that is, large enough to handle, they are planted in sixty-sized pots, filled with very rich compost. When potted, they are first watered, and plunged in the earth of a cold frame not too far from the glass. They must have fresh air daily, by raising the lights at the back, and kept duly watered. As soon as the roots have spread to the outside of the ball of earth, they must be shifted into forty-eight-sized pots, and, in similar compost, watered, and replunged again in the frame. In another month the plants will require thirty-two-sized pots, afterwards twenty-fours, and, ultimately, about the 1st of March, sixteens. When fairly established in these last pots, say about the 1st of April, they are taken into a peach-house or vinery, and set in pans of water along the front flue or platform of the house. Here they should have as much fresh air as possible, and should always be well supplied with water; for if, in any stage of their growth, more especially after being taken into the house, the roots get thoroughly dry, the plants immediately *button*, that is, produce flower-heads no bigger than buttons. About the middle of April the plants may be taken out of the house, and turned out into pits made to receive them, either upon a south border or in the alleys between asparagus beds. In these places they should be let in four inches below the common surface of the ground, and have the earth drawn to their stems to keep them steady. Should frosty nights occur after they are out, a few fir-boughs, stuck so as to lean over them, will save them from injury. Cauliflower plants treated in this way generally produce fine heads about the 1st of May.

An observation may be made here as applicable to the cauliflower, and all other plants whose flowers are terminal, that is, bearing them on the points of the stem or branches. Such plants are composed of a system of organs, namely, a root, stem, a certain number of leaves, flowers, and seed. If such a plant, in its early youth, receive extraordinary excitement, the flower will be brought forward prematurely, as already observed, and before the other members have acquired sufficient volume to yield a flower-head of any considerable size. This invariably happens if the seed be sown too early in August, because the natural tendency of the plant is to produce seeds before the summer is over; but by sowing later, the decreasing temperature of the season affords a longer spring-time, in which the whole system is amplified, and a larger flower produced. So also, if the early growth receive a check, either by being confined in a pot, or for want of water, or from being excited by too much heat, the stem and flower, being the central parts of the system, are suddenly protruded, and come forth diminutive and worthless. To hasten the flowering, it has been lately discovered that, if the stem of a full-grown plant be nearly cut through near the ground, and supported so as not to be entirely broken off, it will put forth its flower a week sooner than if it had not been wounded at all. This is quite a natural consequence, because the growth of the exterior organs are checked, and the remaining vigour is concentrated to expand the flower. Thus we often see plants of the same genus, when pulled up and thrown upon the bare ground, or rubbish-heap, perfect their flowers without direct assistance from the root.

The foregoing observations relate to what may be called the superior methods of cultivating cauliflowers; but they may be cultivated without the assistance of either glass or hothouses, and with no further trouble than protecting the plants from severe frost during winter. With this intention the seedlings are drawn from the seed-bed, and pricked out, as before observed, on narrow beds, on a warm dry border having a south aspect. On the approach of frost, hoops should be placed over the beds, and mats or other materials got ready to cover with. Such covering should only be kept on during the night, or in hard frosty days, which if duly attended to, the plants will be preserved, and be fit to be transplanted to their final station some time in the month of March. A piece of well-dressed ground, in an open situation, is suitable for their reception. On this the plants are dibbed in rows thirty inches apart, and in which they may stand two feet asunder. During their growth they only require deep hoeing to kill weeds, and drawing earth to their stems, to strengthen and keep them steady. Such a crop comes in for use principally in June.

The above are called the spring crop; but in order to have a succession of flowers through the summer, two sowings must be made in the spring. The first should be raised on a little heat, or under hand-glasses, close to a south wall, in the month of February, and afterwards pricked out in a cold frame, to be nursed till they are of sufficient size, and until the season serves for planting them out for good. These, with some of the underlings of the autumn sowings, will come in after the spring crop. The second spring sowing is made about the 20th of April. These are commonly called Michaelmas cauliflowers, and which begin to come in about that holiday, and last till the frost destroys them. But, as many flowers are in prime order in November, when sharp frosts may be expected, it is usual to secure all the best, by digging them up, trimming off the greater part of the outside leaves, and hanging them up by the stems in a warm shed, or stowing them upright and close together in dry earth, in a spare hotbed frame or pit, where they may be protected from frost and damp. In this way cauliflowers may be kept good till February.

There are two varieties of cauliflower in cultivation, namely, the early and the late. The first is the most delicate, the second somewhat more hardy. Both require similar treatment; and both arrive at the greatest size in the richest soil.

In saving seed, the whitish, earliest, and firmest heads, should be chosen; and when the head begins to open, a portion of the branches should be cut out, to give room and more strength to those which are left to mature seed. The curd-like appearance of a cauliflower, when brought to table, is one of its excellencies. This property is preserved by breaking down a few of the leaves over the head for a few days before it is cut for use.

CAULOPHYLLUM (Michaux). A curious tuberous-rooted perennial herb, indigenous to North America. Linnæan class and order, *Hexandria Monogynia;* natural order, *Berberideæ.* Generic character: calyx of six bracte-like sepals; petals opposite the sepals; claws of the petals scaly; stamens opposite the petals, seated below the germen; filaments short; anthers two-celled; seed-vessel inflated, closed, one-celled, three-seeded; seeds globular. This plant (there being only one species) was called *Leontice* by Linnæus.

CAVOLINA (Bruguiere). A genus of molluscs, not protected by an external covering. Second class, *Paracephalophora;* second order, *Polybranchiata;* first family, *Tetracerata,* of De Blainville's system.

CAVY (*Caviadæ*). A very interesting group of rodent or gnawing animals peculiar to South America; but which has not been a little puzzling to systematic naturalists. Indeed the zoology of South America and of Australia, both of which, though differing much from each other, are very peculiar, have suffered from the systematic knowledge of European, Asiatic, and African zoology, which has been brought to the study of them. Those parts of the world, though differing from each other, present, in this respect, singular departures from the zoology of the rest of the world; and in no part of it is the difference greater than in those animals which consume the herbage or seasonal vegetation of the ground. In Europe, and all the rest of the Eastern continent, and generally speaking also in North America, the leading grazing or vegetable feeding animals are ruminants; and the minor ones are different species of hares and rabbits. In South America and in Australia the case is totally different. In the last of these places there is no native ruminant animal; and in the first of them there are only those few members of the camel family, of which an account will be found in the article Camel, and which are confined to the mountainous districts. Some notice of the grass-eating mammalia of Australia will be found in the article Marsupiata, to which they exclusively belong; and as their numbers are limited in every other part of the world, we can conveniently treat them as a distinct order occupying a distinct locality. The grazing animals of South America are, however, much more perplexing, because in some of their characters they fall in with animals of the old continent, while in others they are altogether different. The zoology of the eastern world has, however, been made the basis of their arrangement, and therefore that arrangement contains many absurdities, and even contradictions.

How the matter shall now be remedied is a question not easily settled; but still it is a very important one in as far as rendering the knowledge of the subject at once easy and useful is concerned, for classed as animals are at present we are compelled to associate together species which have scarcely any thing in common; and thus, in the case of animals so peculiar as the rodentia of South America, we not only fail in acquiring a rational knowledge of the animals themselves, but we fail in making them what they ought to be—an index to the natural history of that part of the world of which they are natives. One can see and even excuse the fault here, much more easily than point out the remedy. The different departments of nature have been studied by different individuals, so that the student of animals has known little or nothing of plants, and the student of either has known little of those general physical circumstances upon which the characters of both animals and plants depend. Thus though there has been no want of attention to all the departments of natural history, yet each part has been studied "out of nature," entirely away from the rest as it were; and thus the grand instruction, the relations and connexions of the whole, has been lost; for instance, if one were to ask why antelopes swarm in Southern Africa, while not a single antelope is to be found either in South America or in New Holland, both of which are under exactly the same parallels of latitude, or why the herb-eating animals of New Holland should be marsupial, and those of South America not; no rational answer to either question could be gleaned from all the countless volumes which have been written on the subject of natural history. Yet there is no question that the leading animals in every case are intimately connected, and in fact the result of the general system of nature in the place where they are found; and it is just as evident that, if we could study them in conjunction with that general nature of which they are at once productions and parts, we should be enabled to give the same philosophical consistency to natural history which is found in general physical science. How we should go about doing this is another and a much more difficult matter, but the necessity for doing it, both for the sake of theoretic knowledge and of practical usefulness, is abundantly apparent.

This is a subject which thrusts itself forward most provokingly, whenever one has occasion to notice any of the productions, and more especially the living productions of South America, and it were greatly to be desired that some one, altogether ignorant of the science and systems of the eastern world, should prepare a *fauna* of that country, working out all the details upon its own structural and climatal character, and the relations which the different races bear to each other. Till this is done, we must content ourselves with simply describing the animals of this most interesting part of the world, as if they were mere strangers in Europe, museum specimens, which really had no country, and of which, farther than shape and size, we literally know almost nothing.

Every one must see, without any reflection, that the vegetable productions of the country must depend on its soil and climate jointly, because we cannot travel a day in any country without having visible demonstration of this. It is equally evident that the animals which feed on vegetables, and as we may say preserve those vegetables by destroying the superabundance, must be adapted to the general vegetation of the country. And when we advance a step farther and come to the carnivorous animals, which in their turn keep the vegetable feeders within due bounds, we may be sure that they are adapted to the race on which they feed.

Now in South America we have none of those very powerful carnivorous animals which are met with in the corresponding latitudes of the eastern world; but the smaller species are exceedingly numerous. So also, though we have no herbivorous animals in that country (with the exception above stated) at all approaching in size and strength to the ruminants of the east, yet we have races of smaller size, the fecundity of which is beyond all conception, at least all conception which could be founded upon the habits of any of our eastern animals. Our hares and rabbits breed tolerably fast, but they bear no proportion whatever to some of the group of which we are now to give a short account; for these might breed to the number of a thousand in a year from a single pair.

The animals which we shall bring together in this group have certainly a strong family resemblance; but when we come to class them according to those characters, upon which the systems are founded, we find it no easy matter to express in words in what this resemblance consists. Therefore, we have brought them together more for the purpose of saving space in the general description than for any systematic purpose. Indeed some of them have been so bandied about from genus to genus and from group to group by different naturalists, that their systematic history is more perplexing than the part which they act in nature. They are all ground animals, living chiefly upon vegetable matter, timid in their dispositions, and not, generally speaking, disposed to offer injury to any other animals, excepting perhaps one of the species which is very aquatic in its habits, and is said occasionally to eat fish.

They all bear a slight resemblance to hares, or rather to the marmot family, but in some of their characters they approach the pachydermata. They are also allied to the agoutis, but their habits are different, and their flesh is generally speaking of inferior quality. There are three genera or species, *Cavia*, *Anœma*, and *Kerodon*, of which we shall notice a few particulars.

The *Cavy* or *Capybara*. This animal has four toes on the fore feet, and three on the hinder, all armed with large hoof-like claws, and united by a membrane which, in the hind feet especially, forms very efficient webbed or swimming feet, the nail on the middle toe of which is very long. Their cutting teeth are broad, semi-cylindrical, and bevelled off so as to form cutting chisels. They have four grinders in each jaw, formed, like those of hares, of numerous upright tubes, of enamel, which are flattened anteriorly and posteriorly, and united by bone. The last grinder in the lower jaw is much larger than the rest, and the projecting portions formed on the surface by the enamel are very regular, though each of them is divided into several points. These teeth bear a very considerable resemblance to the grinders of the elephant; and though the size of the animals, and also their general structure, differ very much, yet it may be said that this animal performs, in South America, a similar part in the general economy of nature to that which the elephant performs in Asia and Africa. Of this genus of the group there is but one species, the *Capybara*, of which the following figure is a representation.

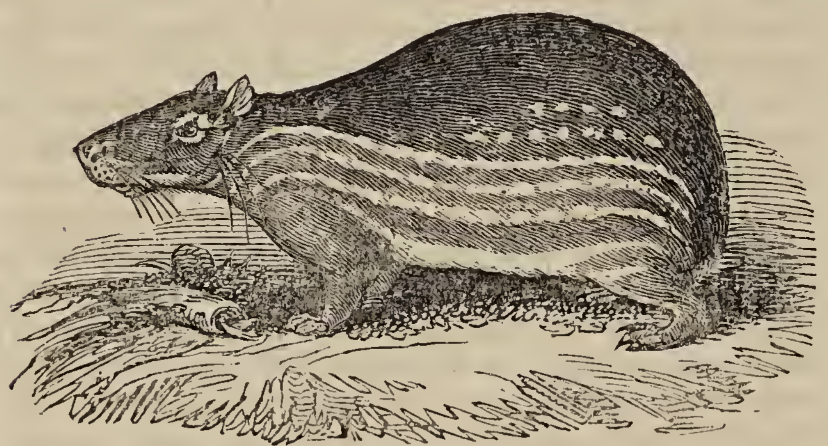
This animal, though allied in many particulars to the rest of the group, yet stands quite alone in others, the most peculiar part of its character being its aquatic habit, and the adaptation of its feet for progressive motion in the water. It is one of the largest

Capybara.

of rodent animals, measuring at least three feet from the muzzle to the hinder part; it has no tail. The general make of the body is thick, and, as one would say, pig-like; but the head is that of rodent animals generally, and like the rest of these the upper lip is furnished with mustachios. The hairs on the upper part of the head and body, and the outsides of the legs, are black at the roots and also at the points, while the intermediate part is yellow. The insides of the legs, a portion of the under part, and also round the eyes, is entirely yellow, and the mustachios are black. The mixture of these two colours gives a dinginess to the animal, and its expression at the same time is rather dull and heavy. The hair is also somewhat bristly in its texture, and sparely scattered over the body of the animal; and this increases its pig-like appearance; the ears are small and rounded. The female has twelve mammæ, which are situated partly on the breast and partly on the belly; the upper lip is divided, though not so much as in the hare, but still in the closed mouth it shows the teeth partially; the eyes are large, and of a black colour; the nose, the ears, and the naked portion of the legs, are blackish ash colour. The colour of the hair changes with age, and in very old specimens the root is black, the middle brown, and the point red. In consequence of these changes, which are in general attended with an increase of size, several varieties have sometimes been described, but there is every reason to believe that there is only one species that exists. The time of gestation is not exactly known, but it is believed to be short. The broods do not exceed four or five, but whether the female is as indifferent to them as some others of the group has not been ascertained.

The cavy is the largest of rodent animals, but its march along the ground is slow and apparently performed with difficulty. In walking it is plantigrade on the hind feet, and this gives it a crawling gait. Generally speaking, it is quiescent in its habits, its favourite position being to squat on its hams, and it may be seen in this attitude for a great part of the day. It is described as being chiefly abroad in feeding during the night, or at least in the dusk. The cavy is strictly speaking a bank animal, and inhabits the margins of all the rivers in South America, but is never seen at the distance of more than one hundred yards from the bank. These animals are social, living in small packs, and herding very peaceably. The jaguar is a great enemy to them, and probably also the alligator, when they are in the water; but that formidable reptile does not attack any animal on land; and Humboldt saw numerous flocks of cavies sitting with the greatest composure on their hams, while a large crocodile passed through the middle of them. When alarmed they take to the water, in which they swim and dive with great dexterity, and they can remain below the surface for eight or ten minutes, rising at a great distance from the place at which they disappear. It is said that they catch fish, which may be true, though it does not accord very well with analogy. Their flesh is eatable, and they are sought after with considerable avidity in some parts of America, though there is a rankness about them which is not pleasant to Europeans. From their aquatic habits the catholics, at least in some places, regard them as a sort of fish, and on that account allow them to be eaten on meagre days. These animals are tamed very readily, are gentle in confinement, and soon learn to come at a call, or follow those who are kind them; but their slow motion, their aquatic habits, and a rather offensive smell which they emit, cause them to be but little esteemed.

The *Cobaya* or *Anæma*. This is the animal which is so familiar in Europe under the name of *guinea pig*, but that name is doubly absurd, first, because the animal is not a native of Guinea, and secondly, because it does not belong to the same genus, or even the same order as the pigs. It differs from the former as being much smaller in size, in having the toes without connecting webs, in having the grinders composed of a simple lamina, with one formed on the



Cobaya.

outside of the upper jaw, and one forked on the inside of the lower jaw. This animal is much better known in a domestic than in a wild state; and indeed there is some doubt, or at least some obscurity as to the original stock. When domesticated it is so liable to diversity of colouring, that scarcely any two individuals exactly agree in this respect. Some are almost entirely white, others spotted with black and fawn colour, with yellow, tawny, &c. The body is short and thicker than that of the rabbit; the neck is not distinguishable from the head and trunk; the ears which are large, naked, and transparent, are in a great measure concealed by the hairs on the upper part of the head; the eyes are round, large, and prominent; the head and nose resemble those of the hare and rabbit; the teeth are similar to those of the rat, but they are placed obliquely outwards in the upper, and obliquely inwards in the lower jaw; and the hair is long, hard, and smooth.

As these animals are easily domesticated, and as they bear the climate of Europe very well, their manners in a captive state are easily studied. They are even said to have one domestic use, rats dislike the smell of them, and do not remain in the same house. Among the most remarkable of the characters of this animal, may be recorded its precocity and fertility; for though it attains not its full growth till eight or nine months, it is capable of propagating in five or six weeks after birth. The female goes only three weeks with young; her first litter consists of four or five, her second of five or six, and her subsequent ones of seven or eight, or even sometimes of ten or eleven. The dam gives suck only for twelve or fifteen days, and chases away her young if they remain longer by her, or if they prove refractory, she permits the male to abuse and kill them. Her parental attachment indeed seems to be much weaker than in most other species; for she will often suffer her young to be taken from her, and even devoured as soon as they are born, without betraying the least concern. As she breeds once in the two months, it has been calculated that a single couple may prove the source of one thousand individuals in the course of a year. To check this excessive fecundity, nature has provided that many of them should fall a sacrifice to cold and moisture, to the feeble and short-lived affection of their parents, to their quarrels with one another, and to their incapacity of defending themselves against cats and other beasts of prey. Their life is almost an incessant round of eating, sleeping, and reproducing their kind. Buffon asserts, that though they never drink they frequently urinate: but this is not strictly correct, for they are very fond of milk, and, in default of it, have recourse to water. They readily feed on all sorts of herbs, but prefer parsley and the tops of carrots even to bread or flour. They are also very fond of apples and other fruits. They eat precipitately like rabbits, and very often, but little at a time. Their usual cry resembles the grunting of a young pig; but they also express pleasure or pain by appropriate sounds. They are very susceptible of cold, and will press together to avoid its effects. Though naturally tame and gentle in their deportment, they are incapable of strong attachment. They affect dark and intricate retreats, and seldom venture out of concealment when danger is at hand. They are at great pains to keep themselves and one another clean, frequently licking and smoothing their own and neighbour's fur. With scarcely sufficient courage to defend themselves against the attacks of a mouse, their animosities against those of their own species are obstinate and violent, and generally originate in a desire of possessing the warmest corner, or the most agreeable food. Their mode of fighting is very singular, for one of them seizing the neck of its antagonist with its teeth, attempts to tear of the hair, while the other turns its posteriors to the aggressor, kicks up behind like a horse, and scratches his rival's flanks to the effusion of blood. The only battles which they fight are, however, battles of gallantry, or at least with one another; for they may be taken and even killed without offering any resistance, farther than very feeble attempts at escape.

Though the origin of the guinea pig, as now domesticated in Europe, is not known, there seems little doubt, that is the *apera* or wild guinea pig, which is found in the dry and rocky parts of Brazil and Paraguay. This animal is of the same size, has the same general characters, and only differs from the tame one in colour. It is reddish grey, or hare colour, on the upper parts, fading into white on the under. These animals lie concealed in holes of the rock and also in thickets; but they are met with in the dry and open places, and not in the extensive and close woods. They do not burrow; their food is wholly vegetable; and they come abroad only in twilight or during the night. There is, therefore, no reason to doubt their being the identical species which present so many varieties of colour in their domesticated state; and those colours vary so much in different individuals of the same litter, that no one of them can be considered ast he natural colour. We have a similar breaking of colour in the domestic rabbit, although the difference between that animal, in a wild and domestic state within the same country, cannot be as great as the difference between an animal wild in Brazil, and domesticated in Europe.

Sufficient attention has not been paid to the changes which domestication makes in the colours of animals; but we have at least something like evidence that the change of colour is, in some degree, in proportion to the change of treatment, including both temperature and food. But though it has been hitherto much neglected, this is a point of very great importance in the progressive history of animals. It should seem that ground animals, which seek their food in herbage, and come abroad at twilight or during the night, have all, in their natural state, less or more of an iron-grey tinge in their covering. We cannot suppose that this answers only as a means of concealment from their enemies; because, though some of them sit on exposed forms, the greater number lurk in concealment during the day, and are abroad in the faint-light. There appears to be some connexion between this shade of colour and the hardihood of the animal, and in proportion as the original colour is departed from, the constitution of the animal seems to be weakened. It is probable also that, in the case of those which are used for food, there is always a falling off in the flavour of the flesh, which accompanies this breaking down of the colour, and this may be observed by dressing a grey rabbit, and a white or a spotted one exactly in the same manner, and taking care that their natural flavour is preserved.

There is one very curious fact in the difference of habit between the tame animal and the wild one, at least if we can implicitly credit the accounts given of the wild animal. In the wild state, the female is described as producing only one at a birth, though the mammæ are the same in number as in the tame one; and we have already mentioned that the tame sometimes, though not always, produces one for each teat, that is twelve. There is reason to doubt the fact of one only being produced by the wild animal; because we know of no other case in which a female having numerous teats, and having them both on the breast and the belly, produces only a single young one. Yet the fact is expressly stated by D'Azzara, and has not been contradicted by any other observer. But from the retired habits of these animals, and the places which they frequent, and also the times at which they are abroad, it is not very easy to get an accurate account of their habits as wild. They are much less frequently seen than the burrowing animals, and therefore we are not nearly so well informed respecting them. It is probable, however, that they may be more prolific in a domesticated state than when left in free nature; and the probability rests upon an analogy which holds very generally both in the animal kingdom and the vegetable. In all cultivated plants, it is in the fruit, or the other portion by which the successional plants are produced, that cultivation produces its greatest and most beneficial effects; and the timber or whatever else constitutes the proper structure of the plant as an individual, may be said, in all cases, to be deteriorated; and though the quantity of it may be increased, the quality is lowered. It is highly probable that a similar effect is produced by cultivation upon animals; and we may suppose that this effect will be great in proportion to their natural fertility, and especially to the shortness of their gestation. This question is, however, one of as much difficulty as that to which we formerly alluded, if, indeed, it is not more difficult; but it is one upon which knowledge is highly desirable; and in the case of an animal which appears so docile, that is so obedient to artificial culture as the guinea pig, the tracing of the few hints which we have ventured to throw out on the subject of colour and fertility, would be of far greater importance than those expatiations on the helplessness of the animal which are usually found in the books on natural history.

The Moco (Kerodon) is the only other known animal of this curious group. It is rather larger than the guinea pig, and of a greyish olive colour. Its grinding teeth are also differently formed, indicating some difference in its food. Each tooth is formed into two triangular prisms, and it is on this account that M. F. Cuvier has given it the name of *Kerodon* (horned tooth). The habits of this species are but imperfectly known, only they are said to have a considerable resemblance to those of the guinea pig. It is, however, found in places which are less dry and rocky, though not near the water. Though from the character of their covering, both this and the former species can bear to be wetted without injury, neither of them are in the habit of swimming.

The systematic names which have been given to the other two genera of the group, are not quite so appropriate as this one. *Hydrochœus* (water hog) is as objectionable as the common name of guinea pig is in the case of the second one; and though *anœma* (powerless) is expressive of one character of the guinea pig, yet that is not its leading, or even its peculiar character, for there are many other animals equally powerless.

Those three animals form a very well defined group; and though rodentia are very numerous in South America, these form a distinct section, both in the structure of their teeth and in the places which they inhabit. We have the largest of them inhabiting the immediate vicinity of the waters, where the productions of nature are richest, and where the largest animals of every natural group and order are to be met with. Then we have the Moco in the intermediate localities where nature is less productive; and lastly, we have the guniea pig among the rocks, or in the dry thickets, upon the margins of the arid plains, or of those savannahs which are burnt up with drought at one season of the year and laid under water at another. When we get into places which are more open, the vegetable feeders of South America are still rodentia, and have sometimes been classed in the same group, and even in the same genus, with the animals above noticed; but a very different structure, or at least power of action, is necessary for animals which seek their food in the dry plains. They are the *agoutis*, the *pacas*, the *biscaches*, and the *chinchillas*, some of which are, however, different names for the same animals. See the articles AGOUTI and CHINCHILLA. These last mentioned animals bring us onward to the barren portions of the country which do not afford food even for rodent mammalia; and animals of this class, from the characters both of their cutting and grinding teeth, can subsist upon much harder and drier food than any of the other vegetable feeders.

Taking them altogether, we find a regular set of animals subsisting upon vegetable matter, varying in the character of the teeth, in proportion as their habitations is farther from the rivers, and varying still more in the appearance and texture of their covering. The cavy, which is always near the banks of the streams, and very often in the banks of the water, has very little hair, and the little that it has, is of a bristly character, or bearing some resemblance to that of the pig; but as we quit the waters, we come to coverings capable of affording still greater protection against extremes of temperature, till we at last come to the chinchilla, the covering of which is exceedingly close and fine, and highly prized as fur.

Of course, this succession of animals is exactly adapted to the state of nature in South America; and from this it follows, that that country was not naturally adapted for ruminating animals, and yet upon their introduction, cattle, in a wild state have multiplied in it faster than in any other part of the world. It would be desirable to know, how far the immense herds which now range the plains, have changed the vegetation, and along with that the climate and even the soil of the country. But it is certain, that pasturing with cattle has a tendency to reduce the surface to a perennial sward, and that this sward is a means, not only of preparing the ground for the plough, but of equalizing the seasons, and thereby improving the climate. Thus, without intending it, the European settlers have been the means of beginning a great revolution in the natural history of South America, to watch the progress of which, will be a most interesting subject for future naturalists. At present, however, the data are few and not well connected.

CEANOTHUS (Linnæus). A genus of prickly shrubs and trees, natives of the tropics both in India and South America. Linnæan class and order *Pentandria Monogynia*; natural order *Rhamneæ*. Generic character: calyx bell-shaped and five-cleft; petals of the corolla clawed, hollow, (rarely none); stamens opposite the petals; stigma tripartite; capsule dry, three-seeded. This is the red-wood of the West Indies; several of the species were included in the genus *Rhamnus* by the earlier botanists, but have been separated by Decandolle, Lambert, and others. They are cultivated in our stoves, and increased by cuttings struck in sand.

CEBRIONIDÆ (Leach). A family of Coleopterous insects, belonging to the section *Pentamera*, and division *Serricornes*, having for its type the genus *Cebrio* of Olivier. These insects have the body of an oval oblong form; in others, however, which from their small size and soft consistence (*Cyphonides*), seem to depart considerably from the habits of the group—it is of a rounded and convex shape. The jaws terminate in a single tooth, and the palpi are of equal thickness throughout or more slender at the tips; the thorax is transverse, broadest behind, with the lateral angles often acute. The antennæ are longer than the head and thorax, serrated or branched in many species, and never clubbed at the tip; and the legs are not contractile. These insects seem to establish an intimate connection between the skip-jack beetles (*Elateridæ*), and the soft winged, soldier and sailor beetles, as they are termed, *Telephoridæ*; thus, in the typical genera, the breast-bone is produced into a point behind, and received into a corresponding aperture in the *mesosternum*, whilst in the *Cyphonides*, the softness of the body and several other characters seem to lead the way to the latter family. Of the early history of these insects, the majority of which are strangers to this country, but little is known. Some curious circumstances have, however, been observed respecting the typical species, *Cebro gigas*, an inhabitant of Germany and France, which seems to confirm the observations which have been made respecting the influence of atmospheric changes upon the lower animals. Thus, Olivier observed, that it was generally noticed flying with great rapidity immediately after heavy storms; and M. Farines has published a memoir upon the history of the same insect, in the Transactions of the Linnæan Society of Bordeaux, from which it appears that this insect only makes its appearance during, or after, the heavy autumnal rains, at which period of the year, if the weather be fine, very few are to be observed.

The males of this species are distinguished by their long and slender antennæ, which organs, in the females, are not longer than the head, terminating in a thick mass; indeed, so different is the appearance of this sex from the males, that Latreille was induced, at first, to form it into a distinct genus. The wings, in this sex, are rudimental.

This family may be divided into two sections:—1st, the *Cebrionides* having the body oblong and of a firm consistence; the legs not fitted for leaping; the jaws strongly curved and extending beyond the lip, which is very short and notched in the middle, and the antennæ often branched.

Here are to be ranged the genera: *Physodactylus. Cebrio, Anelastes, Callirhipis, Sandalus, Rhipicera, Philodactyla* and *Atopa*, with some others proposed by Dr. Leach in a monograph upon this group of insects, published in the Zoological Journal, and by M. Laporte, in a memoir recently published in the Annals of the Entomological Society of France. The genus *Callirhipis* is distinguished by the long and beautifully branched antennæ of the males, which are, however, only eleven jointed; the same character is found in the elegant exotic genus *Rhipicera*, but here these organs are composed of from twenty to forty joints.

The genus *Atopa* (Fabricius; *Dascillus*, Latreille); comprises the only British species belonging to this first section. It is the *Chrysomela Cervina* of Linnæus, a very variable insect as respects its colour, being clothed with pubescence, which is sometimes ochraceous, and at others fuscous. It is nearly half an inch long and is not uncommon in the woods near London. The sexes of this insect have also been regarded as distinct species. Mr. Curtis observes, "The scent of several of the tawny specimens which I took off alders and brambles, was very offensive and powerful, similar to that of the house bug; whereas, the dark ones either had no scent. or smelt merely of the plant on which they were found;" adding, "Mr. Mathews, A. L. S., has informed me that whilst he was collecting Orchideæ in Kent, on the 29th of May, 1825, he found three specimens of our beetle at the roots of

Orchis ustulata, about four inches beneath the surface of the ground, which induced him to suspect that the larva might feed upon the roots of that plant. The dwarf-orchis was in flower upon the spot when I met with two or three specimens ascending Arthur's Seat."

The second section (*Cyphonides*) has the body rounded and of a soft consistence; the jaws small and not protruded; the palpi terminated in a point, and the antennæ simple or but slightly toothed. In many the hind-legs are fitted for leaping. These insects, all of which are of small size, reside upon plants in damp situations. The genera are: *Cyphon*, Fabricius; (*Elodes*, Latreille) *Scyrtes*, Latreille; *Nycteus*, Latreille; and *Eubria*, Zeigler. The two first contain species indigenous to this country.

CEBUS. The name sometimes given to a division of American monkeys (*sapajous*), which have the head round, distinct thumbs on the feet, and the tail, though prehensile, wholly covered with hair. They are very numerous, and the characters of the different species are much more difficult of discrimination from each other than those of the howling monkeys. They are very mild and gentle in their manners, and lively and playful in their motions, but their cry is shrill and wailing, which has procured them the appellation of crying monkeys.

The species are so confused, and they all so nearly resemble each other in their manners, that the general reader could find but little pleasure in the perusal of such a "chapter of doubts," as any attempt at either defining the group, or attempting to divide the number of species, would involve. We shall save much room, and also give a little more interest to the few words we shall have to say on the subject, if we bring the whole together into one general article, MONKEY, in the same manner as we did with the apes and baboons, and as we purpose to do with all other animals which can be brought into natural groups or masses, that have English names.

CECIDOMYIA (Meigen). A genus of Dipterous insects, belonging to the family *Tipulidæ* of Leach, and to the sub-family *Tipules gallicoles* of Latreille. It is perhaps impossible, throughout the countless tribes of the insect world, to select any single genus which contains so many species of minute size, which, nevertheless, are endowed with such surprising powers of destruction, and which is, at the same time, effected in such very different modes. In this point of view alone, this would be an interesting group of insects, since it has been generally conceived that identity of generic construction implied identity of habits,—but this is certainly not the case here. The antennæ and legs of these insects are beautiful microscopic objects; the former being composed, in the males, of a long series of minute balls, connected together by a slender thread and very pilose—(this structure is termed moniliform or necklace-shaped.) In the females, the joints are longer and set nearer together; the legs are long and exceedingly slender, so as to be scarcely discernible when of a pale colour, and the basal joint of the tarsi is very minute; the wings are hairy and furnished with only three longitudinal nerves, and the body is slender, and terminates, in the females, in a long and delicate tubular instrument, of which we shall presently mention the use.

To this genus belongs the Hessian fly, an inhabitant of North America, the ravages of which have spread terror through the agriculturists of various countries in communication with that continent. This insect received its name from the prevalent idea that it had been imported into Long Island, in 1776, with the straw carried over by the Hessian troops. Messrs. Kirby and Spence thus describe the devastation caused by it,—"The ravages of the animal just alluded to, were one time so universal as to threaten, wherever it appeared, the total abolition of the culture of wheat, though, by recent accounts, the injury which it now occasions is much less than at first. It commences its depredations in autumn, as soon as the plant begins to appear above ground, when it devours the leaf and stem with equal voracity until stopped by the frost. When the return of spring brings a milder temperature, the fly appears again and deposits its eggs in the heart of the main stems, which it perforates and so weakens, that when the ear begins to grow heavy and is about to go into the milky state, they break down and perish. All the crops, as far as it extended its flight, fell before this ravager. It proceeded inland at about the rate of fifteen or twenty miles annually, and by the year 1789, had reached 250 miles from its original station. Nothing intercepts them in their destructive career, neither mountains nor the broadest rivers. They were seen to cross the Delaware like a cloud. The numbers of this fly were so great, that in wheat harvest the houses swarmed with them, to the extreme annoyance of the inhabitants. They filled every plate or vessel that was in use, and five hundred were counted in a single glass tumbler exposed to them a few minutes with a little beer in it."—Vol. I. p. 172. So great indeed was the alarm caused by this insect, that the subject was taken into consideration by the Privy Council of England, and caused so great a share of attention that the proceedings fill upwards of 200 pages.

For a length of time this insect did not find a place in the system of Entomology, and Mr. Markwick caused some alarm in the public mind by the account which he gave of the ravages of *Chlorops pumilionis*, (one of the flies belonging to the family Muscidæ) when first observed in England, and which was regarded as identical with the Hessian fly. Mr. Marsham, however, by tracing out the species, proved the alarm to be unfounded. The late Mr. Say, the most celebrated of American Entomologists has, however, cleared up the question by publishing a detailed description of the real Hessian fly, under the name of *Cecidomyia destructor*, in the Journal of the Academy of Natural Sciences of Philadelphia for 1817. A notice of this memoir, with additional observations by Mr. Kirby, will be found in the Magazine of Natural History, Vol. I. The female deposits from one to eight or more eggs, on a single plant of wheat, between the sheath of the inner leaf and the stem, nearest the roots, in which situation, with its head towards the root or first joint, the young larva passes the winter eating into the stem and causing it to break.

If England, however, be free from the ravages of the Hessian fly, another species of the same genus takes its place, destroying, but in a considerably less degree, the same invaluable plant. This is a minute orange-coloured gnat, of which the proceedings are detailed at great length in several of the early volumes of the Transactions of the Linnæan Society. It is during the period of the blossoming of the wheat that this insect, the *Cecidomyia tritici* (*Tipula tritici*, Kirby) makes its appearance, and introduces its long retractile ovipositor into the centre of the corolla, for the purpose of depositing its eggs,

a, C. destructor. *b*, C. tritici. *c*, Larvæ of ditto, feeding; all magnified.

the larvæ produced from which, "perhaps by eating the pollen, prevent the impregnation of the grain, and so, in some seasons, destroy the twentieth part of the crop." Mr. Shireff has also published an interesting account of the proceedings of these insects in the Magazine of Natural History for November 1829, stating, that they were first observed (at East Lothian) on the evening of the 21st of June; and, "from the vast numbers seen, it is probable a few of them may have been in existence some days previous. The eggs were visible on the 23rd, the larvæ on the 30th of that month, and the pupæ on the 29th of July. The flies were observed depositing their eggs on the 28th, and finally disappeared on the 30th July; thus having existed throughout a period of thirty-nine days. The flies almost invariably preferred the ears emerging from the vagina to those farther advanced for depositing their eggs on, and as one side only of the ear is exposed when the plant is in this stage of growth, the other side generally remained uninjured. The fly deserted the fields as the crop advanced towards maturity, and were found longest in the spring-sown portion of the crop. It seemed to feed upon the gum adhering to the newly-emerged ears; and as there is a great diversity in the time of sowing wheat in this neighbourhood, and consequently of the ears escaping from the vagina, I attribute the unusual length of time it has existed this season to the supply of food thus gradually furnished."

Both these insects are providentially kept in due bounds by several species of parasitic flies belonging to the families *Chalcididæ* and *Proctotrupidæ*, the proceedings of which, in destroying the *Cecidomyiæ*, have been also recorded by the authors quoted above.

In these two species of *Cecidomyia*, it is to be observed, that, notwithstanding the differences in their habits, it is only in the larva state that the injury is produced; but in other species of the genus (*Cecidomyia piri, salicina*, &c.), the females, at the period of oviposition, introduce into the plant with their eggs an irritating fluid, which causes the formation of a kind of gall upon the stems. De Geer has given the history of these two insects, the latter of which is found upon a species of willow at the end of April, in the interior of a curious gall, resembling a small double rose of a green colour, occupying the extremity of one of the twigs, in the midst of which is a small conical cell formed of small leaves, in which a single larva of a yellowish red colour, without feet, is found, the body of which is composed of twelve rings, and is a little narrowed at its anterior part, with the head rounded. On the 11th of the following month of May, in the same galls, De Geer found a small white and very delicate cocoon, which inclosed, without entirely concealing, a small red pupa with white legs, and a bright red-coloured abdomen, having a darker central line. Having inclosed some of these galls in a box, several small tipulideous insects made their way out of them, which various authors, and more especially M. Macquart, whose recent work upon the *Diptera* forms a valuable manual upon this order of flies, have also observed subsequent to De Geer, and which they regard as the *Cecidomyia salicina.*

De Geer also describes the habits of three other tipulidans, nearly allied to the preceding, namely, the *Tipula juniperi* (Linnæus), which M. Meigen places doubtingly in the genus *Lasioptera*, and the *Tipulæ piri* and *loti*, which have been considered both by Latreille and Meigen as *Cecidomyiæ*. The galls of the juniper are composed of six leaves, three external, and three internal and smaller; and De Geer has observed, that, as the leaves of this plant are always placed three by three, it would seem that the gall is produced by the germ itself of three smaller leaves, which, without this attack, would have developed themselves, and ultimately produced a new shoot. The larvæ of the *Cecidomyiæ* feed upon the internal leaves, the external ones then growing to an unnatural size. In Sweden, the country people employ these galls as a remedy for the whooping cough, terming them kik-bar, which means berries for the whooping cough, boiling them in milk.

M. Macquart has also obtained the *Cecidomyia salicina* from galls very similar to those described by De Geer, which were found upon the *Salix alba.* He has also observed upon the leaves of *Artemisia abrotanum* the larva of a *Cecidomyia*, which feeds upon the ground leaves of this plant without producing any alteration or gall-like excrescence, and without inclosing itself in a cell; it, however, forms a very long cocoon, in which it becomes a pupa.

The small globular cottony balls which are often to be noticed upon the *Veronica chamædrys, Thymus serpyllum*, and *Glechoma hederacea* (ground ivy), are also caused by the attacks of these minute flies.

The author of this article has observed the proceedings, and reared a large British species, whose habits are very different from those recorded above, residing in company, in large solid galls, the substance of which is even firmer than the wood of the willow trees upon which they are found. These galls are evidently the result of the attacks of the parent fly depositing several eggs on the same spot. We observed; also, that this species is kept in check by not fewer than five or six distinct species of still smaller parasites; and it appeared quite inexplicable to us how these minute and feeble insects, unprovided as they are either with instruments for burrowing or for eating their way out of these hard galls, were enabled to effect their escape.

Under the article Aristolochiæ will be found an account of the mode of impregnation of the *Aristolochia clematitis*, observed by Professor Willdenow by means of the *Tipula pennicornis*, a species belonging to the present genus. A writer, however, in the Annual Medical Review, quoted by Messrs. Kirby and Spence, doubts the accuracy of this fact, on the ground, that he could never find the *Tipula*, although the plant produced fruit two years successively at Brompton. We have observed, however, another species very plentiful in the vicinity of that village, which would, in all probability, act the part of the other species.

Let it not be said, after what has been thus stated of the ravages and other injurious properties possessed by this genus of diminutive gnats, that insects are beneath the notice of mankind, from their insignificance or trivial powers. It has indeed been well said, that the generality of mankind overlook or disregard these powerful but minute dispensers of punishment, seldom considering in how many ways their welfare is affected by them; but the fact is certain, that, should it please God to give them a general commission against us, as he did during the terrific plagues of Egypt, and should he excite them to attack at the same time our bodies, our clothing, our houses, our cattle, and the produce of our fields and gardens, we should soon be reduced, in every possible respect, to a state of the most extreme wretchedness.

Mr. Stephens has enumerated twenty-six British species, in addition to which we have captured several very elegant species, which do not appear to have yet been described by dipterologists, having the wings maculated. We have also discovered another British species of a far larger size than any of those previously described, and which we have dedicated to Mr. Kirby.

CECILIA. The last of the three families into which Cuvier divides the *ophidian* reptiles, and differing in many respects both from the snakes and the true serpents. The present group is indeed one of the most singular in the whole animal kingdom, and it is not very easy to decide with perfect certainty, to what part of the natural system it should be referred. These animals are usually called by the general name of *naked serpents*, because they have no apparent scales. In external appearance they resemble earth-worms more than they do any other creatures, and some of them are described as boring holes in the ground in the same manner that worms do. Their skin is also annulated, or marked with narrow ridges and furrows passing round the body, in the same manner as worms; and it is probable that these ridges are used for progressive motion in the same manner as those of worms. The skin also secretes a viscid slime, such as is secreted by the skin of the common earth-worm, and also by eels, and slugs.

But notwithstanding these external resemblances, and notwithstanding also that the eyes of all the species are exceedingly minute, and so covered by the skin as to be hardly visible, and that one species is perhaps altogether blind, these animals have nothing in common with worms, except those external appearances which have been noticed. They are not annulated animals, and have not the power of contracting and extending the lengths of their bodies, as is the case with worms; they are vertebrated animals, although both their organisation and their habits are very singular.

The name Cecilia, or *Cæcilia*, was formerly applied to the common brittle snake, or slow-worm, which is found in this country, and which may be considered as a sort of connecting link between the Saurian reptiles, and the harmless serpents. It has the rudiments both of shoulders and pelvis, and its ribs are united into entire rings; so that its motion, destitute of feet as it is, is not of the same kind of crawling which belongs even to the true serpents.

The Cecilia of modern naturalists are at the opposite extremity of the Ophidia, and form the connecting link between the true serpents and the footless batrachia; and as, though they are not aquatic animals, so decidedly as these are, they are still near the waters, and produce their eggs in a manner somewhat similar, there is only wanting the metamorphosis which these undergo, in order to transfer them from one class to another, or rather perhaps to separate them from both classes.

The term "naked" applies to these serpents, as contrasted with the clothing of scales possessed by the others, though correct to common observation, is not strictly true. The skin indeed seems quite naked, and, as was mentioned, it is viscous: but it is the epidermis which is so, and when that is removed the true skin is found completely covered over with very minute scales, which form the little annular rings on the skin, and are the real organs of motion in the animals.

The head of these animals is flattened, and the vent is placed about the middle of the length, so that the tail is as long as the head and body. Their ribs are very short, so as not nearly to surround the cavity, and this enables them to have much more complete motion of the spine. The articulation of the spine resembles that of fishes, of the batrachian reptiles, and partially also of the *amphisbæna* among reptiles: that is, each vertebra is made up of two cups of a conical form, having their vertices turned towards each other, and thus the cavities of the adjoining pieces are placed mouth to mouth. Those cavities are filled with elastic cartilaginous matter, and thus the joints bend freely in every direction. The only joint which forms an exception to this is the articulation of the cranium with the first vertebra, which is done by two tubercles, and thus this which is, generally speaking, the lithest of reptiles, has the neck so much stiffer than the spine, that it appears to have hardly any neck at all.

The maxillary bones completely cover, or rather fill up, the orbital fosses, so that there is only a very minute hole for each eye; and the temporal bones, in like manner, fill up the temporal fosses. There are many other peculiarities in their structure, the minute details of which would be inconsistent with the character of this work.

Those singular serpents are found only in the warmer parts of central America, by the banks of the rivers, and the borders of the marshes. It has been said that one species is met with in the island of Ceylon; but it does not appear that there is the least foundation for this. The rich and humid ground, between the forests of Guiana and the sea, are the places where these animals abound the most; though they are found in many other parts, and indeed generally in the warm places of America; and as much of that country is flooded during the rainy season, their habitation agrees remarkably well with their quadruple character of Batrachian, Saurian, Ophidian, and Fish; for they have some of the characters of all these, although that of the reptile certainly predominates. They are very harmless creatures; and if we may judge from the substances found in their stomachs, their food bears a considerable resemblance to that of earth-worms, as the contents of the canal have consisted of mud and grains of sand, with a small admixture of vegetable matter, in all the recent specimens which have been examined. There are about five species described by naturalists.

Cecilia ibiara. This is a short and thick species with a blunt muzzle, the circular folds of the skin very distinctly marked, the mouth under the snout something like the mouth of a shark, and furnished with conical teeth. This species has twenty-five very distinct rings round the body, which are rendered more conspicuous by the ridges being white, while the ground colour of the animal is black. This species is very common both in Brazil and Guiana; and it is met with in the soft and wet ground, at the depth of three feet below the surface. We should have mentioned, that when full grown it is about a foot long, and an inch in diameter.

C. tentaculata. This species has the circular folds much more numerous, but they are chiefly on the tail, where they are arranged two and two, and on the body and tail together there are about one hundred and thirty. This species is black, and marbled with white on the belly.

C. gelatinosa was the first species known and described. It is long and slender, cylindrical in the section, of a brownish colour, and marked with a lateral line. It contains between three and four hundred folds on each side. It is about a foot in length, and the thickness of one's little finger. This is the species which was described erroneously as being met with in Ceylon.

C. albiventris. The body of this species is slender, round, black, but marked on the under side with irregular patches of white and yellow. Its mouth opens below the snout, and its teeth are very short and slender.

C. lumbricoides. This is the longest and most slender of all the species. It is two feet in length, and only a third of an inch in diameter; and the rings upon it are so very minute that they cannot be seen, but by the help of a microscope. Its colour is blackish. This is the species which is said to inhabit holes in the ground, in the same manner as the common earth-worm; and in form it is certainly the most singular of vertebrated animals.

There are probably many other species besides those which we have mentioned; but from the obscurity of their habits little is or can be known respecting them, so that what has been stated must suffice for our purpose; they however form an additional curious feature in the zoology of South America, which is different from any other part of the world in every thing that it produces, even when they have so much external resemblance as to have been classed together.

CECROPIA (Linnæus). A genus of ornamental trees, indigenous to the West Indies and Brazil. Linnæan class and order *Diœcia Triandria;* natural order *Urticeæ.* Generic character: flowers in a dense spiked bundle, which has a deciduous spatha. Male flowers: calyx turbinated, angular, with two holes at top; stamens two or three, exserted through the holes; anthers oblong and four-sided. Female flowers: calyx bell-shaped, two-toothed; stamens sterile; stigma sitting; acenium attached to the calyx. The cecropia is placed in *Diœcia Diandria,* by Sprengel. They are propagated in our hothouses by cuttings, and grow best in a loamy soil.

CEDAR OF GOA is the *Cupressus Lusitanica* of Tournefort, and the *C. glauca* of Lambert. It is a native of Portugal, and requires the protection of a glazed frame in this country.

CEDAR OF LEBANON is the *Cedrus Labani* of botanists, formerly called *Pinus Cedrus* by Linnæus. It is one of the most remarkable exotic trees cultivated in this country. They were introduced as far back as 1683; and there are but few old country seats in this kingdom which do not possess a few of these cedars. Many majestic specimens are met with in different parts; but in no situation have they thriven more prosperously than at the celebrated residence of Moor Park, in Hertfordshire. So numerous and large were they on this estate that, about 1798, scores of them were felled for sale, containing four and five loads of timber in their butts only. These fine trees were mostly purchased by London builders for quartering at a low price; the timber being found far inferior to the common Scotch fir. They are trees of very striking character, and give an air of grandeur to every scene in which they appear. There are two or three varieties of this tree; some assume the conical figure of the other *coniferæ;* others extend their branches horizontally from the top of a short thick trunk, forming a dense canopy over head: others again are very much divided near the ground into many upright stems, which with their horizontal spray, form in the course of years a vast bush.

This tree is raised from seeds which ripen in England, or from seeds imported from the Levant. When got from the cones, which is a work of some difficulty, they are sowed in deep seed-pans or boxes, and when fit for removal the seedlings are placed and nursed in pots, until they are large enough to be planted out for good. While nurslings, many of them, require a stake, to which a leader must be constantly kept trained, in order to ensure a regular growth.

CEDRELEÆ. Mahogany family. A natural order of dicotyledonous plants, containing five or six genera, and about fourteen species. It is nearly allied to *Meliaceæ,* of which Decandolle makes it a subdivision, and is chiefly distinguished by its winged and indefinite seeds.

Its essential characters, according to Brown, are: calyx five-cleft, persistent; petals five, sessile, inserted at the base of a stemmiferous disk; stamens ten, inserted on the outside, below the apex of a hypogynous disk; those which are opposite the petals, sterile; anthers acuminate, bursting longitudinally; disk hypogynous, cup-shaped, with ten plaits; ovary superior, five-celled; style simple; stigma deeply four-lobed, peltate; capsule separable into five pieces, which are combined at the base, before bursting, with a short central axis; placenta central, with five longitudinal lobes; seed erect or ascending, with the apex terminated in a wing; no albumen.

The plants belonging to this order have alternate compound leaves, without stipules, and a terminal inflorescence. They possess bitter and astringent properties, combined with an aromatic principle, and in general they are useful as febrifuges.

They are found in America and India, but none have as yet been detected in Africa. The chief genera of the order are *Cedrela Swietenia, chloroxylon, Flindersia, Oxleya,* and *carapa.*

There are several species of *Cedrela,* or bastard cedar, some of which attain the height of seventy or eighty feet. The wood of these plants, which is agreeably fragrant, is one of the kinds of cedar of commerce, and is imported in considerable quantities from New Holland. This wood, which is soft and light, is hollowed into canoes, and is used for covering houses, as well as for a variety of other purposes. It is apt to communicate a peculiar flavour to liquors, and therefore cannot be made into casks for keeping spirits. *Cedrela toona* is a beautiful large tree, with a straight stem, and a smooth grey-coloured bark. It is furnished with alternate drooping leaves, twelve or thirteen inches long, and numerous small white flowers, which emit a smell like honey. It is common in Bengal, and, as already mentioned, is used for timber. This species and *Cedrela febrifuga*, have fragrant resinous barks, which are used medicinally in fevers.

Swietenia, a genus named in honour of Baron Van Swieten, at whose suggestion the Botanic Garden at Vienna was first established, contains two important species. The first of these, *Swietenia mahagoni*, possesses much interest in consequence of furnishing the mahogany of commerce. It is a lofty tree with spreading branches, bearing a fruit about the size of a turkey's egg. It grows in Jamaica, Cuba, Hispaniola, &c., and was introduced into Kew gardens early in the last century. Mahogany is imported in large quantities from Honduras and Jamaica. It varies in durability and firmness of grain, according to soil, situation, and various other circumstances. The bark of the trunk of the mahogany tree is brown, rough, and scaly, that of the branches is smooth and grey. It has a weak aromatic smell, a bitter astringent taste, and has been proposed as a substitute for Peruvian bark. From the trials which have been made of it, however, it does not seem to possess the febrifuge properties of cinchona.

The second species is *Swietenia febrifuga*, known in India under the name of *Soymida*, and called, on the Coromandel coast, the red-wood tree. It is a lofty tree, like mahogany, found in mountainous districts in India, and yielding a hard, heavy and durable wood, which is employed by the natives in the construction of their temples. The trunk is straight, and is covered with a rough grey bark, which is internally of a red colour, and which is used for dyeing brown. This bark has an astringent bitter taste, and was first brought into notice by Dr. Roxburgh, as a substitute for cinchona in the cure of intermittent fever. It has also been used as a tonic in the remittent bilious fever of India, and in cases of debility and gangrene. Its reputation, however, has not been sufficiently established, to induce practitioners in this country to prescribe it in place of Peruvian bark or quinine. In large doses it is said to occasion giddiness and stupor. An extract prepared from the bark has an appearance very similar to the kino of commerce.

Flindersia, a genus named in honour of Captain Flinders, is distinguished from the other genera of the order, by the insertion of its seeds, and the mode in which its capsules open, as well as by having its leaves dotted with pellucid glands. *Oxleya xanthoxyla* is a large tree, which yields the yellow wood of New South Wales. *Chloroxylon Swietenia* is a middle-sized tree, found in mountainous parts of the East Indies, which also furnishes a wood of a yellow colour.

CEDRUS (Barrelier). A genus separated from *Pinus*, containing two species, the cedar of Lebanon, and the deodora, a lofty timber tree, native of Nepal. Linnæan class and order *Monœcia Monadelphia;* natural order *Coniferæ*.

CELANDINE is the *Chilidonium majus* of Bauhin, and a common British plant, growing on hedge banks in many places. The flowers are yellow, and when the leaves or stalks are broken, a deep yellow coloured juice is exuded.

CELASTRINEÆ (*Celastrus*, or staff-tree family). A natural order of dicotyledonous plants, containing ten genera and upwards of one hundred known species. This order was formerly included under *Rhamneæ*, but was separated by Mr. Brown on account of the ovary being free, the calyx imbricated, and the stamens alternate with the petals. The order is allied to *Hippocrateaceæ*, but differs in the number of the stamens, and in their not being monadelphous.

The essential characters of celastrineæ are : sepals four or five, combined at the base, or imbricated ; petals four or five, alternate with the sepals, rarely wanting ; stamens equal in number to the petals, and alternate with them ; anthers two-celled ; disk large, closely surrounding the ovary ; ovary free, immersed in the disk, with three or four cells ; cells one or many seeded ; ovules erect, rarely pendulous ; style one, or wanting ; stigma two to four-cleft ; fruit superior, either with a capsule, berry, drupe, or samara, various in form ; seeds ascending, frequently provided with an arillus.

The plants belonging to the order are shrubs or trees, with simple alternate or opposite leaves, and white or greenish flowers, growing in axillary cymes or terminal racemes. They are found extensively scattered over the globe. In general, however, they inhabit the warm parts of Europe, North America, and Asia, and are not abundant within the tropics. Many are natives of the Cape of Good Hope, and a few are found in South America and New Holland. Their properties are not well known.

The order has been divided into two sections:—

1. *Staphyleaceæ*, or bladder-nut tribe, including the genera *Staphylea* and *Turpinia*. This division is, by Brongniart and others, made a separate order, characterised by its opposite pinnated leaves, which are furnished with stipules.

2. *Euonymeæ*, or spindle-tree tribe, including the genera *Euonymus*, *Celastrus*, *Elæodendron*, *Maytenus*, &c.

A third tribe, *Aquifoliaceæ* of Decandolle, is now referred to the section of monopetalous plants, and will be noticed under Ilicineæ.

Several species of *Staphylea* and *Euonymus* are valued in shrubberies as ornamental plants. *Staphylea pinnata*, common bladder-nut, is a native of Britain, and grows in thickets and hedges both in Yorkshire and Kent. It is frequently cultivated in gardens on account of its singularity, and in this way has become naturalised in some parts of the country. It is a shrub bearing graceful drooping clusters of white flowers, which are followed by a large curious fruit covered with a sort of bladder ; hence the English name of the genus. The nuts are said to possess emetic properties, and to have a sweet nauseous taste. They are hard and smooth, and are strung for beads by the Catholics in some countries.

Euonymus Europæus, common sprindle-tree or prickwood, is also a native of Britain, and grows generally in hedges and thickets. The plant is reckoned poisonous, and, when bruised, it emits a fetid odour. Its fruit or capsule is of a beautiful rose-colour, occasionally white. The coat of the seed, or arillus, is of an orange-colour, and is finely contrasted with the red or white valves of the capsule. The wood is hard and fine-grained, and is made into spindles and skewers, and, according to Linnæus, affords the best charcoal for drawing. The fruit and inner bark act as purgatives, and in large doses as emetics. The young branches of *Maytenus boaria* are used in Chile as a wash for swellings produced by the poisonous shade of the tree *Lithi.*

The species of *Elæodendron,* or olive-woods, bear considerable resemblance to the olive. The fruit of some of them yields, by expression, an oil which is used at table, and for various other purposes.

CELASTRIS. A genus of Le Heretier's, now merged in the new genus *Maytenus* of Feuillée.

CELASTRUS (Linnæus). A genus of evergreen shrubs and climbers, chiefly natives of the Cape of Good Hope. Linnæan class and order *Pentandria Monogynia;* natural order *Celastrineæ.* Generic character: calyx of five lobes; petals clawed and plain; disk glandular; stamens bearing erect egg-shaped anthers; style thick and short; stigma in three parts; capsule three-celled, one seed in each; arillus of the seed fleshy and banded. The different species of celastrus, or staff-tree, have been long in our greenhouse collections. They are pretty evergreens, and easily propagated by cuttings.

CELERY. An aquatic plant indigenous to Britain, but has been long cultivated in gardens as a salad and culinary vegetable. The wild plant has a heavy scent, somewhat similar to that of its congener, parsley, on which account it formerly had a place in the herb-border, and was used as a seasoner under the name of smallage. This herb has, however, disappeared from gardens since the Italian varieties of it has been introduced under the name of *Celeri,* or celery; and its crude and rank natural qualities being dissipated by blanching, it is rendered one of the most agreeable and wholesome of salad vegetables.

In every large domestic establishment celery, in one shape or other, is wanted every day in the year; its culture is therefore a material part of the gardener's business. One large principal crop will not suffice; there must be a constant supply, as well of blanched as green.

Celery is in its prime state for use when it is full grown, thoroughly blanched, and just before the seed stem comes forth; after that shoots up, the whole plant becomes stringy, and less succulent. The stem rises sooner or later, according as the seed is sown early or late in the first months of the year. The first sowings are made in January, and again about the beginning of March. Both these sowings are made on hotbed heat; and when large enough to handle, are pricked out on a slight hotbed, to get the plants forward for ridging out in May. Both these sowings may be small, because the plants raised from them run to seed almost as soon as they are fit for use; still, where such celery is wanted, it must be cultivated, however fugitive it may be. The next and principal sowings are made about the 1st of April and 1st of May, on warm borders of the richest soil. For the plants from these sowings nursery-beds are prepared, and on which they are carefully pricked out to gain strength before ridging out in the months of June and July. The last sowing may be made at the beginning of June; but little else than green leaves can be expected from the plants of this sowing, because the growth of young celery plants is very slow after midsummer. But as plantations are made at different periods from the April and May sowings, a pretty constant succession of fine celery will be had throughout the autumn and winter months.

For the facility of blanching celery, it is usually planted in trenches in the following manner, viz.: on an open compartment garden trenches are marked out by line, one foot wide and four feet from each other; these are digged out to the depth of ten inches, laying the earth neatly levelled on each side. The trenches being cleared out, a coat of rich rotten dung, two inches thick, is laid in the bottom, and turned in with the spade half a spit deep. This finished, plants raised from the nursery-bed, having a few of their outside leaves trimmed off, are dibbed-in five inches apart along the centre of the trench. A good soaking of water is immediately given, and repeated every other day, if necessary, till the plants have taken hold of their new place.

The dung under the roots assists the plants to grow strongly, and being planted in a trench, induces a quick growth upwards. As the leaves advance in height, they are earthed up gradually, by paring earth from the sides of the trench with a spade, and allowing it to fall towards the plants, but not too much at a time, nor letting it into the hearts of the plants. This work should always be done on dry days, because moist earth might discolour or rot the outer leaves.

Two methods are followed in blanching celery; the first is doing it gradually as the plants advance in height; the other is allowing the plants to attain their full bulk and height, and then earthing them up at once. The latter plan is said to be the best, because the plants grow quicker while unencumbered with earth than if always closely earthed up. The fact is, the first is necessary in private gardens, where great size is of little value; and the second is best in market gardens, where bulk is an object, and where the crop is cleared away wholesale, whether thoroughly blanched or not. By the time the July planted crop arrives at full height, the plants will appear to stand in ridges perhaps two feet high; and the last earthing up is done with much care, by bringing and beating up the ridge to an acute angle at top, to throw off rain, which would soak down among, and injure the hearts. This finishes the culture of the principal crop; and all the other plantings, whether earlier or later, are treated in the same way.

The later in the year celery is ridged out, the shallower the trenches are made; those planted in September need not be deeper than about six inches, the plants rarely requiring to be deeper earthed up.

Another way of blanching celery is sometimes practised in market gardens. Instead of trenches for single rows, a large, say four feet wide trench, is made and dunged as before; the plants are dibbed in rows one foot apart across the trench; and as the plants advance in height, they are earthed up by well broken soil taken from the sides. This plan answers very well, provided the crop is taken up before winter; but the flat surface of such a bed is liable to admit too much moisture for the safety of the plants after they have ceased growing.

Frost is fatal to celery, if it reach it through the ridges. Fine crops should, therefore, not be left in jeopardy; they should either be effectually covered where they stand, or be taken up and stored in sand in some secure place. By this means good celery may be had for table till late in the spring, provided the seed was sowed rather late, for early sowings run to stalk long before Christmas.

There are several varieties in cultivation, viz.:—

Italian Red and White.
Solid Stalked Red.
New Striped.
Solid Stalked White.
Giant Upright.
New Silver.

The solid white and red varieties are mostly cultivated, as being decidedly the best, whether for salad or for kitchen use.

CELESTINE, a mineral nearly resembling prismatic barytes or heavy spar. It is the *Zölestin* of Werner, and is usually divided into five sub-species. The first of these is termed Foliated Celestine. It occurs in the Calton Hill at Edinburgh, and in red sandstone at Inverness. It is frequently found in the neighbourhood of Bristol, and in the islands in the Bristol Channel, particularly in Barry Island on the coast of Glamorganshire; also in amygdaloid at Bechely in Gloucestershire; and it has been procured on the Nidd, near Knaresborough, Yorkshire. It forms a bed, about one-fourth of a fathom thick, in a coal mine, which appears to be connected with shell limestone, at Suntel in Hanover; and also near Karlshütte, on the road from Göttingen to Hanover; in the Canton of Aargau in Switzerland; in the Sysser Alps in the Tyrol; and at Montecchio Maggiore in the Vicentine.

The crystals of this mineral are middle-sized, and frequently rest on each other. They usually form a rectangular four-sided table, in which the terminal planes are bevelled. Its hardness is a tolerably accurate test of its identity as it scratches calcareous-spar, but is itself scratched by fluor-spar.

The prismatic celestine usually consists of a long, oblique, four-sided prism, and occurs in combination with sulphur in the valleys of Noto and Mazzara in Sicily.

Fibrous celestine is of a pale blue colour, and occurs massive, but it has an indistinct cleavage.

Radiated celestine is of a milk-white colour. Internally it is shining and resplendent, with a pearly lustre, slightly inclining to vitreous.

Granular celestine (*Strontiane sulphatée, calcarifère*, Hauy) is of a greenish colour. It occurrs in considerable quantities, with gypsum, at Montmartre, near Paris.

CELLULACEA (Blainville). First class *Cephalophora;* second order of Molluscs. This order includes the families,—first, *Spherulacea*, in which are included the genera *Miliola, Melania, Saracenaria,* and *Tertularia;* second family, *Planulacea*, including the genera *Renulina* and *Peneroples;* third family, including the genera *Nummulites, Helicites, Siderolites, Orbiculina, Placentula,* and *Vorticiales.* The first family are microscopic shells, and only known in a fossil state; the animal is quite unknown, but, from analogous reasoning on the form of the shells, they may be supposed to be entirely concealed in its body; second family are all fossil shells. In the third family two recent species of the *Siderolites* are known; three species of *Orbiculina*; two species of *Placentula*, and four species of *Vorticiales*, all microscopic shells.

CELLULARES. A name applied to flowerless plants, indicative of their structure, in contradistinction to *vasculares*, which has been appropriated to flowering plants. To this grand division of the vegetable kingdom the terms *Acotyledonous* and *Cryptogamous* have also been applied. See article ACOTYLEDONOUS PLANTS. The plants belonging to this division have neither flowers nor sexual apparatus; they are chiefly composed of *cellular* tissue, and have no spiral vessels, and no proper stem or trunk. In them reproduction is accomplished principally by means of bodies called *sporules*, which are sometimes enclosed in particular coverings denominated *thecæ*, and at other times are imbedded in the substance of the plants. Many of them approach very near to the lowest tribes of infusory animalcules, and sometimes can hardly be distinguished from them. The ferns constitute the link between the cellular and vascular plants.

Our knowledge of the structure and physiology of cellular and cryptogamic plants is not by any means in an advanced state; and although the labours of many able botanists have been directed to the elucidation of the subject, still much remains to reward the investigations of future inquirers.

Ferns, mosses, lichens, mushrooms, and sea-weeds, are the orders generally included in what is called *Cryptogamia.* These orders have of late been subdivided into numerous sections. Professor Lindley divides flowerless plants into three sections:—

1. *Filicoideæ*, or fan-like plants, including *Equisetaceæ*, the horse-tail tribe; *Filices*, the true fern tribe; *Lycopodiaceæ*, the club-moss, or wolf's-foot tribe; and *Marsileaceæ*, pepperwort tribe. In these tribes there exists a distinct vascular system, and the sporules are in thecæ provided for their preparation and dispersion.

2. *Muscoideæ*, moss-like plants, including *Musci*, the moss tribe; *Hepaticæ*, the liverwort tribe; and *Characeæ*, the chara tribe. In these no vascular system can be detected, but there is a central axis of development, and the sporules are as in the fern-like plants.

3. *Aphyllæ*, leafless flowerless plants, including *Lichenes*, the lichen tribe; *Fungi*, the mushroom tribe; and *Algæ*, the sea-weed tribe. In these there is neither a vascular system nor a central axis of development, but an irregular ramification of homogeneous masses, and the sporules or reproductive bodies lie imbedded in the plants, and are scattered when it is destroyed.

Such are the chief subdivisions of cellular plants recognised by botanists. Many of the tribes above mentioned are highly interesting, and well deserving of attention. We have already given an account of the sea-weed tribe (see article ALGÆ), and we shall, in the course of the work, treat of the other tribes more in detail.

CELOSIA (Linnæus). A fine ornamental genus of tropical plants long known by the name of cockscomb amaranthus. Linnæan class and order *Pentandria Monogynia;* natural order *Amaranthaceæ.* Generic character is: calyx five-parted, coloured, propped by the bracti; cupela of five teeth bearing stamens; anthers two-celled; style simple; stigma cleft; capsule cut round, many seeded. The deep red colour and conglomerated position of the flowers of this genus attracted the notice of florists at a very early period. They were, it appears, first noticed on Chinese articles of furniture brought from that country to Europe by the first traders to that distant empire. Seeds were soon inquired for, easily obtained, and safely brought to Europe, where they, as tender annuals, have been propagated ever since. The celosia, gomphrena, and amaranthus, were all at first included under the general name of amaranthus, their seeds and habit showing great resemblance. They all yield seeds freely in this country, are sowed in seed-pans placed in a hotbed in March, whence they are potted singly, first in small and afterwards shifted into larger pots, and nursed on heat till about the end of May, when they go into the greenhouse to flower.

The different modes of flowering of the amaranthaceæ are most remarkable; some are arranged in long erect or dangling branched spikes, others in compact globular heads; some are in little tufts in the axils of the leaves, and the celosia, instead of spikes or spherical heads, has its stem flattened and extended laterally; the crest compoundly waved and duplicated; and the whole thickly beset with minute bractes and flowers. This aggregated and contorted formation of the flower stem is increased by suitable culture; and many practical florists excel in bringing them to a monstrous though at the same time a most interesting size; the crest of some of these productions of skill, sometimes measuring twenty inches in length and eight or ten inches across!

CELSIA (Linnæus). A genus of hothouse and greenhouse herbaceous annuals, natives of the south of Europe, Africa, and India. Linnæan class and order *Didynamia Angiospermia;* natural order *Solaneæ.* Generic character: calyx five-cleft; corolla tube short; limb rotate, in five lobes, the two upper ones small, the lower large; stamens ascending, long-bearded; anthers incumbent, roundly-kidney-shaped, bursting upward; style bearing a capitate stigma of two lobes; capsule two-celled, two-valved; seeds rough. These are pretty little plants and flower freely under the ordinary management of a stove or greenhouse. They are usually raised from seeds.

CELTIS (Linnæus). A genus of shrubs and trees, natives of different parts of the world. Linnæan class and order *Polygamia Monœcia;* natural order *Urticeæ.* Generic character: calyx in five or six parts, style none; stigmas variously divided; drupe a one-seeded berry. The North American and European nettle-trees have been long cultivated in our nurseries, and are generally seen in pleasure-grounds and shrubberies. They deserve a place in every arboretum, as they are, strictly speaking, forest trees. Propagated by layers and seeds.

CELYPHUS (Dalmann). An extraordinary genus of dipterous insects, belonging to the section *Athericera* of Latreille, family *Muscidæ,* and sub-family *Gymnomyzides,* having the body short and thick, with the antennæ longer than the head, and apart at the base, but more especially distinguished from every other known group of dipterous insects, by the immense development of the scutellum, which is so large that it entirely covers the abdomen and wings, in which respects it resembles the hemipterous genus, *Scutellera.* The species are of a small size, being ornamented with purple and reddish tints; one only is recorded in the Règne Animal, namely, the *C. obtectus* of Dalman from Java. M. Weidemann has however described a second, and we are in possession of a third species, recently brought from the East Indies. Nothing is known of the habits of the group, but, from the great size of the scutellum, we should conceive that the insects can make but little use of their wings, which it would appear must be very inconveniently acted upon by the scutellum.

CEMBRA. The *Pinus cembra* of Linnæus.

CENCHRUS (Linnæus). A genus of grass found in different latitudes belonging to *Triandria Monogynia,* and to the natural order *Gramineæ.*

CENIA (Commelin). An annual uncultivated plant found at the Cape of Good Hope. It belongs to *Compositæ,* and is of no known value.

CENTAUREA (Linnæus). An extensive genus of European herbs mostly perennials. Linnæan class and order *Syngenesia Frustranea;* natural order *Compositæ.* Generic character: anthodium bellying, egg-shaped, scaly, scales either entire or prickly; florets of the ray neuters, and tubular; receptacle bristly; pappus, of chaffy bristles, deciduous in a ring; hilum of the seed, on the side of the base. The centaureas or napweeds are generally coarse-looking herbs, though some of the foreign ones are ornamental, and admitted into the flower-garden. The cultivated species are easily propagated either by seed or by divisions of the root. The black, brown, and greater napweeds, are common in British meadows; and the blue-bottle of our corn fields is really an elegant plant.

CENTAURIUM is the specific name of one of the *Erithræas,* and one of the most beautiful of British plants.

CENTENUS (*Tenrecs*). A genus of mammalia, belonging to the second, or insectivorous, family or division of Cuvier's great order, *Carnassiers.*

These animals are sometimes popularly denominated Madagascar hedgehogs; and they have some external resemblance to the hedgehog properly so called, but still they differ sufficiently from them, and also from all other animals, for entitling them to be classed as a separate genus. The number of species is not great; the locality in which they are found native is limited; and both the habits and the appearance are peculiar. They are not confined to the island of Madagascar, but occur in Bourbon, and Mauritius, and they may perhaps also be met with in some of the smaller islands of the Indian ocean, which lie toward the eastern coast of southern Africa; but they have not hitherto been found on continental Africa, or in any other part of the world, save the small locality above mentioned. This locality is peculiar in many parts of its natural history, especially in its zoology; and it probably contains more animals not to be met with in any other place, than any region of similar extent. As is the case with most places which contain peculiar animals, those found only in this locality generally partake of the characters of more than one genus of those met with in other parts of the world.

Tenrecs have many of the anatomical characters of hedgehogs, as well as a good deal of the general appearance. They have clavicles; and their intestines are all of small diameter, and without cæca. Their skin is also beset with bristly spines, but it is not moveable so as to enable them to roll themselves into a ball, as is the case with the others. Their teeth bear, perhaps, more resemblance to those of the mole than any other animal; only they have two incisors less in each jaw, and one grinder in each side of the upper jaw. Their four upper incisors are bent, and the six lower ones have trenchant edges, with lateral lobes; to these follow two canines in each jaw, and behind these six cheek teeth on each side, the foremost one small, and having the character of a false molar; the others larger, and with sharp tubercles on their crowns, forming true insectivorous teeth. The head is long, the muzzle pointed, the body long, but low on the legs and without any tail; the ears so short as to be hardly visible; and a slight membrane partially covering the nostrils. In their walking they are plantigrade, and consequently but slow in their motions. They have five toes on each of their feet, armed with sharp claws adapted for digging. They are nocturnal animals, feeding principally upon insects; and, what is rather singular in animals of so warm a climate, they are described as remaining dormant for three months of the year, and this too in the season of greatest heat.

This last circumstance shows the inaccuracy of any attempt to connect the activity of animals with a higher, and their dormancy with a lower temperature, at least by the general law of animated nature. The truth is, that each animal is adapted to a particular temperature, which ranges over a greater or smaller number of degrees of the thermometer according to circumstances, but which may, in the case of every animal, be exceeded either upward or downwards; and mankind find, by actual experience, that when heat is beyond a certain degree, they become languid and sleepy, in the same manner as when exposed to severe cold.

We may naturally suppose, on this general principle, that several of the smaller mammalia of tropical countries hybernate during the hot season, which, if unproductiveness be winter, is the true winter in such countries; the time when vegetation is burnt up, and many of the insect races either buried deeply in the ground, or in the egg, as preparatory for a new race against the return of the season of plenty. This adaptation of animal life to the temperature both ways, is a very beautiful instance of that adaptation and balance of all the parts, of which we have so many in every department of nature, animate and inanimate; and it very forcibly illustrates that unity of design which may be traced through the whole. In order that all the different regions of the globe may enjoy as equal a portion of the genial influence of the sun, as can possibly be enjoyed by the surface of a spherical body exposed to a single light, which can of course act upon only the half of it at any one instant, it became necessary for this purpose to throw the temperature into those different kinds of extremes of season, which we meet with in the tropical and the polar latitudes; and the effecting of this general distribution of one cause, necessarily makes an excess of heat the means of suspending and destroying life in the one extreme, just in the same manner as a deficiency produces the same result in another.

There is in this again a very remarkable instance of adaptation, for we find living and growing creatures always in proportion, not to the average temperature of the year, but to that of the particular season. In fact, the cause of the season, and of the abundance or the deficiency which that season displays, is one and the same, so that in proportion to the activity of nature generally, is the activity of life and growth of all kinds. Upon this principle, the flowers and stems fail, the insects perish, and the face of nature puts on the same appearance of desolation during the dry and burning months of the warm latitudes, as during the frost and snow of the cold; and though in the former the banks of rivers, and all other places which are supplied with moisture, continue fertile throughout the dry season, there is a corresponding local preservation of life in certain parts of the latter: the polar sea is never barren, even when the surface of it is mantled with ice and snow; and it is probable that the drought invades the waters, and thereby produces temporary sterility, to as great an extent in the tropical latitudes, as the frost and winter does in the polar ones. Birds, from the power of flight, can escape from the evil day in both localities by migrating; and fishes have rather more advantage in the cold climate than in the hot ones; because in the first they can move equatorially, so as to avoid the ice, while in the second they are apt to be left stranded, and perish of drought, or become the prey of those wading birds, which frequent the subsiding waters in such multitudes. Some of the fishes are indeed endowed with a limited power of making their way upon the dry land, in quest of new pools and streams; and there is little doubt that some of them hybernate in the warm countries as well as in the cold, just as is the case with mammalia. It is well known that eels, which do not bear the cold so well as many other fishes, hybernate in this country; and that for this purpose they seek the sludge and mud in the estuaries of the rivers, near the average point of the brackish water, at which the temperature is known to be always higher than either in the fresh of the river, or the open sea.

We have thought necessary to offer these few remarks on tropical hybernation, both as contrasted with polar, and we may add mountain hybernation, and as it appears to be a necessary part of the system of nature, partly because the hybernation of the tenrecs have often been described as a sort of anomaly or inconsistency in nature, and partly also for the purpose of showing the beauty and consistency of the system; and before we proceed to give the few details which are known of the tenrecs, we may further remark, that whenever birds come seasonably, we may rest assured that, if the country is in a state of nature, we shall meet with hybernating animals, especially if the birds resort to the place during what may be regarded as its summer. We might naturally conclude that nocturnal insectivorous animals, which are generally plantigrade and have but limited powers of locomotion, would both, from the failure of their food, and the influence of temperature, be among the first to hybernate, whether in the cold latitudes or the warm. We find that such is the case in cold countries and on lofty mountains; and the tenrecs are one instance of the same in a tropical climate, to which there is little doubt that further observation will add many more.

There are three species of this genus, differing from each other in size, in colour, and in the texture of their covering; but their habits, as far as known, are all much the same.

1. The Bristly Tenrec (*Centenus setaceus*). This is the tenrec of Buffon. It is longer in the body than the common hedgehog, and altogether a little larger, but it is more slender. The front, the top of the neck, and the shoulders, are beset with stiff bristles, annulated with black and pale yellow; and there are true ones which form a sort of crest on the nape; the back, the flanks, and the rump, are covered with stouter bristles; but even these are partly flexi-

ble, and do not come under the denomination of spines, properly so called. The cheeks, legs, and under parts of the body, are covered with whitish hairs.

2. THE SPINY TENREC (*Centenus spinosus*). This is rather smaller than the first species. All the upper part of the body is covered with spines, stiffer than those of the former, but not so much so as the spines of the hedgehog. These spines are white at their bases, reddish-brown in the rest of their length, and with black tips. The head, limbs, and under part of the body, are covered with reddish-white hair.

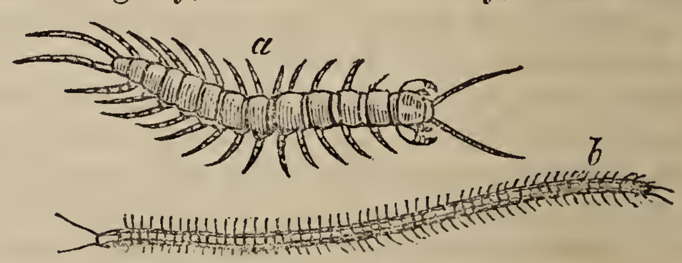
3. THE RADIATED OR VARIEGATED TENREC (*Centenus semi-spinosus*), is a much smaller species than either of the former, being only about the size of a mole, that is, about four or five inches in length. It was at first supposed to be the young of one or other of the species already mentioned: but it has since been ascertained to be distinct. The spines in this one are short and interspersed with hairs, and its markings consist of three longitudinal bands of yellowish-white upon a black ground. The spines on the nape form a sort of crest, as in the bristly species. The incisive and canine teeth of this species, are all very slender and crooked.

The whole of the species are quiet and inoffensive animals, lurking in concealment, and generally found not far from the water. The use of their bristly or spinous covering is not very well known, but it probably protects them against carnivorous animals, to whom creatures so covered would not be a very agreeable mouthful. The predatory animals of that part of the world are not however very formidable: there are none of the more powerful cats even in Madagascar; and the leading beasts of prey are said to be a species of leopard, and an animal resembling the jackall.

CENTIPEDES (Hundred-legs. SCOLOPENDRA, Linnæus). A group of annulose animals, forming the order *Myriapoda chilopoda*, divided by Latreille, Leach, &c. into several distinct genera, and distinguished from the *Julus* of Linnæus (forming the order *Myriapoda chilognatha*) by having the body flattened, membranous, composed of numerous segments, each of which is covered by a coriaceous plate, and bearing generally a single pair of legs, the last pair is turned backwards and lengthened into a pair of tails; the antennæ are more slender towards the tips, and composed at least of fourteen joints; the mouth is provided with a pair of strong curved jaws, furnished with a small appendage in the form of a palpus, and exhibiting in the centre the appearance of a soldered connexion; the lower lips are also formed of two dilated basal portions, terminated by a strong moveable claw, which is pierced at its extremity for the discharge of a supposed venomous fluid.

These animals have been considered venomous by all authors, and especially by travellers, because their bite is attended by much pain; but although the bite of the large exotic centipedes is even much more violent than that of the scorpion, it is not deadly. M. Worbe (in the Bulletin of the Philomathic Society of Paris, 1824) has published some statements which tend to prove that the bite of the *Scolopendra morritans* of Linnæus (which is termed by the inhabitants of the Antilles "le malfaisant," and "mille pattes," on the coast of Guinea) is dangerous, but it appears that by treating the wound with the application of ammonia, it is easily cured. Amoroux, the author of a work upon poisonous insects, states, however, that the ordinary centipedes of France are not provided with poison, although Leuwenhoeck, who examined the hooks of these insects, observed near their tips an orifice communicating with a cavity, which extends to the base of these organs. Be this as it may, it is evident from the common occurrence of these insects, which are met with every where, hiding themselves under stones, the barks of trees, in the ground, and especially in over-ripe fruit, creeping also into every darkened situation, and even entering beds, that they must become a very great nuisance in warm countries, where they not only abound in a greater degree than in more temperate climes, but also attain an immense size, if we may credit the account given by Ulloa, (quoted by Kirby and Spence) who states that at Carthagena these animals sometimes exceed a yard in length, and five inches in breadth, the bite of which is mortal. This, however, is evidently a traveller's wonder, for notwithstanding the more extended attention paid to exotic entomology during the last quarter of a century, we believe no species of this group have been received in Europe exceeding a foot in length, although Dr. Martin Lister, a more veracious author than the former, has figured a species eighteen inches long, and three quarters of an inch broad. In Europe, however, few species exceed two or three inches in length.

These insects, unlike the *Julidæ*, run very quickly; according to M. Veiss, quoted by Griffith, the *Scolopendra forcipata* (belonging to Dr. Leach's genus *Lithobius*), when walking, successively moves its numerous legs, one set of which are brought in contact with the line of position, whilst the others are raised up; the latter are quickly put down to the ground, and whilst the under pair of each division (comprising two segments*) is raised. All these various movements, which follow along the body from the head to the hinder extremity, produce an undulated motion. The insect varies its movements and their degree of force, according to necessity, each foot resting on the line in which it walks, and transporting the body in the same way as do the muscles of the snail, to the distance in which the limb can act. These insects are also able to run backwards with much agility, at which time they, however, make



a, Lithobus forcipatus. *b*, Geophilus longicornis.

use only of the two hind pairs of legs, which, when walking forward, are dragged motionless after the body.

These animals have been considered to be univer-

* The segments of the bodies of insects have generally two spiracles. If the bodies of the centipedes, especially those of the large exotic species, be regarded in this point of view, in which there are twenty-one pairs of legs, it will be observed, that the spiracles are placed upon alternate segments, whence, in comparison with the structure of the true insects, these segments must be considered as representing only semi-segments, from whence it is evident that each entire segment is provided with two pairs of legs, but with only one pair of breathing holes, one pair of the former organs, at the tail, being supernumerary. Mr. Mac Leay has followed up this theory of M. Latreille, in his memoir upon the thorax of insects, published in the Zoological Journal.

sally carnivorous, but from the situations in which we have repeatedly found some of the English species, we should be disposed to assign them, at least in some degree, an appetite for decaying vegetable matter. Dr. Leach has also given the name of *Geophilus carpophagus* to one of the species, from its feeding upon fruit. One of the British species, the electric centipede, (*Scolopendra electrica*, Linnæus,) possesses the remarkable property of emitting a phosphorescent light by night, nearly as bright as that of the glow-worm. We have often met with this insect in foot-paths near London, and have observed that it leaves a strong light upon the fingers when handled. It resides under stones and in moss during the day. It is about three quarters of an inch long, of a dirty buff colour, with a black line down the back. It is destitute of eyes, at least the small shining tubercles upon the head of the common scolopendra, which have been regarded by all authors as eyes, are here entirely obliterated. This is a remarkable circumstance with reference to the luminosity of the insect, as it has generally been supposed that the emission of this kind of light by insects, has for its object the enticement of the opposite sex, which in this instance would of course be unable to see or to be attracted by the light of its mate. Dr. Leach observed beneath the earth in a garden, in the month of January, a cavity containing a female of the *Geophilus subterraneus*, and twenty-six young ones, varying very much in the number of their legs; they were of a pale yellow colour, with their heads darker yellow, and the joints of their legs slightly ferruginous.—Zoological Miscellany, vol. iii. p. 44.

There are numerous small British species, of which Dr. Leach has published a very good monograph in the Zoological Miscellany, forming several genera.

CENTRANTHUS (De Candolle). A genus of herbaceous perennials, two of them British. They belong to the first class and second order of Linnæus, and to the natural order *Valerianeæ*.

CENTRARCHUS. A genus of spinous-finned fishes belonging to the perch family, and having, as their most distinguishing characters, a compressed body, with an oval section, and a produced membrane at the angle of the gills; they have also membranous spines in the anal fin, and small teeth upon the tongue. They are inhabitants of the fresh waters of America.

CENTRINA. A genus of cartilaginous fishes, belonging to the shark family, and not differing greatly in their families from the sharks properly so called. For an account of the general habits of the family we must refer to the article Squaloidæ.

CENTRISCUS. A genus of spinous-finned fishes, belonging to Cuvier's fifteenth, or last family (*Bouches en flute*), pipe-mouths, so named from the great elongation of the jaws and the smallness of the opening of the mouth. They in fact form a division, or sub-family, including all those species which have the mouth of the pipe-form, but the body compressed and oval, instead of being drawn out, as in the pipe-fishes properly so called. The fishes of this division are sometimes called sea-pies. They have the body compressed at the sides, and trenchant at the under part, and only two or three small rays in their gill-flaps. It is not very long, and indeed they are altogether fishes of small size. They have the first dorsal spinous, and small ventrical fins behind the pectorals; their mouth is extremely small, and opens obliquely. Their intestinal canal is without cæca, but it has three or four duplications; they are furnished with air-bladders of considerable size.

They consist of two genera or sub-genera, AMPHISITE, of which a notice will be found under that name. The characters of *Centriscus*, properly so called, in brief, are these: the foremost dorsal situated far backwards, and having its first spine very long and strong, and articulated to the bones of the head and shoulders, over which there are some large scaly plates, toothed in the centre. There is one species (*Centriscus scolopax*), which inhabits the Mediterranean, attains the length of some inches, and is of a silvery colour. Sailors, who sometimes catch this species as a curiosity, call it a "sea-snipe."

CENTROGASTER. A genus of spinous-finned fishes belonging to the lancet-fish family, and presenting altogether a singular appearance. Their ventral fins have a spinous ray upon each margin, and the three intermediate ones with jointed rays, as usual. They have five rays in the gill-flaps, and a crooked spine in advance of the dorsal fin. Their most singular characters, however, is in the styloid bones of the shoulders, which are prolonged, bent backwards, and connected at the extremities with the first spinous ray of the anal fins. The species of this genus are numerous, and they are all found chiefly in the warmest seas.

CENTROLOPHES. A genus or sub-genus of spinous-finned fishes, included in the group CORYPHÆNA, under which some notice will be found.

CENTRONOTUS. A genus of spinous-finned fishes belonging to the family of *Gobioidæ*. They are very nearly related to the *Blennies*, from which, however, they differ in as many respects as warrants the separation. They have their ventral fins much more minute than any of the other blennies; these organs are always without much power of action, and they sometimes consist of only a portion of one single ray. Their head is very small, their body long and blade-shaped, furnished all along the back with a fin of nearly uniform height, of which all the rays are spinous. Their teeth are crooked, pointed, and wide apart from each other, but consist of several rows.

There is one species very common on the shores of western Europe, the common gunnel, which grows to the length of from six to ten inches, is yellowish brown on the body, but whitish on the belly, and marked with a variable number of ocellated spots ranged along the base of the dorsal fin. There is also another species, larger in size, being from twelve to fifteen inches in length, brownish on the upper part and yellow on the under, and with the former mottled or marbled. This is the viviparous gunnel, or blennie, as it is called. Both species lurk among stones near the shore for great part of the year; but the viviparous ones take to the water as a surface fish, though generally in estuaries, or places near the coast, about the middle of summer. At these times it is rather provoking to amateur fishers, as it is always in the way, very ready to take their bait, and not worth the catching. Its flesh is good for nothing, and the spine has the curious property of turning green when boiled, on which account the fish is in some places called the "green bone."

CENTROPRISTES. A genus of spinous-finned fishes, belonging to the perch family, and bearing some resemblance to the sea perches. Some of them attain a considerable size. See the article PERCOIDÆ.

CENTROPUS. A species or sub-genus of climbing birds, or, at all events, of tree birds, combining the general characters of the cuckoo, with a long and straight claw on the hind toe resembling that of the lark. There are several species, all natives of the eastern continent, for some notice of which see the article CUCKOO.

CENTROTUS (Fabricius). A genus of insects belonging to the order *Homoptera* of Latreille, family *Cicadidæ*, and sub-family *Cicadellæ*, of the same author. The head is inserted very low, the antennæ are very small, and terminated by a long slender seta, and the scutellum, although covered by the prothorax, is developed. Nothing can exceed the grotesque and extraordinary forms exhibited by some of these insects, more especially those inhabiting the tropical countries, the thorax being produced into such strange and monstrous horns and spines, varying in their position and direction, that nothing parallel to them can be found in nature. In some species we find this part produced over the head into a helmet, in others the sides stand up like the ears or horns of various animals, while in not a few this part is extended over the back into a long slender tail; two of the most remarkable species are the *C. globularis*

a, C. globularis. *b*, C. cruciatus.

of Fabricius, an inhabitant of South America, which we have represented from nature, and which is about one third of an inch long, and the *C. clavatus* of Fabricius, an inhabitant of the same country, having the most extraordinary appendages in the shape of spines, balls and crescents. "What is the precise use," observe Messrs. Kirby and Spence, "of all the varieties of armour with which these little creatures are furnished, it is not easy to say, but they may probably defend them from the attacks of some animals." These insects are of small size; they feed, in the preparatory states, upon plants, employing their articulated rostrum as a sucker to pump up the juices of the leaves. Mr. Kirby has published the descriptions and figures of some extraordinary species of this genus, in the Magazine of Natural History. Like the whole of the Linnæan *Cicadidæ*, these insects are able to leap to a considerable distance. Our second figure represents another curious Brazilian species.

We possess two British species, namely, the *C. cornuta*, Linnæus, an insect which we have often met with in the early summer months upon the nut, white-thorn, &c., and which has a triangular horn on each side of the thorax, with the posterior part of the latter extended into a long and slender tail over the back. The other species, *C. genistæ* of Fabricius, is smaller, and is found upon the genista tinctoria.

CENTUNCULUS (Linnæus). The Roman name of the bastard pimpernel, a very small annual plant found on most heaths in Britain. It belongs to the natural order *Primulaceæ*.

CEPA. The specific name of the common onion.

CEPHÆLIS (Swartz). A genus of West Indian shrubs belonging to *Pentandria Monogynia* of Linnæus, and natural order *Rubiaceæ*. Generic character: flowers, aggregated in a head, having an involucrum; calyx small, of five teeth, supported by the bracti; corolla somewhat bell-shaped, throat bearded, limb in five divisions; stamens included; stigma in two parts; drupe dipyrenous.

CEPHALACANTHUS. A genus of fishes, with spinous fins, belonging to the peculiar division which Cuvier names "armed cheeks," from the strong scaly plates with which their heads are furnished. Their muzzle is very short, and has the appearance of being divided like a hare lip, with the mouth situated under it; the helmet is flat, four-cornered, and rough. They bear a considerable resemblance to the flying fishes, only, they are without the supplemental fins, or wings, as they are called, of these singular inhabitants of the ocean. There is only one known species, of small size and little value.

CEPHALANTHUS (Linnæus). A North American shrub, there called Button-wood.

CEPHALARIA (Schreber). A genus of undershrubs and herbs of various duration, natives chiefly of Europe and the Cape of Good Hope. Linnæan class and order *Tetrandria Monogynia*, natural order *Dipsaceæ*. These plants resemble the scabious, the flowers forming round heads.

CEPHALOPHORA or CEPHALOPODA (Cuvier; Lamarck). A molluscous animal, so called from having their heads furnished with long appendages, adapted to progressive motion; they have two orders of muscles, one belonging to the body, the other to the feet or tentacula. The animal's head is quite distinct from the rest of the body, and provided with all the special organs of sensation, as well as with very large sessile eyes; the body oval, sub-cylindrical or conical, naked or partly concealed in an univalve shell, constantly many chambered and without an operculum; the mouth terminal and anterior, furnished with a pair of horny teeth, acting vertically against each other, and surrounded by numerous tentacular appendages, probably used as feelers or baits to attract their prey. Organs of respiration branchial, in symmetrical pairs, and generally, if not always, concealed. The sexes separate.

This class of Molluscs, at least from all that it at present known of them, including the species of this type, are the most complete in their various parts of organisation; they, in fact, enjoy all the animal faculties—see well—hear—possess the power of moving rapidly and of pursuing and seizing their prey. This class is divided into the first order,—*Cryptodibranchiata* (two concealed branchiæ) forming the Linnæan genus *Sepia*, which is now sub-divided into the first family, *Octocera*, including the genus *Octopus*, having eight tentacular appendages; second family, *Decacera*, (ten tentacular appendages) including the genera *Loligo* and *Sepia*. Second order, *Cellulacea* (which see). Third order, *Polythalamacea* (many chambered). First family, *Orthocerata*, (like a horn) including the genera *Belemnites*, *Conularia*, *Conolites*, *Orthocerata*, and *Baculites*; second family, *Lituacea*, including the genera *Icthyosarcolithes*, (stony fish eaters) *Lituola*, *Spirula*, *Hamites*, and *Ammonoceratita*; third family, *Cristacea*, including the genera *Crepidulina*, *Orcas*, and *Linthuris*; fourth family, *Ammonacea*, including the genera *Discorbites*, *Scaphites*, *Ammonites*, and *Simplegas*; fifth family, *Nautilacea*, including the genera *Orbulites*, *Nautilus*, *Polystomella*, and *Lenti-*

culina; sixth family, *Turbinacea*, including the genera *Cibicides*, and *Botalites;* seventh family, *Turriculacea*, the genus *Turrilites*. Under the alphabetical arrangement of these species, genera, families, and orders, detailed accounts will be given of each.

CEPHALOPTERES. A genus of cartilaginous fishes, with fixed gills, belonging to the family of the rays. These are singularly-shaped fishes. The head is blunt in front, but the pectoral fins advance so much on each side of it, as to give the fish the appearance of having horns, or rather a winged head, on which account the generic name is given to it. The tail is slender and eel-shaped. A farther notice of them will be found in the article RAY, in connexion with the rest of the family.

CEPHALOTES. The brown bat of Lima, for a notice of which see the article BAT.

CEPHALOTUS (Labillardiere). A curious New Holland herbaceous aquatic plant brought to England in 1822. Linnæan class and order *Dodecandria Hexagynia*, natural order *Rosaceæ*. Generic character: calyx six-cleft and coloured; corolla none; stamens inserted in the base of the calyx; anthers twined, glandular at the back; style cylindrical; capsules six, many seeded. This, like the Nepenthes, is called a pitcher-plant, because the leaves are formed into little pitchers with beautifully fringed lids, and finely varied in colour by streaks of pink or pale purple. They are kept in frames or in a shady part of a greenhouse planted in peat earth, and surrounded by pieces of grassy turf to keep them cool and moist.

CEPHALUS—Moon-fish. A genus of fishes belonging to the order *Plectognathes*, or those which have the bones of the jaw and head soldered together, and to the division *Gymnodontes*, or those that have the jaws covered with ivory plates instead of teeth. The characters of the present genus are: each jaw united into one piece; the body compressed, incapable of being inflated, as is the case with the globe-fish, and destitute of spines; the tail so short, and ending so abruptly, that the whole body has the appearance of only the half of a fish. Their dorsal and anal fins, which are long and pointed, are united with a cordon which is exceedingly short. Three or four species of the genus are known, and one found in the European seas (*Cephalus mola*) is sometimes more than four feet in length; but, from the great thickness of the body, it weighs between three and four hundred pounds. The profile of this one is very round, but the posterior extremity appears over where the thickness is greatest. The back is short, of a bright black colour, marked with blue spots. The sides are silvery, and the fins black. The eyes are large and round. The flesh is eaten, but the animal requires to be skinned, as the skin is very thick and rough, bearing some resemblance to a piece of leather. There is another species, found chiefly in the southern Atlantic, which is more oblong, and has the skin very hard, and reticulated into a number of small angular compartments. A third species is said to be furnished with some spines. It is very small in comparison with the others. These fishes range the ocean much more extensively than their singular figure would lead one to expect. Their food is understood to consist of sea-weed and crustaceous animals.

CEPHUS (Latreille). A genus of hymenopterous insects, belonging to the section *Serrifera*, and to the family *Tenthredinidæ*, or saw-flies. The body is compressed, the antennæ thickened towards the tips, composed of about twenty joints; the posterior tibiæ spurred in the middle, and the wings have two marginal, and four sub-marginal cells. In several respects this genus materially differs from the family of the saw-flies, approaching to the genus *Sirex;* indeed the type, *C. pygmæus*, was described by Linnæus as a species of sirex. Latreille has stated that the larvæ of these flies are six-legged grubs, destitute of false abdominal legs; those of *C. abdominalis* attack the flowering buds of fruit trees, doing considerable mischief; and from some statements published in M. Ferussac's "Bulletin," it appears that the larvæ of the typical species live in the stems of wheat: in support of which we may state, that we have met with one of the species in the perfect state, in some abundance, in wheat fields. The insects, of which there are about a dozen British species, are of moderate size, and are ornamented with bands of yellow on a black ground.

CEPOLA. A genus of spinous-finned fishes, belonging to the eighth family of the order. They are riband fishes, and forming the characteristic species of that division. It gets its common name from the brightness of its colours, and the wavy bands which mark the sides. It is also, for the same reason, sometimes called the band-fish. These fishes have the body elongated and flat; the dorsal and anal fins very long, and the caudal fins very distinct. Their ventral fins are of mean length, and consist of many rays. One of their most remarkable characters is the way in which the mouth opens. The upper jaw is very short, and the under one is not only longer, but advances upwards in front, so that the mouth is on the upper part of the head, and the chin in front of the muzzle. The teeth are very pointed; the abdominal cavity is very short, but the air-bladder is long, extending to the root of the tail.

The common riband, or band-fish (*Cepola rubescens*), occurs on the south coast of England, but rarely, if ever, on the more northerly coast of Britain. It is a poor fish, and of very little value as food, but its appearance is curious, and its colours are very showy. The ground colour on the sides is carmine red, waved along the sides with glistening silvery bands. The length is about a foot on the average. The mouth large, turning upwards, as already mentioned, and furnished with a single row of curved teeth in each jaw. The eyes are large, and the aniles silvery mottled with bright red. The body tapers from the head backwards, and is smooth, and even partially transparent to appearance. Fishes which have this latter appearance are usually of but little value. This one is, however, taken in the Mediterranean, though it is in little esteem even in a country where there are many fish days in the calendar. In the water it is a very beautiful fish. It swims near the surface, gliding about like a serpent, and showing its bright colours to the greatest advantage. It is understood to subsist chiefly upon floating crustacea, and radiata, which the peculiar form of its mouth renders it very expert in seizing. For a general account of the family, see the article TÆNIOIDÆ.

CERAMBYCIDÆ (Kirby). A family of coleopterous insects, belonging to the section *Tetramera*, and to the sub-section *Capricornes* or *Longicornes*. These insects are distinguished by the great length of the antennæ, which often exceed that of the entire body; the upper lip is distinct, and reaches across the lower part of the face; the upper jaws are robust and horny, alike in both sexes; the lower jaws are terminated by two very distinct hairy lobes; the eyes are notched, or rather kidney shaped, the antennæ being inserted in the notch; the thighs are generally thick towards the tip, but slender at the bar; and the body is mostly long and narrow.

These insects are, for the most part, of a large size, and from their very great numbers, especially in tropical climates, it is evident that they must be important instruments in checking the overpowering masses of vegetation. Their forms are, in general, very elegant, and their colours much diversified. Except in the genera *Necydalis* and some of the *Callidiums* which frequent flowers, the majority are found upon the trunks of large forest trees, where they may be observed sucking up the sap which flows from the wounded parts. The females are, in general, distinguished by their larger size and shorter antennæ. In this sex also, the abdomen is terminated, in many species, by a long horny and retractile borer, with which they are enabled to introduce their eggs into the cracks and crevices of trees. In these insects we also perceive a peculiarity of structure, which is especially adapted to their mode of life. In the ground beetles, *Carabidæ*, the feet are terminated by an articulated tarsus, composed of several long and slender joints having two strong claws at the tips; but in the *Cerambycidæ*, and, in fact, in the majority of wood and plant feeding beetles, we find the feet terminated by a short tarsus, having dilated points, and furnished beneath with a spongy kind of cushion, which is evidently adapted to enable them to retain a long stationary position upon the upright stems of trees, just as the cushioned feet of the fly permit it to creep, head downwards, on the ceiling of a room. By the assistance of this piece of mechanism, the *Cerambycidæ* are able to creep up the standing trunks of trees, but their walking motions are not distinguished by that activity which is found in some of the groups of beetles, a circumstance, in a great measure, dependent upon the nature of their food, which, unlike that of the last mentioned insects, of course requires but little running after. They fly, however, with more quickness, but they may be easily captured, since they fall to the ground on meeting with the least obstruction. During the day they generally remain motionless upon the trunks of trees or in the crevices of the bark, coming forth by night for the purpose of coupling. When seized by the hand, they make a sharp and tolerably loud sound, by rubbing the inner lining of the thorax against the base of the abdomen which is introduced into the thoracic cavity; the motions which the insect makes in raising or lowering the head, causes the posterior part of the thorax to rub against the base of the abdomen, and so to produce the sound in question.

It is during the larva state that these insects are the most injurious to timber, boring it through and through in various directions. These larva are white fleshy grubs, the body narrowed behind, composed of twelve distinct segments, the head broad, horny, and armed with two short but very robust jaws, with which they gnaw their way through the wood, they have also six almost rudimental legs. The antennæ which, in the perfect state, are such conspicuous and beautiful organs, are, in the larva, scarcely visible.

An account of the ravages of one of the species of this family is recorded by Professor W. D. Peck, in the fifth volume of the Massachusetts Agricultural Repository and Journal, belonging to the genus *Stenocorus.* It appears to be diffused over a large portion of the United States, probably from Maine to Georgia, indeed, wherever the oaks, upon which it feeds, are found, it is to be met with. For several years the ground beneath the black and white oaks had been observed to be strewed with small branches of those trees from eighteen inches to two feet in length, sometimes even reaching the length of five feet, and an inch in diameter. The falling of these branches is occasioned by the larva of a species to which he gives the name of *Stenocorus putator,* which, when the duration of its existence in the larva state is nearly complete, eats away the wood in a circular direction leaving only the bark entire; this is broken by the first strong breeze, and the branch, with the larva in it, falls to the ground. From the effects of its labours it has received the name of the oak pruner. Professor Peck, in order to determine whether the larvæ descended to the earth to undergo their transformation, as might be inferred from the proceedings of the grubs, placed several branches inclosing them into a vessel nearly filled with light garden mould, imagining, that as the larva is inclosed in the fallen branch, with a sufficient supply of nutriment to carry it through the feeding state, it was intended it should enter the earth when that state was passed, and that it was therefore impelled by instinct, to eat off the branch, that it might be brought in safety to the ground, before it was quite ready to quit the wood; but this conjecture proved erroneous, whence it is evident that there must be some other reason for the process. This may perhaps be found to exist in the necessity of a degree of humidity, to favour the development of the parts of the perfect insect, whilst in the pupa state; in the body and larger branches of trees, the moisture is sufficient for this purpose, but in these small branches which are killed, the moisture would be exhaled by the action of the sun and wind, if they remained on the tree; whereas, by their falling and being thus placed nearly or quite in contact with the moist earth their humidity is preserved. It was not precisely with this view that the prepared branches were treated as above mentioned, but the purpose was attained. The vessel was kept in a warm room, the wood was kept moist and one perfect insect made its appearance in November, and another in December; but probably they would not have been disclosed before spring if the branches had remained abroad. The perfect insect itself is of a slender form, about half an inch long, of a dark brown colour, dotted with impressed points, and sprinkled everywhere with short white hairs. As the leaves are in full vigour in July preparing the descending sap, and as the greatest part of the new wood is formed after the summer solstice, the loss of leaves at this season must diminish. The trees increase in diameter in proportion to the quantity of leaves taken from them, but the falling of the branches with the larvæ in them, enables nature, though the species cannot be destroyed, to check its ravages in some degree. It is recommended to collect and burn the branches from the time they begin until they cease to fall.

The Rev. Lansdown Guilding has also published, in the thirteenth volume of the Transactions of the Linnæan Society, an interesting notice of the ravages of another species of these beetles, belonging to the genus *Lamia,* and which, from its remarkable habits, he has termed *Lamia amputator.* It is found sufficiently common in the Islands of South America, and is occasionally noticed in St. Vincent, where it was observed to make a noise by rubbing the thorax against the base of the elytra. It delights in the mimosa groves, preferring *Mimosa lebbeck*, Linn., which it attacks and prevents it from becoming too luxuriant, and thus depriving the neighbouring vegetation of the necessary supply of air. This it effects in a two-fold manner. The larva excavates the branches by means of its powerful jaws, which produce a sufficiently distinct sound when in motion, and in order the more readily to make its way through its labyrinth-like passage, it occasionally turns backwards and expels its excrement through an orifice in the branch. When it is full grown, the surface of the branch alone remains entire, the wood inside being consumed, it then forms its nest of chips of wood and becomes a pupa. The perfect insect having made its way out of the tree is not less destructive, gnawing off the branches, by cutting circularly round their axis, when the wounded branch falls to the ground at the first wind, and soon dies. It likewise wounds the bark with its jaws, in order the more readily to deposit its eggs, by means of its retractile ovipositor, in the puncture thus made.

The larva of the *Cerambyx heros* of Linnæus, is reputed to have been the Cossus of the ancients, which was served at their tables as a very favourite dish. See Cossus.

In this state the insect remains several years, and it is owing to this circumstance that, in the neighbourhood of our dock-yards, timber warehouses, &c., many very splendid exotic species of this family are occasionally found alive, having been brought from their native countries in the logs of wood. We understand that a gentleman connected with the London Docks has made a very extensive collection of such imported insects.

In the Linnæan system, the Longicorn beetles composed the three genera *Leptura*, *Necydalis*, and *Cerambyx*. Of these, the first is now formed into the family *Lepturidæ*, the second is still considered as a genus, but the last, from the vast accession of new species, exhibiting various important modifications of structure, has been divided into two great divisions, which have been regarded as families, namely, the *Pronidæ* and *Cerambycidæ*, (the genus *Necydalis*, forming part of the latter). More recently, several French authors have divided the *Cerambycidæ* into two groups, namely, the *Cerambycidæ* and *Lamiidæ*. As, however, our chief English authors have adopted the former method of distribution, it will perhaps be deemed more convenient that we should follow in their steps; premising, however, that the *Lamiidæ*, as a sub-family, are distinguished by the vertical position of the head, the filiform palpi which are not thickened at the tips, and the thorax, which is cylindrical with the sides, armed with one or more strong points.

M. Audinet Serville has just completed a revision of the characters of the *Cerambycidæ*, and some idea may be obtained of the extent of his labours and of the group itself, when it is stated, that (exclusive of the *Lamiidæ*) he has characterised not less than ninety genera of the true *Cerambycidæ*, in the annals of the French Entomological Society, for the last year. As the distinguishing peculiarities of these groups are, for the most part, structural, we shall content ourselves with this notice of them, without giving even their names, as we have generally done in such cases.

In this country we possess only fifteen genera, including those of the *Lamiidæ*, namely,—*Hamaticherus*, Meig. (*Cerambyx*, Serv.), *Cerambyx* (*Callichroma*, Latreille, *Aromia*, Serv.), *Acanthocinus*, *Monochamus*, *Pogonocherus*, *Lamia*, *Aphelocnemia*, *Saperda*, *Obrium*, *Callidium*, *Clytus*, *Tetrops*, *Tetraopes*, *Molorchus*, and *Stenopterus*.

The musk beetle, *Cerambyx moschatus* of Linnæus, has been generally considered as entitled to retain the Linnæan name of the genus, although Latreille and Serville have given it a different generic appellation, founded upon the fragrant odour which it disseminates during its living state, which has been compared to ottar of roses, and which is retained for some time after death. M. Serville states that this scent becomes more intense at the time of coupling. It is, indeed, sufficiently strong to be perceptible when walking near the tree on which the insects are standing. The name of *musk* beetle given to this species is not, however, correct, as the scent is very different from that of the drug whence its appellation is derived. The insect varies in length from an inch to an inch and a half, and is of a fine green colour, with bluish legs and antennæ. It is very abundant on willow trees in the neighbourhood of London.

C. moschatus.

CERANTHERA (Beauvois). An ever-green tropical shrub belonging to the fifth class and first order of Linnæus, and to the natural order *Violarieæ*. Generic character: calyx, upper lip marginate, the lower divided; corolla, throat inflated, upper lip long and two-lobed, the lower in three divisions; stamens standing apart and protruding; anthers incumbent, two-lobed, with awns on each side; style divided at the apex.

CERAPHRON (Jurine). A minute genus of hymenopterous insects, belonging to the section *Terebrantia*, and family *Proctotrupidæ*. The wings are furnished only with a narrow stigma, and a single nerve running from that point nearly to the tip of the wings; the antennæ of the females are composed of ten joints, of which the first is very long, and the remainder gradually thickened to the tips. According to Mr. Say, it is to a species of this genus, which he has named *Ceraphron destructor*, that the inhabitants of North America are indebted for the partial destruction of the Hessian fly (see Cecidomyia), all the species of the genus having habits very similar to those of the *Ichneumonidæ*. Latreille and Curtis have confounded a very distinct group (which we have named *Megaspilus*) with Ceraphron, and in which the antennæ are eleven-jointed, and the stigma of the upper wings very large. The species are very numerous. One of them, described by Mr. Curtis under the name of *Ceraphron Carpenteri*, is distinguished by the beautiful knotted antennæ of the males. It was reared by Thomas Carpenter, Esq., from female *Aphides*.

CERAPTERUS (Swederus). A very curious genus of coleopterous insects, belonging to the family *Paussidæ*, and composed of two or three exotic species, of whose habits we possess no information. The name of the genus is indicative of the singular structure of the antennæ, which are very broad, each being nearly half the size of the entire body, and composed of ten short flat joints. The body is small and flattened; the legs are very broad and retractile. The species are inhabitants of the East Indies and New Holland. Dr. Horsfield has also brought another supposed species from Java, which is deposited in the fine collection of insects at the East India House.

CERAPUS (Say). A genus of crustaceous insects, belonging to the order *Amphipoda*, and probably forming the type of a distinct family, having the antennæ very long and thick, the two pair being of nearly equal size, the upper four-jointed, and the inferior or lateral pair composed of five joints; the body is long, linear, and semi-cylindrical, formed of twelve segments, the last of which is armed with a small forked appendage on each side; there are seven pairs of legs, of which the anterior pair is very small, but the second pair, although short, are terminated by a broad triangular claw, with a bi-articulate finger. The genus at present consists of a single species, the *Cerapus tubularis*, described by the late Thomas Say in the Journal of the Academy of Natural Sciences of Philadelphia, vol. i. This curious animal, about half an inch long, resides in a small cylindric tube, in the same manner as the caddice worms, showing only the head, antennæ, and four anterior legs. It is found abundantly in the ocean near Egg Arbour, on the coast of the United States, in the midst of *Sertulariæ*, upon which it seems principally to feed.

CERASSUS (Jussieu). A genus of well known timber and fruit trees, found wild in many parts of the globe. Linnæan class and order *Icosandria Monogynia;* natural order *Rosaceæ.* This genus contains all the various fruits called cherries, as well as some other plants which inhabit, and to common observers, do not appear to belong to them, namely,—the common and Portugal laurels, all of which will be treated of under their proper names.

CERASTIUM (Linnæus), is a numerous genus of European weeds, commonly called mouse-ear chickweed. Some of them are pretty; but, in general, they are neglected weeds, and only interesting to the scientific botanists. They belong to the natural order *Caryophylleæ.*

CERASTUS (the Horned Viper), so called from having a pointed horn, or horny scale over each eye standing up from the eyelid. It is of a greyish colour, and found chiefly in the sandy places of Africa. See Viper.

CERATINA (Latreille). A genus of small but elegant hymenopterous insects, belonging to the family *Apidæ,* and placed by Latreille in his sub-family *Dasygastres*, or woolly-bellied bees, of which the leaf-cutter bees (*Megachile*) are the types. The maxillary palpi are, however, composed of six joints; the wings have three complete cubical cells; the body is long and narrow; the antennæ are thickened towards the tip; and the jaws have three terminal teeth. The abdomen, likewise, is destitute of that ventral clothing of down which is characteristic of the true *Dasygastres,* being in fact the organs whereby their supplies of pollen are carried to their nests. Hence M. St. Fargeau considers that this genus (being supposed to be thus destitute of pollinigerous organs) is necessarily a parasitic bee, depositing its eggs in the nests of other bees already stored with food. M. Maximilian Spinola, in his interesting account of this insect, published in the tenth volume of the "Annales du Musée," considered the small channels along the head to be organs supplying the place of the real pollinigerous organs, having observed a small portion of pollen paste upon this part of the head. M. St. Fargeau, however, considers that this was but an accidental occurrence, having observed a similar circumstance in other insects, *Lepturæ, Eristales,* and *Sesiæ,* which certainly are not pollinigerous; and indeed he affirms that the *Ceratinæ* deposit their eggs in the nests of small species of *Osmiæ* or *Heriades* (two genera of woolly-bellied bees); and if the observation of M. Spinola, that the *Ceratinæ* are noticed from time to time entering the hollow stems of plants, be correct, he considers that it is owing to the fact, that the real pollinigerous bees above mentioned had fixed upon those places for their nests, and that the *Ceratinæ* were about to deposit their own eggs in the already provided nest. Spinola, however, mentions other circumstances which seem to militate against M. St. Fargeau's opinion. Thus he states, that in breaking off the bramble branch into a hole, in which he had observed a female *Ceratinæ* enter, he found that it was perforated, and that the insect was in the very act of excavating its burrow in the pith of the branch, where it constructs a canal a foot long, and one line, or sometimes more, in diameter, with from eight to twelve cells, separated from each other by partitions of particles of pith glued together, each of which contained a supply of pollen balls kneaded with honey. As the *Ceratinæ* is stated to work only in the pith, the mandibles not being fitted for working in the hard wood, Spinola found instances in which the bee had been unable to finish her burrow in the branch of a wild rose, the pith not being of sufficient diameter.

There are not more than half a dozen species known of this interesting genus, one of which, *Ceratina cœrulea,* Villars; *cyanea,* Kirby; *albilabris,* Latreille), is an inhabitant of this country, but very rare, two other species are European, and three South American.

CERATONIA (Linnæus), is the carob tree of the Levant; Linnæan class and order *Polygamia Diœcia:* natural order *Leguminosæ;* generic character: flowers polygamous; calyx in five parts; stamens, filaments long; anthers large and double; stigma sitting and headed; pod quadrangular, unequal in breadth, containing a mealy pulp. The old trivial name of this fruit is called St. John's bread, it being an article of diet in countries where it grows naturally; indeed, it is cultivated for economical purposes. In this country it is kept in general green-house collections, but is of no value either as a fruit or ornamental tree.

CERATOPOGON (Meigen). A genus of insects, belonging to the order *Diptera*, section *Nemocera*, and family *Tipulidæ*, and being nearly allied to *Cecidomyia*. These insects are very numerous, of small size, with the antennæ in both sexes nearly moniliform, having the last five joints elongated, and with a strong brush of hairs at the base in the males only. The eyes are lunate, and the wings laid flat upon the body when at rest, the nervures, of which the number is very small, being longitudinal. These insects are found upon hedges, brambles, flowers, &c., especially in low moist and woody situations, whence it is to be presumed, observes M. St. Fargeau, that their early states are passed in the water, although neither their larvæ, nor the nature of their transformations, had been observed. Latreille, indeed, affirms that they reside, in the larva state, in vegetable galls. Whether the latter statement has been made from direct observation or not, is not mentioned; but M. Guerin has more recently published an account of these larvæ in the second volume of the Annals of the Entomological Society of France, from which it may be inferred, bearing in mind the diversity of habits existing in the kindred genus *Cecidomyia*, that the species of *Ceratopogon* are not less varied. M. Guerin found the larvæ described by him in considerable numbers under the moist bark of decaying trees, where they appeared to form a sort of society, and some of them were already (25th August) in the pupa state. The larvæ were long and slender, of a white colour, composed of twelve segments, each of which, with the exception of the head, is furnished on the upper side with four long hairs, each bearing at its extremity a small globule perfectly spherical, opake, of a milky white colour, and having the appearance of a small pearl, the series of which, placed along the back of the larvæ, gives them a most singular appearance. The pupa is shorter than the larva, thicker towards the head, the extremity of the body remaining within the exuvium of the larva. The perfect insect proved to be a new species, to which this assiduous author gave the name of *Ceratopogon geniculatus*. He likewise described, in the same Memoir, a second new species, *C. flavifrons*, the pupa of which he had found in the moist wounds of elm trees at Passy, near Paris. When the perfect insect is ready to make its escape, the body of the pupa is protruded half out of the earthy matter in which it was placed. The skin is then split, and the new-born fly creeps out, trailing its old covering after it.

There is considerable difference in the structure of the different species. In some, forming the sub-genus *Culicoides*, the legs are slender, and not spined. These species possess, in proportion to their size, and in a surprising degree, the power of stinging the naked skin of the hand, or other exposed part of the body, as we can affirm from experience; and M. Macquart has captured one of the species in the act of sucking a gnat much larger than itself, which it had seized; whilst others, as the sub-genera *Prionomyia*, *Palpomyia*, and *Ceratopogon*, have some of the thighs very thick and spined. These are much less mischievous than the former.

CERATROPHRIS. A genus of Batrachian reptiles, of which the distinguishing characters are: the head large, the skin all over granulated, and a membranous prominence, something in the shape of a horn, upon each of the upper eyelids. They are inhabitants of the warmer parts of America.

CERBERA (Linnæus). A genus of tropical shrubs and trees, belonging to the fifth class of the sexual system, and to the natural order *Apocyneæ*. This genus is described as possessing poisonous qualities; but several of the species are cultivated in our stoves, as ornamental plants, where they flower abundantly. They strike root readily from cuttings, treated in the usual manner.

CERBERUS. A sub-genus of serpents, belonging to the genus *Coluber*, in which are comprehended all the serpents, whether poisonous or not, which have two rows of scaly plates on the tail. This species has the whole head covered with small scales, except between and over the eyes, and it has frequently single plates at the root of the tail, but not along the whole of that member, as in the boa. See COLUBER.

CERCERIS (Latreille). A genus of hymenopterous insects, belonging to the section *Aculeata*, sub-section *Fossores*, and family *Crabronidæ*, (wood and sand wasps,) and readily distinguished by the form of the abdomen, the articulations of which are narrowed at the extremity, giving this part of the body a knotted appearance; the second sub-marginal cells of the upper wings is pedunculated, and the antennæ are inserted in the middle of the face. These insects, of which the *Sphex arenaria* of Linnæus is an example, and of which we have about a dozen British species, are very ferocious in their habits. Of one of the species, *Cerceris ornata*, the Baron Walckenaer has published an interesting account in his Memoir upon the Bees composing the genus *Halictus*. Numbers of these insects make their nest in the sand in the situations where the *Halictus terebrator*, Walckenaer (*Fulvocinctus*, Kirby), have established their colonies. For this purpose, the fore-legs of the female cerceris, which alone undertakes the construction and provisioning of the nest, are armed with numerous strong spines, which are employed in loosening the sand, and sweeping the loose particles away. They are thus occupied from the month of June to the commencement of September, at which latter period the *Halictus* has entirely disappeared. The entrance to these burrows, when newly constructed, is lined with an inner rampart of sand, well polished, and agglutinated with a whitish mortar, which lining is sometimes carried upwards above the surface of the ground. The entrance itself is larger than the insect, being adapted for the admission of the latter when laden with its prey. These burrows are not perpendicular, but curved somewhat in the shape of an S, being about five inches deep. When this task is completed, the deposition of the eggs, together with a sufficient supply of food for the larva when disclosed, is the next care of the parent fly; and now commences the murderous warfare with the *Halicti*, which, in fact, are employed by the cerceris for this purpose. It is only in fine hot weather, and between eleven and four o'clock, that the parent cerceris is occupied in the chace of the poor bees, one of which no sooner makes its appearance near the mouth of its own nest, on its return from a wearisome flight, than the cerceris pounces upon it, hawk-like, seizes it by the neck, dashes it to the ground, throws it upon its back, and then introduces its sting immediately beneath the head, leaving it half dead and palpitating, in which state it is buried in the burrow of the cerceris. So intent is the cerceris when thus engaged, that it will allow any one to stoop close to the ground so as the better to observe its motions. Three specimens of *Halictus terebrator*, and one of *Halictus cuprea*, serve for the nourishment of a single larva of the cerceris.

Several other species of this genus, the *Cerceris aurita*, Latreille, and *C. quadrifasciata*, Bosc, render considerable service to agriculture, by selecting several destructive kinds of weevils (*Curculionidæ*) for the supplies of their progeny; and it would seem that they have the instinct to discover these beetles at the time when their wing-cases are soft, and have not acquired their firm consistence. To convey one of these weevils to its burrow, the cerceris lays it upon its back, so that the beetle clasps the body of the cerceris with its own legs, leaving the legs of the latter free, which are employed in retaining it in this situation, and in walking.

The males have a large moustache on each side of the face, just above the jaws. The colour of these insects are black, variegated with yellow, and their length varies from one half to nearly one inch.

CERCIS (Linnæus), is a hardy ornamental shrub or small tree, natives of both continents; Linnæan class and order *Decandria Monogynia;* natural order *Leguminosæ;* generic character: calyx pitcher shaped, gibbous below, obtusely five-toothed; corolla wings marked, divaricating, keel of two petals; stamens declining, four of them longer; anthers incumbent; style, bearing an obtuse stigma; pod long and membranaceous, many seeded, attached to the sutures. This is a handsome plant both in flowers and in foliage, and is particularly suitable for planting either singly on grass plats, or among other trees. It is remarkable for producing its tufts of purple flowers from the the bark of the trunk and branches. The plant is best raised from seed; but it may also be increased by layers.

CERCOPIDÆ (Leach. Cicadellæ, Latreille). A family of insects belonging to the order *Homoptera*, and section *Cicadaires* of Latreille, and forming that part of the great group of *Cicada*, to which Linnæus gave the name of *Ranatræ*. These insects have the head of a small or moderate size, not produced in front as in the *Fulgoridæ;* the antennæ, which are composed of only three short joints, with a long terminal seta, are inserted between the eyes; the ocelli are only two in number, and unlike the true *Cicadæ*, the individuals of neither sex are furnished with instruments for the production of that chirping noise which has rendered the latter insects so notorious, from the earliest ages of natural history. The upper wings of these insects are often opaque andcoriaceous, they are, however, of the same substance throughout, thus differing from the Linnæan *Cimices*, in which the same organs are composed of two distinct kinds of membrane. Their legs are also formed for leaping to a distance, which, in proportion to the size of the insect, seems immense: thus the cuckoo-spit insect, *Aphrophora spumaria*, which is perhaps the most active of all leaping insects, will sometimes spring two or three yards; hence taking the length of the body of this insect at one sixth of an inch, the distance is nearly 650 times greater. This is as if a person of ordinary stature were to vault through the air to the distance of about six furlongs, thus bringing to mind the feats of that friend of our childhood—him of the seven league boots. This extraordinary locomotive power is of course brought into action by the great strength of the muscles of the locomotive organs, which, in this group of leaping insects, are confined to the hind legs.

Hence it cannot be denied, that amongst the various means which have been bestowed by an all-wise Creator upon the little animals which are now the peculiar objects of our attention, for the purpose of aiding them either in escaping from the numberless enemies to which they are exposed, or of facilitating their means of procuring food; this saltatorial power which so many possess, of effecting an instantaneous change of place, is one of the most remarkable. To some great running powers are given, to others, great strength of wing, but this far exceeds the rest, and cannot be found in so surprising a degree in any other group of animated nature.

This effect is produced in different modes in different insects. Thus the cheese maggot, which is the larva of a dipterous insect (*Piophila casei*, Meig.), performs its leaps in the same manner as the salmon, by taking hold of its tail with its mouth, contracting the rings of its body, and then suddenly letting go its tail. The voracious masked larvæ of the dragon flies suddenly propel themselves forward in the water by a still more remarkable manœuvre, which is performed by no other insects. They are furnished at the extremity of the abdomen, with an apparatus of five plates, capable of opening and shutting, and in which a quantity of water is from time to time inclosed, for the purpose of the absorption of its oxygen, which having been effected, the water is violently expelled, and the insect suddenly propelled to a considerable distance. In the click beetles (*Elateridæ*) the leap is produced by the sudden jerk given to the body when the insect is laid upon its back, by forcibly striking the acute spine of the breast into the corresponding cavity of the mesosternum. In the ground fleas (*Poduridæ*), the spring is produced by the sudden striking backwards of a forked appendage, fixed beneath the extremity of the body.

It is, however, to the peculiar construction of their legs that insects are, for the most part, indebted for their saltatorial powers—of these, the tormenting flea is the most notable example. Furnished with thighs of great muscular power, having the hind legs longer than the others, with the tibiæ and tarsi strongly spined, by means of which they are well enabled to take a hold for themselves so as to take a spring, and clothed in a tough and highly polished cuirass, no wonder that it effects an escape in almost every situation, and, to use the words of a favourite French author, "Comme l'Amour, rit en sureté de la blessure qu' elle a fait, et de la colère qu' elle occasionne."

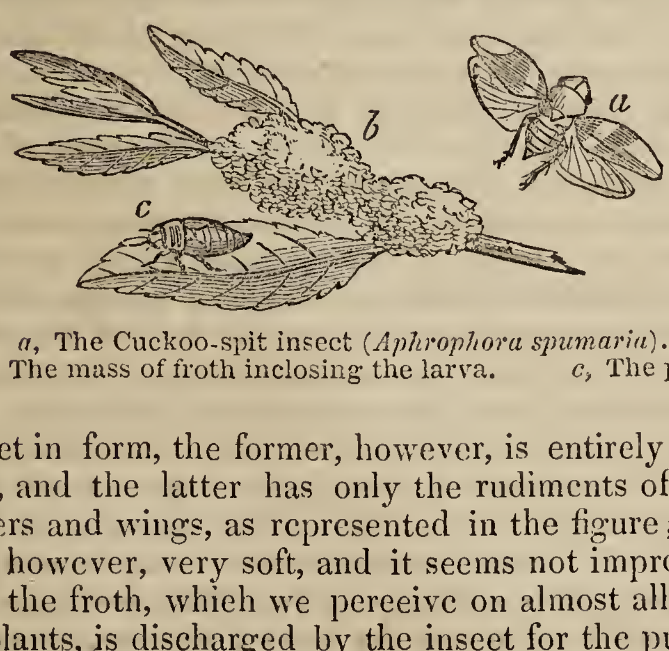
The locust, grasshopper, cricket, garden fleas, (*Halticæ*, amongst which the destructive turnip-fly is found) and the the fleawee vils (*Orchestes*) may also be mentioned as examples of leaping powers, originating in the peculiarly incrassated form of the hind legs. It is to be borne in mind, however, that many insects exist, which have thickened hind legs, but which do not possess the powers of leaping, whilst on the contrary, many species which leap well are not provided with thickened legs.

In the particular group of insects which have led to these general observations, and, indeed, in the whole of the Linnæan genus *Cicada*, now forming two families, the leaping apparatus is different from that of any other insects, and consists of a coronet of short thick spines or spurs of nearly equal size, placed round the extremity of the posterior tibia, in the midst of which, the basal part of the tarsi is implanted; besides this, some of the species have the the two basal joints of the tarsi similarly provided, and these are enabled to leap more strongly than any of the rest.

This family is divisible into two groups; first, those having the head inserted very low, the thorax very elevated in the centre, and prolonged behind into a point, and the tibiæ scarcely spined along their edges. Here are to be arranged the genera *Membracis*, (of which the body is so compressed that it is scarcely thicker than a card), *Tragopa*, *Darnis*, *Bocydium*, and *Centrotus* (which see); and second, those with the head not lower than the upper surface of the thorax, with the latter not elevated in the middle nor prolonged into a point behind, the mesothorax forming a distinct scutellum, and the tibiæ densely spined along the edges. Here belong the genera Ætalion, *Ledra*, Ciccus, *Cercopis*, *Aphrophora*, *Ulopa*, *Eupelix*, *Penthimia*, *Jassus*, Tettigonia, and some others recently established by Germar and Lewis in the first number of the Transactions of the Entomological Society of London. Those marked in italics in the second group are British.

The genus *Cercopis* is characterised by having two distinct ocelli, the head much smaller than the thorax, and the latter of a hexagonal form. This genus is of great extent, and comprises some of the largest insects in the family; their colours are also brilliant and they are chiefly inhabitants of tropical regions; one species only has hitherto been found in this country, namely, the *Cercopis vulnerata* Rossi, confounded by most Entomologists with the *Sanguinolenta* of Linnæus. Of this latter insect we are also in possession of a specimen, purchased at the sale of Mr. Donovan's collection, which has all the appearance of a British specimen, having been found amongst a quantity of English insects.

The cuckoo-spit insect or frog-hopper, (*Cicada spumaria*, Linnæus,) forms the type of Germar's genus *Aphrophora*, a name derived from the Greek, and alluding to the curious property which the larva and pupæ of this insect possess of emitting a frothy secretion, somewhat resembling saliva, which has, from a vulgar error, been termed cuckoo-spit, appearing as it does during the months when that bird visits us. The larvæ and pupæ resemble the perfect



a, The Cuckoo-spit insect (*Aphrophora spumaria*).
b, The mass of froth inclosing the larva. *c*, The pupa.

insect in form, the former, however, is entirely destitute, and the latter has only the rudiments of wing covers and wings, as represented in the figure; they are, however, very soft, and it seems not improbable that the froth, which we perceive on almost all kinds of plants, is discharged by the insect for the purpose of forming a covering against the overpowering effects of the sun. In certain seasons, this insect is so multiplied, that persons walking beneath willow trees are wetted with the continual dropping of the fluid. Another nearly allied species (*Aphrophora Goudoti* of Bennett), has recently been found in very great quantities upon trees in the island of Madagascar, the larva of which, has the power of discharging a considerable quantity of clear water, especially in the middle of the day when the heat is greatest. An account of this species has been published in the Transactions of the Society of Natural History of the island of Mauritius, for 1832, and a farther account of it appears in the proceedings of the Zoological Society of London, for January, 1833, from which it is evident that, instead of remaining as a frothy mantle, as in our British species, the fluid which has been pumped up from the trees into the stomach, is ejected in great quantities, and falls to the ground in a constant and considerable shower.

Messrs. Stephens and Curtis have given to these insects the generic name of *Tettigonia*, proposed by Fabricius for the true *Cicadæ*, but from the great confusion which has occurred in the employment of this name by various authors, we have thought it more advisable, and indeed, more correct, to adopt Germar's very appropriate name of *aphrophora*.

CERCOPITHECUS. This name, which means "tail-deep," is sometimes given to that division of the quadrumana which are furnished with such an appendage, and have it not prehensile, or adapted for laying hold. We shall, however, defer noticing the general characters, till we can bring the whole into one article, MONKEY; and the species are too numerous for our notice.

CEREOPSIS. A web-footed bird of Australia, bearing some resemblance to the bernacle goose, but having a much smaller bill, and the naked membrane at the base of the bill more enlarged, and extending more upon the forehead. Its colour is grey; it is about the same size as a goose, and very little different in its manners.

CEREUS (Haworth). This is a remarkable and highly interesting genus of South American plants; Linnæan class and order *Icosandria Monogynia*; natural order *Opuntiaceæ;* generic character: calyx bell shaped, imbricated or equal; petals of the corolla six or more, close to the calyx, campanulate and rotate; stamens numerous, joined to the petals and calyx; filaments awl shaped; anthers oval, and two celled; style and stigma radiating, or crowded, being one celled, many seeded. Many species of this fine genus, as well as several other congenial genera, were formerly included under the old name of cactus. The late A. H. Haworth, Esq., and other contemporary botanists have re-arranged this old Linnæan genus, and from it have separated four or five new ones, of which cereus is one. They have succulent stems, of very different forms, destitute of leaves, but instead thereof, many are profusely covered with spines. The flowers of all are striking, some of them magnificent, those of speciosissimus, and grandiflora particularly; and even the humble flagelliformis, seen in many a cottage window, is very showy when is full flower. It is found that by exposing these succulent plants to be hardened by the summer sun, they flower more abundantly than if always kept in the house. They grow best in a rich sandy loam, though they succeed in any garden soil, if they are kept rather dry when not in active growth, and allowed plenty of water when they are coming into flower. Hybrid varieties are easily raised by cross impregnation, several new sorts are already in the gardens, and many more, it is highly probable, will be obtained. The late Mr. Sweet was of opinion that several of the new imported species are only varieties; as where the different kinds stand closely together, which they are known to do in their native habitat, their seeds cannot fail to be impregnated by the pollen of each other. All the sorts are easily propagated by cuttings; only they require to be dried for a few days before they are planted; the fresh wound being liable to rot without this precaution. The greater number of these succulents do very well in the green-house; some few require the dry stove to flower in.

CERINTHE (Linnæus). A herbaceous annual native of Europe, called honey-wort by English herbalists. The genus belongs to the natural order *Boragineæ*.

CEROCOMA (Geoffroy). A genus of coleopterous insects, belonging to the section *Heteromera*, and family *Cantharidæ*, and distinguished by the extraordinary and irregular shape of the antennæ, which are only nine-jointed, the last joint being large and oval, the preceding joints, as well as the maxillary palpi, being of very unequal sizes, and unequally produced into various sized branches. These insects, which inhabit the warmer regions of Europe, appear often in great quantities about the summer solstice, and are found upon flowers, especially those of wild camomile, millefoil, &c. They are about three quarters of an inch long. The type is the *Meloe Schaefferi*, Linnæus.

CEROPEGIA (Linnæus). A genus of various tuberous rooted herbs, under-shrubs, and climbers, found chiefly in India. Linnæan class and order *Pentandria Digynia;* natural order *Asclepiadeæ;* generic character: calyx five parted; corolla swollen at the base, tube funnel shaped, limb cut into conniving tongues; corona double, perigynous, exterior a five lobed leaf, interior five leaved; leaflets linear bearing anthers alternately; gynostegium included. The flowers are of a curious structure and beautifully fringed; grow well in the green-house, potted in light loam and moor earth; require but little water when dormant, and at all times requiring the pots to be well drained.

CERTHIA—the tree creepers. A very interesting genus of small birds, belonging to the order *Anisodactyli* (uneven-footed creeping birds), or *Tenuirostres* of Cuvier. It is distinguished by a slender and compressed, curved, sharp-pointed, and rather long bill; narrow and tapering tongue, which is stiff and rather horny at the tip. The wings round and hollow as in the woodpeckers; the fourth and fifth feathers longest. Tail also, as in that genus, wedge-shaped, and composed of twelve stiff sharp-pointed feathers, which however are proportionably longer and weaker in the shafts than the woodpeckers, though quite stiff enough to support the much lighter comparative weight of the bird, which, in the hand, appears little more than a mass of feathers. The plumage on the upper parts is soft and very loose in its texture, the filaments of the feathers not adhering; on the under surface white, silky, and glistening. Feet, of very perfect anisodactyle construction, adapted for creeping about upon the bark of trees, with three toes before and one behind, which are rather long, the outer and middle ones united at the base; claws long, thinly compressed, and the front ones very much curved, almost semicircular, and extremely sharp-pointed, hitching into the slightest inequalities of surface; that on the hind toe is the longest, and not so much curved as the rest.

This genus was by the earlier systematists made to comprise an immense variety of species, which are now distributed into various independent genera, as *Cæreba*, *Tichodroma*, *Millephaga*, *Nectarinia*, *Cinyris*, *Climacteris*, &c. It became, in short, a general receptacle for every small bird with a slender and long curved bill, however dissimilar they might otherwise have been. By Illiger it was reduced to three or four species, to such only as exhibit the more essential generic characters above given; and some of the more eminent ornithologists of the present day are now for confining it, at least in its more restricted sense, to a single bird, the common mottled tree-creeper of this country,

C. familiaris, which is certainly the most typical bird of the kind. This species has a very wide geographical range, being found in all suitable localities within the northern temperate zone, and is equally common in Europe and North America. It is a very small bird, about five inches in length including the bill, which, in old specimens, measures rather more than half an inch; weight, about a quarter of an ounce; extent of the wings nearly seven inches. The upper parts are brown, darkest about the head, each feather having a whitish streak along the centre. Over each eye is a broad streak of whitish; the lower part of the back, rump, and tail-coverts, rusty brown; ground colour of the wings dark brown, prettily mottled with a lighter tint and with markings of pale yellowish brown. Tail brown, sometimes obscurely barred across. The under parts are of a glistening white, which is purest upon the chin and throat. The sexes are exactly similar in plumage, and the younger individuals (distinguishable by the fainter tints of the upper parts) are also very nearly about the same size, but (as seems to be the case also with the common wren, *Troglodytes Europæus*,) the male tree-creeper appears to continue growing for three or four years, as the older individuals only of this sex are often much larger than the females, and have the bill of rather more than the usual dimensions. The young of the year are, in their nestling plumage, mottled on the upper parts somewhat differently from the old birds, and they do not acquire their full beauty till the second moult, when their colours appear brighter, and the various contrasts which they afford become, in consequence, much more decided.

This curious little bird is everywhere abundantly distributed over the British islands, frequenting gardens, parks, and all places where trees are to be found. "A retired inhabitant," as a pleasing writer describes it, "of the woods and groves, and not in any way conspicuous for voice or plumage, it passes its days with us, scarcely creating any notice or attention. Its small size, and the manner in which it procures its food, both tend to secrete him from sight. In these pursuits its actions are more like those of a mouse than of a bird, darting like a great moth from tree to tree, uttering a faint trilling sound as it fixes upon their boles, running round them in a spiral direction, when, with repeated wriggles, having gained the summit, it darts to the base of another, and commences again." Its manner of flying much resembles that of the various woodpeckers, "*volatu undoso*," as White of Selborne gives it, "opening and closing the wings at every stroke, and so always rising or falling in curves." The timid retiring habits of this bird cause it to be very little noticed by people in general; but it requires only to be listened for, and its faint *tsint, tsint,* is sure to be heard in almost every clump of trees; and if watched for, it will very soon be observed, as it flits from one tree to another, alighting generally on the trunk within a few inches of the ground, and then either ascending spirally, or creeping quietly along the outline, with a rapid uniform motion, its tail bent inward towards the tree, now and then peeping round to take a glimpse at the spectator, and as soon as it thinks itself observed, disappearing behind. It will often flutter down after it has ascended a few feet, and again alight near the ground, ascending the same tree several times in different directions. This we have seen it do repeatedly, but we have never yet observed it to descend perpendicularly, or even obliquely, creeping with the head downward, though it is very commonly stated in the books to run with equal facility in all directions, upwards or downwards. It creeps with wonderful ease, however, along or across the lower side of a horizontal bough, inserting its slender bill into the cracks and crevices of the bark, and there finding abundance of minute insects and larvæ, chiefly of the coleopterous order, which, in such situations, often lurk in perfect security from the attacks of most other insectivorous birds. Sometimes the little active creeper may be descried searching about upon the topmost branches of a tall tree—sometimes it may be seen examining the smaller twigs and sprays—and sometimes, again, the same indefatigable little creature may be observed creeping about upon a mossy lichen-covered paling, pulling out minute spiders from their lurking holes, and drawing forth the tiny inhabitants of every chink and cranny. Upon such a situation the writer of this once saw one descend obliquely backwards, which rather tends to confirm his opinion that this species is unable to creep (as the nuthatch often does) perpendicularly downwards.

The foot of the common nuthatch (*Sitta Europæa*), though another beautiful example of the anisodactyle conformation (fully described in the general article Bird), is very much stouter, and more strongly formed, than that of the tree-creeper, and it has proportionably much greater power of grasping; and the whole weight of the bird (which is more equally poised than in the creeper) pressing wholly upon the feet, and not being in part supported by a stiff tail, as the creeper is, its hold is much more exclusively by the muscular contraction of the toes, whilst its claws, though larger and stronger than those of the tree-creeper, are rather less curved, and are also very far from being so sharply pointed and *hitching* as those of that bird. Thus constructed, however, the nuthatch ascends and descends the perpendicular boles of trees with equal facility; whilst the tree-creeper, notwithstanding all that has been said and written about it to the contrary, is enabled to hold on and creep upon a perpendicular surface, more from the extreme sharpness of its long, narrow, and very hooked front claws, than by any other means. When ascending perpendicularly, it requires to be further supported by its stiff deflected tail, and is thus enabled to creep in a straight downward direction. Even the hind claw, which, in the nuthatch, is curved, and adapted for taking a very firm hold when descending, in the tree-creeper is much longer and straighter than either of the others, and is fit only to assist in the ascent.

The tree-creeper, in short, appears to hold on upon the perpendicular bole of a tree much more in the manner of a cat than the nuthatch does, by means of the sharpness of its front claws, and, so far as the observation of the writer of this article goes, it can only descend a steep declivity in the same way as that animal does, backwards, the form of its claws precluding the possibility of its taking a very firm hold with the head downward; and, accordingly, though it may very commonly be observed to ascend the same tree many times successively in different directions, it never creeps down again like the nuthatch, but always flutters down again and again, as soon as it has arrived at a certain height, and re-alights, as it did the first time, near the ground.

There would appear therefore to be this difference between the only two strictly anisodactyle birds of this country, that the nuthatch holds on to the bark of a tree solely by the muscular contraction of the foot, which, as a hold, is equally available in any direction, upwards or downwards, whilst the tree-creeper hangs more as a cat does, by its very sharply-hooked front claws, and requires, therefore, to be further propped up by its tail, the stiff-pointed feathers of which, hitching upon every inequality, furnish, in conjunction with the toes, a very efficient support for so light a creature, but a support which can only be available in an ascending direction. This species is indeed so very light, that, being held up in great measure by the tail, as it creeps up the perpendicular bole of a tree, there is hardly sufficient pressure upon the foot to cause much contraction of the toes; and it is only when on the under surface of a horizontal bough, with its nadir uppermost, that the whole weight of the bird hangs by the feet; and the tendons of its legs are so admirably constructed, that the greater pull there is thus upon them, the more closely do the toes contract, and the firmer consequently is their hold, so that the bird is thus enabled to creep with its back downward with little or no muscular exertion.

The food of the creeper mostly consists of the various insects and larvæ, (chiefly coleopterous), which it finds abundantly in the crevices and chinks of the bark of trees, under the scales of the bark, and among mosses; its own incurved slender bill being unable to penetrate even into the decayed wood, it may commonly be observed, in winter, to follow in the rear of a train of titmice, gleaning up various insects and spiders which their more powerful bills had aroused and startled into day-light. The eggs of spiders also, and of various lepidopterous insects which are glued to the bark, often furnish it with a repast; and it appears also to feed on certain seeds, as these are often found in its stomach. Upon the whole, it is not only a very harmless little creature, doing no sort of injury to any property on which man sets a value, but from the immense number of injurious insects it destroys in the egg or rudimental state, it confers a real benefit to the possessors of growing timber. The peculiarity of its actions and habits, also, so unlike those of the generality of British birds, render it a very interesting object to look at, to whoever is fond of studying natural history in the wild woods.

The tree-creeper has but very little song, and most writers have described it not to have any; but in the spring months, and even in fine weather during the winter, it may often, sometimes on the wing flitting from tree to tree, and just as it settles, continuing after it has alighted, and sometimes whilst creeping up a branch, be heard to utter a faint but not unmusical sort of trill, something like the song of the chaffinch, but much shriller, more resembling the rich note of the hedge-chanter; this is often repeated several times, in a deliberative kind of manner, as the bird ascends the tree. Its nest is usually situate in a hole, or behind the bark of some decaying tree, often within two or three feet of the ground, and not unfrequently it is placed in the hollow where a limb has been broken or torn off; nature not having provided it with the means of excavating a hole for itself. It is composed of dry grass and pieces of the inner bark of wood, loosely put together, and lined with small soft feathers; the eggs, six or eight in number, are semi-transparent white, with numerous small rust coloured spots at the large end. In Wilson's ornithology of North America, the tree creeper's eggs are described to be "of a dull cinereous colour, marked with small dots of reddish yellow, and streaks of dark brown;" and this is the only particular in which his very minute description is at all at variance with the species as observed in this country; but we are inclined to notice even this slight discrepancy, never having found the eggs of our own bird to vary, and in other respects the detailed account given by that accurate observer of the plumage, and habits of the American bird, corresponds exactly and entirely with those of the common tree-creeper of Europe.

During the period of incubation, whenever the hen tree-creeper quits the nest, the male may often be seen to follow her, and offer her food; and as the young birds do not venture to fly away for some time after they begin to creep like so many mice about the tree, the sight of a nest of them at this time is particularly interesting; the old birds continually arriving with a fresh mouthful, with which they may be seen to feed their young.

There are two or three other species mentioned as approaching nearly in form to our bird, especially the *Certhia cinnamomera*, and *C. spinicauda* of authors; these are rather more strongly built than our tree-creeper, but we know little of them besides the names, and are not aware of any peculiarity in their habits which would entitle them to have here a separate description. They are inhabitants of the forest trees of warm countries, where they probably perform a very similar office to that of their northern and better known congener.

CERURA (Schrank). A genus of lepidopterous insects, belonging to the family *Bombycidæ* of Latreille (*Notodontidæ*, Steph.), and comprising the puss and kitten moths of English collectors. The body is very woolly, the wings semi-transparent, with numerous dark waves; the antennæ bi-pectinate in both sexes, and the mouth is furnished not only with a short straight tongue, but also with two pair of palpi, the maxillary ones being developed.

The caterpillars in this genus are amongst some of the most extraordinary formed British insects, having a large hump on the back, with the tail terminating in two long and toothed spines. That of the *C. vinula*, is thus quaintly described by old Izaak Walton, "which," says he, "I will show you feeding on a willow tree, and you shall find him punctually to answer this very description: his lips and mouth somewhat yellow, his eyes black as jet, his forehead purple, his feet and hinder parts green, his tail two-forked and black, the whole body stained with a kind of red spots which run along the neck and shoulder blade, not unlike the form of St. Andrew's cross or the letter X, made thus crosswise and a white line, drawn down his back to his tail, all which add much beauty to his whole body."

When about to cast their skins, they spin a web on the leaves of the poplar or willow trees upon which they have been feeding, to which they attach themselves firmly by the assistance of the hooks of the abdominal legs.

When full grown, in the course of six or eight weeks' feeding, they are about as thick as a man's thumb, and then commences the formation of the cocoon, which is so strong as to be cut with difficulty by a penknife; this cell is composed of chips of the bark of the tree upon which it is built, and which are cemented together with a glutinous matter, which quickly hardens into the firmest plaster. Many of these caterpillars, however, fall a prey to the ichneumons, which, notwithstanding the statement, that the larva endeavours to lash them off with its tail, (emitting at the same time a black fluid from the neck) contrive to deposit their eggs upon its body. An account is given of these cocoons in the Insect Architecture, pp. 195 and 326. In the former instance it is stated that "notwithstanding its strength, one of the ichneumons had *contrived to deposit its eggs in the case*," and in the latter it is stated, that in another case five empty cells (being those of the ichneumons) has been *surreptitiously introduced into* the original case of the cocoon. Both these statements are incorrect; indeed we believe no instance has yet been recorded, in which the ichneumons bore through cocoons to deposit their eggs in pupæ; and in fact the proceedings of this ichneumon (*Ophion vinulæ*) have been observed and are very extraordinary, the eggs not being deposited within, but upon the body of the larva. See Gravenhorst, Ichneumonologia, vol. i. p. 97.

The appearance of the puss moth is very elegant, the legs, which are very hairy, being stretched out in front of the body. The wings vary in expanse from two and half to three inches. There are nine British species belonging to this genus.

CESTRACIONS. A genus of cartilaginous fishes, with fixed gills, belonging to the shark family, the principal character of which is that of having pointed jaws, with sharp teeth at the middle, and larger ones at the angles of rhomboidal shape, bearing a slight resemblance to some of the spiral shells.

CESTRUM (Linnæus). A handsome genus of mostly tropical shrubs, belonging to the fifth class of Linnæus, and to the natural order *Solaneæ;* generic character: calyx pitcher shaped, five toothed; corolla funnel formed, limb plaited and five cleft; stamens inserted in the tube, often toothed; capsule one celled, many seeded. Some of the species of this genus are ornamental, most of them having fine foliage. Their qualities are said to be poisonous. The cestrum tinctorum, a native of the Caraccas, is used by the dyer. The greenhouse kinds are increased by cuttings.

CETACEA—Whales. A very singular but well defined, and to man exceedingly useful, order of mammalia. They have the internal structure, the vital functions, and the mode of production of land animals, while in external shape and in habitat they resemble fishes. Their blood is warm, warmer than that of many of the terrestrial mammalia. They have a double circulation; they breathe the free air by means of lungs; and they bring forth their young and suckle them with milk. Their bones, their muscles, in short, all the parts of their bodies, when we come to examine them, are in their textures really the parts of mammalia, only their shape has some resemblance to that of the fishes.

In their leading characters they are mammalia, altogether destitute of hind feet, or indeed any lateral appendages to their bodies, excepting short fore legs, which are formed into swimming paws. Their vertebral column is continued beyond the cavity of the body in a long and thick tail, which terminates in a very powerful fin; but this fin is very different, both in form and texture, from the fins of fishes. The muscles by which it is put in motion do not consist of a series of transverse flakes superposed upon each other, as is the case in fishes. They are longitudinal fibrous muscles like those of the land mammalia; and when, as is the case in some of the muscles of these, they are divided by septa, these are always cartilaginous, and the fibres are firmly united to them. These muscles have distinct tendons; and thus the single fin in which the tail terminates has much more range, variety, and even power of motion, than the caudal fin of a fish. The natural position of the lobes of this fin is horizontal, while that of all fishes is vertical, though there are some fishes which swim on their sides, and those have the appearance of a horizontal fin on the tail. It will be always found in those fishes, however, that when they swim with the tail thus apparently horizontal the cavity of the body is on one side; and though their necks are twisted so that both the eyes are on one side of the head in appearance, yet this twist is a permanent one; and they have no rotatory or twisting motion of the tail, which is always moved by the flexure of the joints of the vertebræ only.

The cetacea, on the other hand, have very considerable motion in that organ; they can twist it to a great number of angles; and the portion of it nearest the fin has also much more motion than that part of the tail of any ordinary fish; they can bend it upwards, downwards, laterally, or obliquely.

Their brain is larger in proportion and much better developed than the brain of fishes; their eyes have expression, which is not the case with those of any fish; and though they have very small openings, and no external production of ears, they have them tolerably well formed in the interior, and possess a distinct sense of hearing in the air, which is not, according to appearances, possessed by any fish.

Generally speaking, the cetacea are large animals, and some of them far exceed in their dimensions any other members of the animal kingdom; but there are considerable differences among them in this respect, and in other respects they differ much more. We shall point out the differences upon which the divisions and subdivisions of the order are founded; but the animals, taken altogether, are so peculiar, and have in common language been so much associated with fishes, that it may be proper first of all to take a slight structural view of the whale.

Anatomical Structure. The external form of the cetacea is not made out by that of the skeleton, as in those mammalia which have motion upon land: it is even much inferior in this respect to that of the seals and walruses, especially the former. The bones are of a loose and coarse texture, greatly inferior both in specific gravity and in strength to those of land animals. These fibres, in the larger bones such as the jaws and ribs, are easily separated; and none of them have any medullary tube or marrow in them like the round bones of land mammalia. They are, however, in most of the species very copiously supplied with oil in all these pores or openings, which supports their loose and spongy fibres.

This character of the texture of the bones is a very marked one, and a very remarkable instance of adaptation. The bones of a whale when recent and saturated with oil are not much, if anything, heavier than water; and as the whale skeleton is every where defended from the shock even of the water, by the mass of muscles and fat which make up the body to its fish-like shape, there is nothing that can very much injure their loose and comparatively weak bones. So completely indeed is the whale always carried upon elastic springs in its liquid element, that to have given it the same compact bones as animals which move upon and come in contact with solids, would have been only loading it with an unnecessary weight of salts of lime.

When the whales are seen in entire carcass, they seem to have hardly any neck; but when the skeleton is examined, they are found to have the same number of vertebræ, seven, which is common to all mammalia,—to the giraffe and the camel, as well as to the porpoise and the whale. The cetacea have not, however, the same necessity for turning or otherwise moving the head as land animals have, because they can turn the whole body in the water with much more ease than a much smaller animal standing upon feet, and thus having its weight supported at most on four points, can do upon land; and therefore they have exceedingly little motion of the vertebræ of the neck. The dolphins and porpoises have the two vertebræ nearest the head anchylosed, or soldered together; while the spermaceti whales, which are remarkable for the enormous size of their head, have the one next the back united in the same manner, so that they have hardly any motion of the neck.

The dorsal vertebræ, and with them the number of ribs, vary much in the different species, some having as many as thirteen ribs on each side, and others not more than eight. Posterior to the dorsal vertebræ there cannot be the same distinction made as in animals which have a pelvis and hind legs; but some of them have the vertebræ of this part very numerous. We find here one gradation from land mammalia through the seals to the cetacea. Seals have the hind legs and tail united so as to form a sort of fin or swimming flap, while in cetacea the whole organisation of the body, posterior to the ribs, is concentrated into the action of the tail. Analogically, therefore, we may consider the tail of a whale as combining the energies of a tail and pair of feet not merely soldered together, but actually formed into a single organ; and the length of spine and number and power of muscles which belong to this organ make it one of great efficacy; and as the proboscis of the elephant has, in reality, though a clumsy thing in appearance, more mechanical power and working in it than many hands; so the tail of a whale, huge and unwieldy as it seems, is far more curious in its action, and also far more efficient than many a pair of apparently well-formed feet.

Singular and powerful, however, as is this part of these animals, perhaps the swimming paws are even more curious. The bones are not quite the same in shape, or in relative size, as those of the human arm, but they are about the same in number, and they hold the same relative situations with regard to each other. There is a regular scapular or blade bone, a humerus, a radius, and ulna, as in the fore-arm, and there are five fingers to the hand, which, however, act all in one plane.

The whole of this curious apparatus, the only extremity which the cetacous animal has, is flattened, and the motions of the joints have not the same freedom as in land animals; but still it acts pretty readily as a clasper, the use to which it is often applied, especially by the female, which carries her young in her arms the same as the quadrumana do upon land.

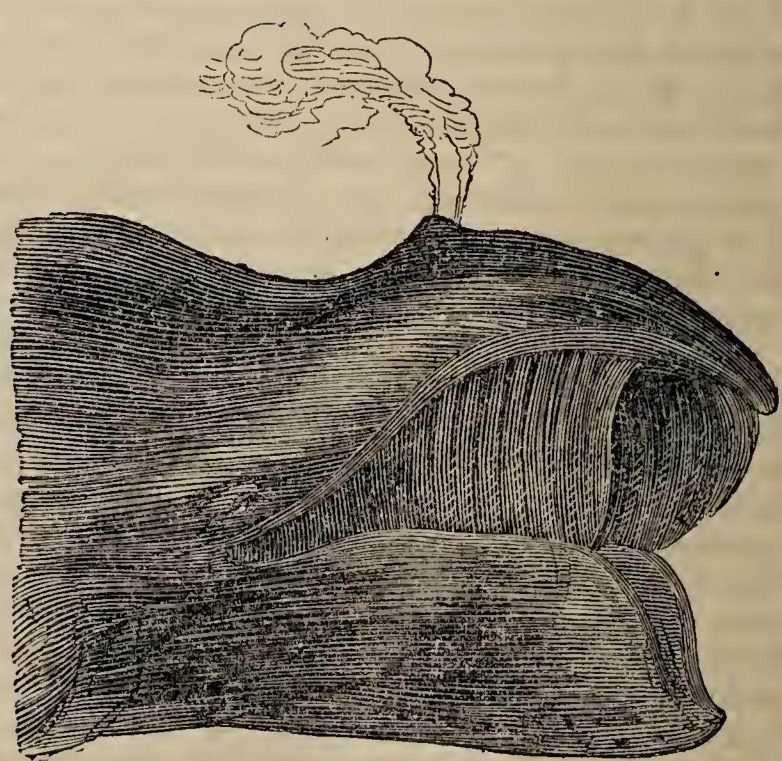
The muscles, the membranes, and all the soft textures of the cetacea, though they have very much the colour and structure of those of the larger ruminantia, and of some of the herbivorous species which are used as food, have that tendency to putrify in the air which is common to almost all animals which are inhabitants of the water. In mature animals, the flesh is hard and firm in the recent state, though stringy and dry, the fat being all accumulated in the cellular tissue under the skin; but the flesh of the young is more tender, and it is eaten with zest by the inhabitants of some of the dreary regions of the extreme north.

The tail is the most curiously organised portion of the whole animal, and it is always powerful in proportion as the head of the animal is less capable of doing violence, and the animal less inclined to attack any other living creature. This, however, is in accordance with a general law both in the water and on the land. It is well worthy of remark, both on account of the fact and the moral, that murderous animals are never what we may call "armed." Their only weapons are their feeding ones; and when we come to any animal that has what may be called a weapon for war only, whether that weapon be a horn, a spear, a spine, as in many fishes, the lancet fish family, for instance, that animal never preys upon other animals, and (unless in the battles of gallantry) never uses it but in self-defence. The tail of the whale, especially that of the common Greenland whale (see BALÆNÆ), is a very powerful weapon, but the owner of it is never the first to make an attack. The lobes of this powerful organ sometimes measure as much as twenty feet across; and they are not a merely radiated structure, covered with membrane, a sort of aquatic feathers as it were, as is the case with the fins of fishes. They consist of a very compact tissue of fine and strong tendons, elastic in so far in themselves, and pulled to their remotest extremities by the muscles to which they are attached, so that the fin has rigidity to the very extremity, and is in truth a mass of force all over. There are three layers of those tendinous fibres, one on each of the external surfaces of the fin, or lobes rather, and one internal. These can act either in concert or against each other, so that they can produce an endless number of degrees both of motion and rigidity. This organ is less powerful in most of the toothed whales than it is in the balænæ, or whalebone whales; but in the whale genus it is a very efficient instrument, having far more varied and powerful motion than the tail of any fish.

Alimentary System. When we consider the cetacea in this point of view, we feel the imperfection of even the least objectionable classifications of animals that have hitherto been made. In this respect they bear at least some resemblance to the ruminating animals; but they include in their number, portions which, in respect of their feeding apparatus, and also of the value of their food, bear a resemblance to many orders of the terrestrial mammalia. Some are herbivorous, some live on the small animals which float in the sea, and some, again, prey upon the largest fishes. The characters of the alimentary organs, at least those of the prehensile, or masticating ones, are therefore rather means of distinguishing the different groups and genera of the cetacea from each other, than as being characteristic of the whole, as an order.

In many of the smaller species, as, for instance, in the dolphins, the jaws are long, but the mouth is narrow; while in others, as in the whales properly so called, it is very broad and deep. The lengths of the jaws vary in different species; and, indeed, there are so many different forms of the head and mouth, that not one of them can be taken as part of the general character of the order.

All have not teeth; and on those that have them, some have them in one jaw, and some in both, so that there can be no general character founded on the teeth. Those that have teeth have them as prehensile instruments only, and not as organs of mastication. The food of the cetacea is therefore, generally speaking, taken into the stomach entire, and, what would not, *a priori*, be expected in swallowing animals of such large size, the throat is in general of small dimensions—that of the whalebone whale not being larger, even in specimens of the full size, than to admit a pullet's egg. The more voracious species have the gullet wider; and the dolphins, and especially the porpoises, have it wider in proportion than the true whales.



Whale's mouth.

The curious apparatus, by means of which the whalebone whales capture their prey, may be understood from the annexed cut and description, the last being in substance from the illustrious Cuvier.

The maxillary and palatial bones of the baleen, or whalebone whales, form, on their interior surface, two inclined planes, which are concave, but resemble in some respects the roof of a house inverted. It is to these bones that the blades or plates of baleen are attached. They are widest at a point of the immense mouth, which is nearer to the bottom of the gape than to the snout; and they diminish in size as they approach both extremities. They are attached to the bone by an elastic cartilaginous substance, not differing much in consistence from that by which the bones of the swimming paw and the phalanges of the fingers are united, and which perform their motions rather by the flexibility of this cartilaginous substance than by the motion of bone upon bone, which is common among land animals. This is characteristic of an aquatic joint, and in fact one of the best distinctions of a structural kind between land and water mammalia. The extremities of the latter are not, in the native element of the animals, props by means of which they have to support the weight of their bodies; these are supported by the whole surface, and thus the moveable member has nothing to support but its own weight; and as that weight is very little different from that of water, the member moves very freely on its cartilaginous pedicle, and the same motion is produced by a far less violent muscular effort than is necessary in land animals. In this way the aquatic tribes have an advantage; they having only to move, while the land ones have to carry their own weight at the same time.

The laminæ of the baleen or whalebone, have motion on those peduncles, but it is doubtful whether this motion is voluntary. When the mouth is shut the plates fall down upon the inclined planes of the palate in an imbricated manner, and when the mouth is opened, they hang down with their points touching the tongue.

The plates are parallel to each other, and have a transverse direction with respect to the axis of the body. Several hundred of laminæ may be counted on each side, and in the Greenland whale they often exceed ten feet in length. They are fixed to the bone by a kind of fleshy or ligamentous substance. Each lamina presents on its internal side a layer of horny fibres, growing from the horny plates, but less fine and more divided than the plates from which they proceed. These fibres extend between the plates, and form a fringe or loose border on the lower part, so that the whole palate is covered with fringes, the tips of which rest upon the upper surface of the tongue.

This last organ is large in all the species, but it is especially so in the whalebone whales, in which it is popularly, and not inaptly, compared to a feather bed. It consists partly of muscle and partly of fat; and it is a portion of the animal which their enemies attempt to seize with great avidity. This vast tongue is convex on the upper part, so that it applies to the points of all the fibres of the whalebone; and it is necessary to take both into consideration, in order properly to understand the economy of this vast and singular mouth.

The plates of whalebone consist of an immense number of fibres slightly soldered together, and covered with an epidermis in the living animal; but whether this epidermis is endowed with sense either of taste or of touch, is not ascertained; but it is not very probable, neither is it likely, that the cartilaginous peduncles by which the plates are attached to the roof of the mouth, are possessed of the same sensibility as the bulbs which are at the roots of the hairs of land animals. There is no question, however, that the tongue is a sentient organ: and that through its whole length it is enabled to distinguish between substances that are fit for being conveyed to the gullet, and those which require to be ejected between the blades of whalebone. The sense which it has cannot, however, be considered as quite analogous to what we call the sense of tasting; because the substances which pass over it do so in the entire state, and there is little taste in any entire animal, in one sense of the word.

The form of the tongue, and of the palate with its pending plates and their fringes, gives a curious form and appearance to the mouth of the whale when it is open for feeding, and the animal generally swims with it in this state. From the form both of the upper and under part, the anterior part of the mouth, and as far backwards as the place where the blades of whalebone are longest, it presents a sort of funnel to the water, only this funnel has a curved plane for its section. The water enters in great quantity at the anterior part, but it meets with resistance from the plates, and also from the contraction made by the approach of the tongue and palate towards each other. By this means the small animals, which the water holds suspended, get entangled among the fringes, as in a net, and they are left behind, while the greater part of the water, filtered of its eatable contents as it were, escapes by the sides of the mouth towards the bottom of the gape, where the plates of bone are shorter. There is still some portion of the water that reaches an opening of the gullet, but it does not enter into that organ, and of course not into the windpipe, as no animal which breathes the air can admit water into its breathing apparatus. The water which reaches the extreme part often, and the return of it by the same passage, would intercept the current of food to the throat, which, as it comes in small quantities, must come regularly and frequently, is received into membranous sacs adapted for the purpose, and situated in the volume of the enormous head.

These sacs are furnished with muscles, by means of which the water is ejected when they become inconveniently distended; the water thus ejected passes at once into another reservoir or reservoirs, into which the air passages from the lungs open by means of valves rising upwards. When these reservoirs have received the water, a strong expiration of air from the lungs raises the valves, and blows the water up in those jets, the appearance of which forms a curious feature in the economy of these animals. The feeding thus goes on constantly, and the small quantity of water which is flowing toward the entrance of the gullet, and delivering to that orifice the food with which it is charged, gradually accumulates in the lower sacs, without in the least interrupting the breathing of the animal whose nostrils are all this while above water. But when these lower sacs become filled, the water passes into the reservoirs with which the nostrils communicate, and is got rid of in the manner it has been stated.

The same valves which prevent the water which is squeezed from the sacs into the reservoirs, from entering the lungs by the breathing passages, equally prevent the entrance of water into these organs by the pressure from without, even when the animal plunges to a great depth. In such cases, the water has of course access to the upper reservoirs, from which the water is expelled in blowing; but the valves at the lower part of these are closed the more firmly, the greater the pressure of the water; that is, the greater the depth to which the animal plunges. Hence a whale always blows when it comes to the surface after a plunge.

There is no inconsiderable resemblance between the stomach of the cetacea, and that of ruminating animals; and this holds in most varieties of the cetacea, whatever may be the nature of their food. It consists of four or five distinct cavities, the connexions between which are very like those in the ruminants. But there is this difference between them, that, in the cetacea there is no rumination, or even approach to it; the food once taken into the stomach does not again return to the mouth; and indeed there is not, even in those which have teeth in both jaws, any apparatus by which the food could be further prepared for digestion, than it is by simple capture at the first.

In the porpoises and dolphins, the species with which we are best acquainted, and have the best means of examining, as they are plentiful on many parts of the coast, indeed on all parts of it, at some seasons; in them the first stomach is the largest, and it is of an oval form, having thick convolutions on its central surface, and elevated ridges round the opening, by which it communicates with the second one. At the end of this first stomach, and connecting it with the second one, there is a short canal. The second stomach is oval as well as the first, but it is of smaller dimensions, and has its sides with rounded longitudinal and transverse ridges; and this one also communicates by a short canal with the third. The third is of much less diameter in proportion to its length than the others, and has a contrary flexure which gives it something the figure of the letter S laid flat. This portion bears some resemblance to a wide intestine, and its walls have their furrows and ridges much finer than those of the first and second. Indeed this one is generally almost smooth in its walls, and also soft and pliant in texture. The outlet of this third stomach has a coat or valvular shutter, composed of three membranes. The fourth stomach is rather round in its form, and much smaller than any of the others. It is nearly of the same structure and consistency with the third stomach.

The intestinal canal is usually very long, with many folds of the central membrane, which appears to serve as valves in propelling, or at all events preventing the return of the contents of this long and tortuous canal. This intestine becomes very small in diameter towards the final opening.

The food of the cetacea, notwithstanding the great simliarity there is in their digestive apparatus, varies considerably in consequence of the differences in their teeth and capacity of swallowing. The *Balæna* and narwhals subsist chiefly upon floating mollusca and radiata, though they also swallow great numbers of small fishes, especially herrings, one of which is about the largest morsel which can enter the throat of the black whale. The toothed whales are much more voracious. The large spermaceti whale is a very voracious animal, capable of swallowing seals, moderately sized dolphins, and most fishes; and it is said to chase and capture the white shark with great avidity, which is a remarkable instance of a huge monster of the deep preying upon an exceedingly voracious and daring one. The dolphins are chiefly fishers, in the captures of which they are rather indiscriminate; but they are usually found in crowds near the cod banks; the larger ones, which are usually styled grampuses, do not hesitate to prey upon the latter or upon seals, and they are said to tear the flesh and suck the blood of the whalebone whales, though they keep a respectful distance from the spermaceti whales. The common porpoise hunts indiscriminately all fishes which are near the shores; and it is peculiarly destructive of salmon, especially when they are ascending the estuaries of the rivers for the purpose of spawning. It is not, however, very easy to say what may, at all seasons of the year, be the food of animals but occasionally seen.

System of circulation. The system of circulation in the cetacea does not differ much in its general structure from that of land mammalia, and, indeed, the chief difference is that which runs through the whole structure, namely,—a coarser, softer, and less compact texture in the vessels of the cetacea; this is general, and we might expect it to be so, for in every order or other natural division of animals, if the division is formed with sufficient ease, we may expect a uniformity in the texture of all the parts. The chief one here is, that the heart is softer, and indicates less muscular action than that of land animals; and from this we may conclude that the circulation in the whale tribe is slower. That they have as high, or even higher temperature than land animals, is no argument against a slower circulation; because the heat is not in proportion to any motion considered simply in itself, but in proportion to the motion and the resistance with which that motion meets, taken jointly. Now, it is easy to see that an animal which has generally more than the half, and sometimes the whole of its body immersed in the water, which water must exert a very considerable resistance or pressure upon an animal of so great size; it is easy how this pressure may, with a slower circulation, produce as high a temperature as a much more rapid circulation would produce, if there wer eno other resistance than that of atmospheric air.

This is a consideration worthy of notice when we come to consider the temperature of animals, and also the effect that pressure has upon them. It is well known that animals on high mountains, where the pressure of the atmosphere is greatly diminished, are cold and languid in their circulation, and that they are much more prone to become dormant than animals which inhabit lower down; and from this we may safely conclude, that an animal under the pressure of a fluid so much more dense than the atmosphere or water is, may produee a high temperature with much smaller action of the system. There have been various attempts at theories of animal heat, as if it were brought about by some mysterious process, connected with the function of breathing; but any one who has felt the burning heat arising from the resistance offered to the circulation in the small vessels, in the case of even a common whitlow on the finger, may thereby obtain demonstrative evidence of the real source of animal heat, sufficient to overturn all the theories that ever were fancied or fabricated.

The cetacea have two ventricles and two auricles to the heart, and a pulmonic and systematic circulation, just in the same manner as all the other mammalia. But there were once some inaccurate notions on the subject of their circulation, which are still retained in many of the books made up by compilers, who, as they must go back till they clear the time of copy-right, are, very often, the means of digging old errors out of their graves, to the injury of beginners in science. The error in the present case is this:---there is, in the fœtus of all the mammalia, while it remains *in utero*, an opening in the partition which separates the two ventricles of the heart; and the blood which, in the animal after it has begun to breathe, is carried to the lungs, is not so carried in the uterine fœtus, but returns through this opening into the systematic ventricle, the lungs being then inactive. This opening was called the *foramen ovale*, and it was supposed and said that, in order to enable a warm-blooded and air-breathing animal to live under water, it was only necessary that this foramen should be kept open, and the blood would circulate, and all the functions of life be carried on without breathing; that, in fact, this foramen did remain open in the cetacea, and also in all the animals which used to be called "amphibious," and this was the cause why they could live under water.

No error can be more subversive of all that we know of the physiology of animals than this. The *fœtus in utero* does not carry on the functions of life there, because of the circulation of the blood through the foramen ovale; and that opening exists only because the lungs are not in action; and the reason why their action is not necessary is, that the blood of the fœtus undergoes the necessary aëration in the placenta; but, the moment that the umbilical cord is divided, and there is no more aëration by means of that viscus, the lungs act, and the foramen closes, and though the opening were to remain, the circulation continued through it would be death rather than life to the animal. It is not the mere circulation of the blood that is necessary to a healthy state of the animal; it is that the blood may obtain the proper action of the air, whether by lungs or any other apparatus; and if lungs be the organs, there can be no circulation under water, or anywhere else than in the free air. That the whales can remain longer under water than land animals is true; and they are enabled to do so, partly by the valves which shut down upon, and close the breathing passages, and partly also by the less energetic action of their system, which, as we have said, is to some considerable extent compensated by the re-action of the dense fluid in which they are always, in part at least, immersed.

Frogs and other batrachian reptiles, which breathe with gills in the early stage of their being, and by lungs after they undergo their change, cannot breathe under water after they have got their lungs, any more than these animals which never have gills or breathe in that fluid.

And here it is worthy of remark, as a point which is not usually adverted to, that all placental mammalia undergo a metamorphosis at their birth, not very dissimilar to that which frogs undergo, when they change from the tadpole to the perfect frog. We know less of the physiology of marsupial animals which have a double gestation—one in the internal uterus and one in the marsupium, but we can trace clearly in them, a sort of intermediate character between the placental mammalia and oviparous animals; and when we survey the whole of the living tribes, and scan the growing ones, there breaks in upon us a very wonderful light, dim in many places no doubt, but still, such as we may yet see beam on the whole economy of nature, and disclose many principles, and clear up many doubts. It is this:---*every living and growing thing, animal or vegetable, is, in some early stage of its being, so organised as that it can breathe in a liquid, whatever may be its mode of breathing when full grown.*

This principle has not been marked out, nor hitherto, we believe, so much as even enunciated; but it is one, the consideration of which we earnestly recommend to those readers who are fond of studying the working of nature, and we are strongly persuaded that they will find it true in every case. In that of the *fœtus in utero*, of all the mammalia, there is not the least doubt. The membranes by which it is enveloped are perfectly air-tight, so that the free-air cannot reach the fœtus. We know that the lungs are never inflated till the membranes are ruptured; we know, also, that there is a distinct partition between the mother and the young—nay, that this partition is double, and that not only the whole of it, but each of the pellicles of which it is made up, is perfectly air-tight. The consequence is, that there can be no breathing of the free air in the case of the fœtus of even the land mammalia, and that therefore there must be sought some use of the fluids contained in the membranes which has not yet been attended to.

We very much suspect, nay, we are quite sure, that the same will be found to be the case with the whole of the animated races, and even in the generation of the seeds of plants, until they put forth their radicle and plumula, or otherwise display to the free air some organ upon which that air can act. We mention this incidentally, and of course briefly; but it is a subject of far greater importance than any one connected with, or forming part of the history or physiology of any one order, or any one class of animals.

System of Sensation. In this system, also, the cetacea follow the law of, and are in reality mammalia. It is true that, in the larger species, and especially in those with very large heads, the mass of the brain bears a small proportion to that of the animal, and especially to that of the head, but what is of it is well developed, and it displays a distinctly fibrous texture. The whole mass of the brain is proportionally largest in the porpoise, and smallest in the great spermaceti whale; but, on the other hand, the spinal cord is larger in that whale than in any of the others—that is, larger in proportion. The nerves are also very analogous to those of the other mammalia, only, the proper olfactory nerves are wanting, and it is probable that the animals have not much sense of smell, as indeed, from their habits, they cannot have much use for it. There are some circumstances, however, which render it probable that the animals are not wholly destitute even of this sense.

As the whole surface of the skin is beset with papillæ, it is probable that the cetacea have a general sensation of touch all over their bodies, though, from the thick layer of soft fat which is accumulated under the skin, it cannot be supposed that this sense is very delicate.

The whole structure of the tongue, its size, its softness, its moistness, and the apparently great use of it in enabling them to *feel* (rather than taste) what is fit for food and what is not, would lead us to suppose that the function which this organ possesses, whatever it may be, is a very powerful one, because it is one upon which they must have considerable dependence, indeed (in the case of the whalebone whales, their only dependence) in that most important of all their functions, the finding of their food. The fact that the tongue is the largest, and also, to all appearance, most endowed with sentient qualities in the whalebone whales, which have the greatest dependence upon it, as they do not in any ease see their food, is a strong corroboration of the view now taken; but we shall be better able to notice profitably this part of the subject when we come to the enumeration of the several divisions of the order.

The sense of hearing, even that of sounds not naturally loud, is understood to be rather acute in the cetacea. They have indeed no external conchæ to their ears, as such an appendage would be rather an inconvenience to them when they plunge in the water; but otherwise, their ears are very well formed. The auditory canal and the eustachian tube are both of considerable, or rather of large diameter. The labyrinth, the semicircular canals, the cochlea, the vestibule, and the tympanum, are also well formed; and the little bones of the ear, the use of which in any animal is not very well known, are very delicately formed. The membrane which lines all the sentient part of the ear is peculiarly delicate; and the bones which support the soft parts of that organ are much more compact and solid than any others in the body. The eustachian tube communicates both with the mouth and the blow-holes; and indeed, the whole structure of the auditory organs indicates not only an acute sense of hearing, but a strong probability that the animals hear through the vibrations of the water when the head is wholly immersed in that liquid.

The eye of the cetacea is unquestionably a very delicate organ. It is very small for the size, not being larger than that of an ox, but it is exceedingly well formed. There is one peculiarity of it; whales shed no tears, for they are not furnished with lacrymal glands; but the frequent ablution of the eye in salt water, which is one of the best applications to the eyes even in man, may render the use of any saline secretions for the eye itself quite unnecessary. There is a firmness in some parts of the eye exceeding what is met with in land animals; the choroid coat is more strongly united to the sclerotic, and the choroid is in its own structure very vascular and fibrous, indicating powerful action. The crystalline lens resembles that of fishes, in being nearly spherical.

System of Integumentation. The skin of the cetacea is worthy of considerable attention. It resembles, in its general structure and composition, that of the land mammalia, consisting of an epidermis or cuticle, a mucous tissue, a true skin, and an adipose membrane, the latter containing in its cells an immense quantity of fat.

The cuticle is very like that on the sole of the human foot, composed of several layers, and altogether dense, tough, and inelastic. It is, generally speaking, smooth, and often bright and splendent, from the quantity of oil with which it is furnished. There are few hairs, scales, or other external appendages to it, but it contains a great number of pores. On the internal surface it is rough, and in the larger species it has the appearance of velvet. It is variously coloured, but, in general, it is dark on the upper parts of the animal; but in some it is spotted; and in others, as in some of the balænæ, it is piebald. Some species are half brown half white, and others are striped with black and yellow. The upper part is often brown or dusky; and, though the element in which these animals live is much more uniform in its temperature than the air, there seem to be nearly the same elimatal variations in their colour which are found in land animals. The whales of the extreme northern latitudes, as, for instance, about Spitzbergen, are almost all uniformly of a white colour; and these differences appear to be entirely climatal; or, if not so, they are occasioned by the differences of age, not of species.

The mucous tissue is much thicker than in land animals, and it is not easy to distinguish between the first layer of it and the epidermis. This, as in land animals, is the seat of colour, the real epidermis being in both perfectly transparent. There may be albinos among whales, as there are among land mammalia; but even in the purely white specimens that have been examined, there has not appeared to be that want of the mucous tissue which is found in land albinos; we must therefore consider the whiteness as the result of elimate rather than of any imperfection of structure in the animals themselves.

The outer surface of the true skin is villous, or beset with papillæ, which run into small ridges like those on the tips of the human fingers. These *villi* run in ridges, and in some of the species, the spermaceti whales especially, they are at least a quarter of an inch long. In general, the skin of these animals has but little elasticity, or, at all events, it is stretched to the full extent by the immense quantity of fat in the adipose membrane, though there are some of the species in which the elasticity is so great as to draw the skin into distinct ridges and furrows, as may be seen in the piked whales, in which the whole skin of the neck, throat, and all the under part of the body, as far as the middle of the belly, is formed into very decidedly marked transverse ridges.

The most curious part of the covering of these animals is, however, the adipose tissue, the cells of which are loaded with that immense quantity of fat which makes the animal so eagerly sought after by the fishermen. This quantity of fat varies in amount and in consistency in almost all the species, but upon the body it always consists, for the greater part, of *elain*, or soft fat; and where there is any accumulation of *stearine*, or hard fat, that is usually found in the head of the animals, and it is called by the absurd name of *spermaceti.* In the common whale, this soft fat is called the *blubber*, or *spick*, and in good-conditioned whales it is sometimes from twenty inches to two feet in thickness, though in the smaller and more active species, as in the dolphins and porpoises, it is much less. The land animal to which the fat of the cetacea has the nearest resemblance is the hog, but the fat of the cetacea is far softer than lard, and may be regarded as a substance which is perfectly *sui generis* in its mechanical structure, though, in its chemical composition, it differs little from the fat of any other of the mammalia.

System of Reproduction. In this part of their economy the cetacea are all, strictly speaking, mammalia, though they differ a good deal, the females especially, from land animals. Very little is, however, known about their mode of pairing, or the period of gestation in the female, and the conjectures which have been advanced on the subject are so palpably absurd and contradictory, as not to be worthy of any attention. The milk of the females is wholesome, and peculiarly rich, resembling, both in taste and consistency, cream rather than milk; and, strange as it may seem, it is by no means improbable that a dairy of tame whales would be an important addition to domestic economy, although the food and manner of feeding in the common whales, which are certainly the most gentle and docile of the order, would render it a very difficult matter to keep them on any part of our shores.

The young are, generally speaking, only one at a birth, though there are two in some instances. It is said that the female goes ten months, but the fact is not established upon any satisfactory evidence. Little is known of the length of their lives; but if we may judge from the analogy of land animals, which are generally, though not invariably, long-lived in proportion to their size, we might perhaps assign to the larger whales a duration of at least a thousand years. There seems to be little doubt that, in their growth, they agree with fishes rather than with, at least the majority of, terrestrial mammalia. They continue growing, not in the flesh only, but in the skeleton. This is in so far at least the case with the boas, and with some other genera of land animals; and it seems that, in all cases when this fact is well established, the animals are remarkable for length of life. All statements which are made, or indeed can be made on this part of the subject, are, however, in a great measure, conjectural, though it is well ascertained that they are, the common whale especially, very slowly-breeding animals, and have been very much thinned by the assiduity with which the fishing in the north seas has been carried on. More attention than it has hitherto received is worthy of being paid, and necessary to be paid to the growth of the bones of animals, as connected with the duration of their lives; and when this highly important subject has been investigated with the attention which it merits, it will in all probability be found that the bones of animals are the parts which first die, and which thus bring about the mortality of the whole; and that, from the time that new matter ceases to be added to the bones, not merely in the repair of them, or in the replacement of those parts which have become unfit for use, but in the enlargement of their structures, the decay of the animal may be dated. We know that all the soft parts are frequently replaced; and that there appears to be a power of replacing them, even to the latest period of the life of the animal; but in all the shorter lived species, including man in the number, the bones cease to grow at a comparatively early period. After age and decrepitude come on, there is a wasting of the bones, a taking up of their earthy parts, or salts of lime, by the absorbent system; and this is often done to an unnatural extent, so that the matter taken up in this way loads the circulation of the blood, and is thrown upon the coats of the vessels in those accumulations, to which, in common language, we give the name of ossifications, or conversions into bone.

It does not appear from the information that we have on the subject, which it must be allowed is very scanty, that the animals whose bones continue to grow are subject to these casualties, or that they ever fall into decrepitude. In toothed animals there is, indeed, a boundary set by the decay of the teeth, though in some instances, even in man, these are reproduced in the extreme old age of the individual; and the author of this article once knew a very old man, who got a new set of teeth when he was between eighty and ninety years of age, and about the same time recovered the sense of sight which, for several years previous, had been very dim and weak.

But in cases where the bones do not decay, but continue to grow, as they do in the greater number at least in the cetacea, it is not very easy to see what part of the animal can decay; and if the system goes on assimilating all the substance which is necessary, not only for the repair, but for the growth of the several parts, it is not easy to see how it can cease to live in consequence of any other than a violent death. That the cetacea partake of this durable character to a very considerable extent is certain; but how far they possess it has not been ascertained with any thing like certainty. It is, however, a subject which is well worthy of the most minute and careful examination, not only on account of the interest and value of the animals themselves, but as one of the most interesting points in the whole economy of animated nature.

This order of animals has been variously subdivided and arranged by different naturalists. Linnæus made only four genera: *Balæna*, or whale-bone whales; *Physeter*, or spermaceti whales; *Dolphinus* or dolphins, and *Monodon*, or narwhals. La Cepède, on the other hand, makes ten genera, and, besides, he has augmented the number of species apparently much beyond the truth, by introducing many which are only varieties, if they are even entitled to that character. The animals, of which it is probable that the bones continue growing for a long and indefinite period, size cannot be admitted as a ground of distinction; and colour—conspicuous in all cases—cannot, from what has been already hinted at, be very readily admitted as a specific character in these animals. We shall, therefore, take an intermediate ground of distinction, that of the character of the teeth.

Viewing them in this light, there are four divisions or sub-orders: 1, *Edentatæ*, or toothless whales; 2, *Prædentatæ*, or those with teeth in the anterior part of the upper jaw only; 3, *Subdentatæ*, or those with teeth in the lower jaw only; and, 4, *Ambidentatæ*, or those with teeth in both jaws. To these may be added, perhaps as a separate sub-order or group, those cetaceous animals which are understood to subsist chiefly, or wholly, upon vegetable food, and which are chiefly, though not exclusively, found in the rivers of the warmer parts of the world.

I. *Toothless whales.*—These consist of the common whales, *balænæ*, which have no dorsal fins, and the "finners," *balænoptera*, which have one; and some account of them is given in the article BALÆNA, so that we have now only to notice the other divisions of the order, to which the remainder of this article will be devoted. See cut on next page.

II. *With teeth in the fore part of the upper jaw only.*—These are known by the general name of *narwhals*; and their most remarkable external character is that of having one, or sometimes rudimentally two, large teeth projecting from the snout. They are, on this account, sometimes called *sea unicorns*.

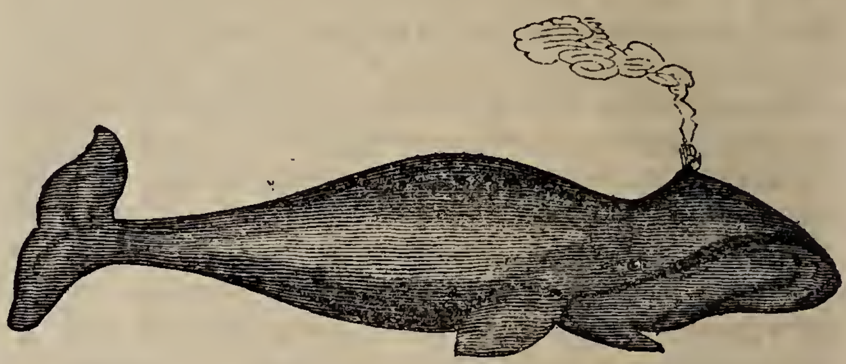
These animals have only a single opening for the blow-holes, which is situated far back on the nape of the neck, rather than on the head, The only teeth which they have are those projecting from the snout, usually one, sometimes on the right side of the snout, sometimes on the left, and very rarely two, or, if two, one of them is usually much less produced than the other. These seem, however, always to be two rudimental ones; and they are the only teeth which the animals possess. They are not of the smallest use in mastication, or in the capture of the food of the animals, farther than that they *may* sometimes use them in detaching shell-fish from the rocks, as these form a considerable part of their food. They also use them as weapons; and in this respect they are very formidable; long, strong, spirally twisted, generally sharp at the point, and formed of very compact bone or ivory. Their heads are much smaller in proportion to the size of their bodies than those of the whales properly so called; their muzzle is rounded, and they have no whalebone or horny plates in their mouth. The upper part of their body is, in general, spotted, and there is a sort of edge on the posterior part of the back, extending a considerable way from the tail; but the most typical species are without any fin on the back.

They are chiefly inhabitants of the northern or polar regions; are fast swimmers, and altogether very active animals, driving about with great velocity, and keeping all other inhabitants of the deep at a distance, by means of the formidable weapon with which their snout is armed. As they have no teeth or other instruments of division or mastication in the mouth, they do not prey upon large animals, not even on large fishes; but they are voracious in proportion to their activity, and swallow a number of the smaller fishes, as well as of radiated and molluscous animals, and they use the tooth in detaching the shelled ones from the rocks.

There are, perhaps, two sections of this division, those without a fin on the back, and those with one; and there are two, or probably more, species of each section, but their history is imperfect and obscure. Those without the fin are systematically termed *Monodon*, one tooth; and the others *Anarnacus*, from a real or supposed purgative quality of their flesh and fat. We shall first notice the species without the dorsal fin; they are *Monodon vulgaris*, the common narwhal, and *Monodon microcephalus*, the small-headed narwhal.

Monodon vulgaris.—The common narwhal grows to the length of from twenty to twenty-two feet, the general form of its body is a sort of oval, and it has a prominent ridge on the back, extending all the way from the tail to the blow-holes at the nape. Specimens of much larger dimensions than those above stated have been mentioned, but it does not appear that the accounts of them are very well authenticated. Indeed, the whole of the accounts of the northern seas require to be read with caution, and received with considerable allowances, as many of the describers of their productions appear to have caught no small portion of the romancing and fabulous spirit, for which the natives of these wild regions have, in all ages, been celebrated.

The general shape of the body when viewed laterally is, as has been mentioned, an elongated oval; the upper part is grey, with deeper spots, which vary considerably in size and number in different individuals, and the under part is of a pure and intense white, which is indeed the prevailing colour of the under part of all the cetacea which are inhabitants of the cold seas in high latitudes; and there is no doubt that this white colour tends much to protect the viscera and other working structures of these animals, from the intense cold to which they are exposed among floating ice and ice-water.



Greenland whale.

To appearance, there is hardly any distinction between the body and head of this animal, further than a slight depression immediately in the rear of the blow-hole, which may be considered as the neck. The blow-hole is crescent-shaped; the forehead low; and the snout obtuse and rounded. The mouth is very small in comparison with the size of the animal, and would not admit a body of more than between three and four inches in diameter.

The swimming paws are about a foot long, and eight inches in breadth; and, as is the case in all the order, they are much flattened, and their motions are in the cartilage, by which bone is united to bone, rather than in the one bone sliding upon the other, as in the joints of land animals. The dorsal ridge commences immediately in rear of the blow-hole, and continues all the way to the tail, only it becomes lower as it approaches that organ. The tail itself is formed into two lobes, which incline away from the body; and though it is horizontal, and therefore has its most powerful action in striking the water upwards and downwards, yet it has considerable twisting motion, and is a very efficient swimming instrument. The skin of the common narwhal is thin, and the blubber, or fat in the cellular tissue, only in small quantity; but in quality it is said to be much superior to that of any of the other whales, yielding, by simple expression, an oil which is said to be superior to that obtained from even the hard fat of the spermaceti whales.

The most singular part of this animal is the tooth, or, as it is sometimes called, the horn. It is deeply inserted in the bones of the skull, generally to the depth of at least a foot in moderately-sized specimens. This part of it is hollow, and filled with a sentient cone, the hollow terminating about the point at which it issues from the head. From this point it tapers gradually, and comes to a fine but in general not a very sharp point. In its direction it is not exactly parallel to the axis or general line of the body, but inclines toward that side in which it has its origin, which is sometimes the right and sometimes the left. When there are two of these teeth, they generally spread so much, that their fronts are about a foot and a half asunder; and even when there is only one, which is the general case, that one deviates about nine or ten inches from the mesial plane at its point. When there are two of these teeth, the distance of their bases at the snout of the animal is not more than about two inches.

The substance of these teeth is ivory, and ivory of a more compact texture than that of the teeth of the elephant, though it is perhaps more brittle. It is not, however, so liable to turn yellow as that kind of ivory, and is perhaps, on the whole, the more beautiful substance of the two.

Notwithstanding the powerful weapon with which it is furnished, the narwhal appears to be a very inoffensive animal, and even kind and gentle. It has been sometimes said that it attacks the whale, and gores it with this formidable horn; but the probability is, that the narwhal has, in these instances, been mistaken for the sword fish, which, though belonging to a different class of animals, is much more predatory and voracious than the narwhal. Indeed, if we except the whalebone whales, the narwhal is perhaps the least offensive of all the large inhabitants of the sea. These animals are usually found in the bays or open places of the northern ice; and, when they are annoyed there, they huddle together till they are apt to injure each other with their tusks; but even then they offer no violence to any other creature.

But they are of considerable value to man. The oil is, as we have said, of very fine quality, and the people of the northern countries are very fond of the flesh, and also of the intestines. They use the horn, or tooth, as timber, for which purpose it is well adapted, being both strong and beautiful. The king of Denmark is said to have a beautiful throne wholly composed of this material, which is carefully preserved in the castle of Rosenburgh; and in this country the large teeth are sometimes used as bed-posts, and the smaller ones as walking-sticks, for which, though rather heavy, they are not otherwise ill adapted.

Monodon microcephalus. The head of this species is, as the name implies, smaller than that of the other. It is of about the same length, or sometimes longer, being met with as much as twenty-six feet long, though it is found in smaller sizes, and sometimes not exceeding twelve feet. Its body is narrower than that of the common narwhal; and the ridge on its back is not so prominent. The upper part is also darker in the general colour, which renders the spots upon it less apparent. The spots on the sides are much more apparent than those on the back, and the belly is pure white. The skin is smooth and glossy, very thin, and firmly united to the adipose tissue. The mouth of this species is very small, the upper lip extending a little beyond the lower. The eye is far back, just immediately under the blow-hole; it is about an inch in diameter, and has the iris of a chestnut colour.

This species appears to be much more discursive in its habits than the common narwhal, having been found, not only on the coasts of the northern islands, Shetland in particular, but also, at least in one instance, upon the coast of England, near Boston in Lincolnshire. The individuals which come so far to the south must, however, be considered as stragglers; and though they are more frequent on the coast of Shetland than on any place farther to the south, they are only occasional visitants even there. It is probable that this species, on some of its southerly excursions, has been mistaken for the common narwhal, an animal which does not appear ever to have been seen out of its polar haunts, though in these it is no means rare.

The Anarnak (*Anarnacus Grœnlandicus*). This species, of which the history is very obscure, is unquestionably entitled to rank as a distinct genus, and not as a "spurious narwhal," as it has sometimes been called.

This species, like the former, is an inhabitant of the Greenland seas; but, according to the accounts, it keeps much more at sea than they do, and is, in consequence, much less frequently seen. It is also an animal of much less interest to the Greenlanders and other natives of the extreme north. It is but of small size, perhaps the smallest of all the cetacea; and, as one might infer from its seaward habits. it contains but little fat. Pelagic, or wide-sea animals, whether mammalia or fishes, are generally very fast swimmers, have their flesh firm and rather dry, and seldom have much fat upon them; and the anarnak does not form an exception to this general rule. Besides, it has been mentioned that the flesh of this animal has a cathartic or purgative quality, which renders it unwholesome for food; and there is no part of it to compensate the fishermen for the trouble of capturing it, which is considerable, as it drives about in the open water, and cannot be driven into bays, as is the case with the narwhals.

This animal is of nearly the same shape as the others, but its colour is black, and it has a fin on the back. The teeth are also very different, though they belong to the same class as the narwhals. They project from the snout, as in these species, and consequently are of no use either in the capture or killing of its food. They are very short and curved, and though the small portion that there is of them is compact ivory, they answer none of the purposes to which the teeth of the narwhals are applied. Their length is only about an inch, while the tooth of the narwhal is often six feet or more. Of these teeth there are generally two, as they are not subject to the same casualties as the longer teeth of the narwhals, though there are instances in which only one tooth appears. The mouth is small, as in the other species; and, as it contains no teeth or grinding apparatus of any kind, the animal must swallow entire all those creatures upon which it feeds. The teeth of all sea animals are, indeed, only prehensile or wounding teeth, and never answer for mastication; even the teeth of sharks, which have a motion upon the jaw, and by that means cut and tear at the same time that they hold, are not grinding teeth.

3. *With teeth in the lower jaw only* (*Subdentatæ*). The animals of this group are the true monsters of the deep. They attain a vast size, are very active, when irritated exceedingly ferocious; and they answer, in the water, to the lions and tigers upon land. They are not, like the balænæ, confined to the polar seas, or, like them, peaceful inhabitants of the waters; collecting small animals in a net, or, as one may say without much exaggeration, grazing the deep, for, though they do not eat vegetable matter, they eat only those substances which float near the surface. It is chiefly from the balænæ that we take our common notion of whales; and, therefore, we are apt to mistake the characters of those which form this group. On the other hand, it does not appear that the ancients had any knowledge of the Greenland whale, though probably specimens of the finned species may have been seen on the coast of Britain by the Romans when they circumnavigated the island. At that period, whales of some description or other appear to have been common much further to the south than

they are now to be met with; and it is certain that, at this time, there were very large specimens not unfrequently seen in the Mediterranean; and, as these are all described as toothed whales, there is no doubt of their being the spermaceti whales, which are now more abundantly found in the opposite hemisphere, where they form the principal subject of attraction in the south sea fishing.

These animals are the *Cachalots* or *spermaceti whales*, forming the genus *physeter* in the systems of zoology. As many as eight species or varieties are mentioned; but we must confine our brief notice to two or three of the principal ones.

The most remarkable character of these animals is the enormous size of their head, which is never less than equal to a third of the whole animal, and sometimes it is equal to a half. Much of the great mass is occupied by the upper jaw, which is excessively broad and deep, while the lower jaw is long and narrow, and so thin, as compared with the other, that it appears to apply to the rest of the head as if it were the lid of a box, only that it opens and shuts on the under side and not the upper. The upper jaw has no projecting teeth, but is covered with a very firm cartilaginous gum; but, in the body of this gum, a greater or smaller number of imperfectly developed teeth are usually found, though even their points do not reach the surface. In the lower jaw there are strong and thick teeth, of a conical form, usually rather blunt at the points, but formed of very strong and hard ivory, and therefore, when the size and motion of the jaw, and the immense volume of head against which it acts, are taken into the account, these teeth are very powerful weapons. The blow-holes are two in number, within the skull; but they open by one external orifice in the top of the head. Before them, and occupying a considerable portion of the snout, there is found the spermaceti, stearine, or crystallisable fat, on account of which the animal gets its common English name. As is the case with the whalebone whales, some of the species of this genus have a fin on the back, and others not; but those that have no fin have a dorsal protuberance, or rudiment of a fin, imbedded in the substance of the back. The substance known by the name of ambergris (or grey amber, which has no resemblance to amber properly so called,) is said to be chiefly found in the intestines of this genus of animals, or discharged by them, and floating in the sea, or cast upon the shores.

Physeter macrocephalus, the great-headed or great spermaceti whale, is one of the largest of the genus. It is found in the Greenland seas, but it is a much more ranging animal than the whalebone whales, and thus it is not unfrequently met with on different parts of the shores of Europe, specimens measuring upwards of sixty feet in length, and ten in diameter, have been met with; and they are perhaps the most shapeless of all mammalia, appearing on the water like the summit of a black rock of no inconsiderable dimensions. The head justifies the application of the term *macrocephalus*, or great-headed, for it occupies nearly half the length, and more than half the volume, of the animal when young. This head has the appearance of a great clumsy box, blunt and rounded at the fore part, and marked posteriorly by a slight elevation above the line of the neck. The eyes are very small in comparison with the size of the animal, and they are furnished with eyelids very much resembling those of the land mammalia. These eyes are very distant from the extremity of the snout, so much so that they are not very far from the middle of the length, exclusive of the tail fin. From their position, it is quite impossible for the animal to see before it in any way, and an object must be at a very considerable distance before it can be seen with both eyes in any position. The blow-hole, which is about six inches in diameter, is placed forwards, just above the end of the snout; and the external openings of the ears are so small as scarcely to be discernable. Indeed when the animal is in a state of repose upon the water, in which state it floats high, especially with the head, which is rendered specifically light by the vast accumulation of spermaceti,—this whale, seen at a little distance, has very little appearance of being a living creature at all. In the upper jaw, that is, in the hard cartilaginous gum with which the lower surface of this jaw is covered, there are holes answering to the teeth in the under jaw, which fit into those holes, so that the two hard gums can be made to bear firmly against each other; and, independently of the teeth, the animal can give the same sort of bite as is given by the horny jaws of the larger water tortoises, only the bite is more formidable in proportion as this whale is the larger animal of the two. The upper part of the body is dark, a sort of deep slate-colour, approaching to black, but having a tinge both of blue and of green. The under is white, and there are often white spots on the sides, and sometimes on the back. The tongue, which is large and square, is of a dull red colour. The swimming paws, and also the tail, are proportionally smaller than those of the whalebone whales, and the lobes of the tail are long and pointed. This organ does not form nearly so powerful a weapon as the tail of the great whalebone whale; but the action of the rest of the body of the animal is much more energetic; and it dashes along the water with great velocity, appearing to ride very light and buoyant, compared with many others of the race. From the size its weight must be enormous, and its gambols in the water make much agitation, and render the approach to it in a boat a matter of much hazard. Still, even the Greenlanders, simple as are their weapons and other instruments, attack this formidable animal with great readiness, and esteem it one of the greatest prizes which the sea affords. The capture of it is altogether a much more hazardous matter than that of the whalebone whale; but from the superiority of spermaceti to the blubber fat of the other, it is a much more valuable prize. The greatest accumulation of fatty matter is in the head of this animal; for the blubber or accumulation in the adipose tissue over the general surface of the body, is small in quantity and inferior in quality, consisting in great part of membrane. On the back, where it is thickest, it does not exceed five or six inches, while on the belly it is less than this.

The Greenlanders however turn it to great account. The tongue, which is of a very large size, is one of their dainties; and they also eat the flesh, the skin and the intestines, the first of which is pale coloured, not unlike pork in appearance, and, in young specimens, said to be not much inferior. The bones are used as timber, and partially also in the manufacture of weapons and smaller articles.

Physeter Trumpo. This is the blunt-headed spermaceti whale, one of the largest of the species, and a very valuable one; but it is even more daring than the species last mentioned; and it is also more excursive. It is found of nearly the same length with the other; but the body is rather more slender, while on the other hand the head is thicker, especially towards the snout, which is rounded, projects about five feet beyond the lower jaw, and measures at least eight feet in depth, from the crown to the opening of the mouth. The lower jaw is about ten feet long in the opening, which makes the bottom of the gape fifteen feet behind the extremity of the snout. This thick and projecting portion of the snout consists for the greater part of spermaceti; and the fat upon the body is more abundant than that on the great-headed species, and also of superior quality. When we speak of great-headed as applied to these animals, the term is by no means accurately descriptive, for the species now under notice has really the greater head of the two, although the thickness and bluntness of the snout form a distinction. The lower jaw, the depth of which bears but a small proportion to that of the upper, fits into a sort of groove in the upper one. It has about eighteen teeth on each side, which have their points turned outwards; and the two hard gums close with oblique edges, so as to crush or hold with great force. This animal is very bold, attacking its enemies with great determination, so that it is very dangerous to come near it if wounded, and not mortally.

Physeter microps. This is the small-eyed spermaceti whale; and though there is necessarily a good deal of confusion in the accounts of animals which are generally attempted to be killed the moment they are seen, and which cannot be very well or very closely examined alive, yet this seems to be the most active and also the fiercest of the whole genus.

This species which is found both in the cold and the warm seas, and which has been occasionally stranded on the west coast of Europe and on the British shores, is generally understood to be the great sea-monster of the ancients; the one from the peril of which Perseus delivered the fair Andromeda, and for which act the whole three have had a place assigned them among the constellations. It is also the one against which, according to Pliny, the Emperor Claudian mustered his army in the port of Ostia, and probably also the one alluded to in the prophecy of Jonah, although the description there must be considered figurative, as no doubt the others are in great part at least fabulous.

This has some resemblance to the species already noticed, but it differs from them in many particulars. Its colour on the upper part is blacker, indeed almost entirely black; it has a dorsal fin, which is straight, high, and pointed; its eyes are very small, and though its head is very large it is not quite so much so at the muzzle as that of the blunt-headed. The swimming paws and the tail are larger than in the others; and the body is rather more slender. There is not nearly the same tendency to accumulate soft fat on the body as in the whalebone whales, or even in the other species of this genus; but the quantity of spermaceti is great, and its quality is excellent.

The mouth of this animal is very formidable; the upper jaw does not extend wholly to the extremity of the snout, but it is a little longer than the lower jaw, and the two close upon each other more firmly perhaps than in the blunt-nosed species. The teeth in the lower jaw are about forty-two in number; they have hollow roots resembling the tusks of elephants, and of the narwhals much more than they do common teeth. They do this both in their structure and in their texture; and this structure is common to the teeth of cetaceous animals, whether those teeth be in the one jaw, in the other, in both, or projecting from the snout, unconnected with the opening of the mouth as they do with the narwhal. These teeth have their hollow bases inserted in the gum for about two-thirds of their entire length. The portion which stands above the gum is white like ivory, conical in its general form, and sharp at the tip, but bent first backwards and then a little outwards. They are, in short, very dangerous teeth to come in contact with, and the animal has great power in its jaws. As is the case in the species formerly described, these teeth lock into corresponding holes in the hard gum of the upper jaw; but though they appear but little above the surface of the gum, there are teeth also in all the intermediate parts of this jaw, so that this whale may be said to begin its bite with the teeth of the lower jaw, and finish it with those of the upper.

This species is described as being much more ferocious than the former, though hardly equal to them in size. The peculiar formation of its mouth enables it to bite in pieces, though not to grind or masticate, and therefore it ventures to attack much larger prey. It masters not only the largest species of fish, but also many of the animals of this family. Dolphins, porpoises, and even the larger dolphins which sometimes attack the whalebone whales, are among the every day prey of this indiscriminate devourer. Nor does it confine itself to these, it attacks the balænoptera even when they are full grown, and the young of the great whalebone whale itself.

By the fishermen, all the species or varieties of physeter which have been enumerated, together with five or six more which are not so well defined, are classed under the general name spermaceti whales. They are probably all found in one place or other of the Greenland seas, or northern parts of the Atlantic; but that is not the district where they are found in the greatest numbers, or captured to the greatest advantage. The Pacific is their grand field, and their range along that great ocean from Behring's Straits to the Antarctic ice. They are also found, seasonally at least, in the Indian Ocean, and they are very common upon some parts of the shores of Australia. They are very interesting animals, and highly valuable in a commercial point of view; and as the Pacific is a very wide pasture, and from their indiscriminate feeding they have a much wider range than the more peaceful whales of the north, there is less danger of thinning, or, at all events, of exhausting their numbers, than there is in the case of these.

4. *With produced teeth in both jaws* (*Ambidentatæ*). The cetacea which have regular teeth in both jaws are of much smaller dimensions, more numerous, some of them at least better known, and all of them more easily examined than those more gigantic species which form the third group in our enumeration. They are usually arranged into two genera, *Delphinus* (dolphins and porpoises) and *Hyperöodon* (beaked whale). There are several species of the former genus, but only one of the latter, and there is some confusion in the history even of that one.

Dolphin (*Delphinus*). Scarcely any specimen of this genus has been met with exceeding five-and-twenty feet in length. They must not be confounded with the dolphin of the ancients, and what is still called the dolphin by the Dutch and some other nations. It is a true fish (the coryphene) and not a warm-blooded animal as the real dolphins are. It is probable that the ancients did not always mean the coryphene when they spake of the dolphin, though that fish was certainly the dolphin of the Mediterranean—*Arion's dolphin.* But when Juvenal, in his tenth Satire, makes use of the simile of the dolphin and the whale, in a sense not very dissimilar to that of the fable of the frog and the ox, it is possible that he may have meant the warm-blooded dolphin: "Quanto delphinus balæna Brittanica major."

The dolphins have not the enormous head which is characteristic of the whales; and on that account they are more shapely animals. Their jaws are lengthened, and both are furnished with conical teeth, placed in an even row, but varying in number with the species. The blow-holes pass the upper jaw in two separate apertures, but the openings are conjoined into one externally, which is on the top of the head, and of a crescent shape. The eyes are placed near the angle of the mouth. All the species have dorsal fins, with the exception of one, and these fins are often of vast length, appearing like the sail of a boat as the animals swim, or rather tumble along through the water; for their march, which is much more rapid than it seems, is made by a series of leaps, at the middle of each of which the fin, and indeed the greater part of the body, is seen above the water, while, at the beginning and end of the leap, the whole disappears.

This is the mode of swimming in all the cetacea; and it is easy to see, from the formation of the tail, the most powerful organ of motion in them all, that this must be the case. Their action, like that of land mammalia, is in the vertical plane, while the most powerful action of fishes is in the horizontal. Their tails strike upward and downward, and those of fishes strike laterally; the resistance to the stroke upwards is less than to the stroke downwards, because the pressure of the water increases with the depth; and thus when the cetaceous animals make great exertions in swimming, they always to a considerable extent work themselves up to the surface. This agrees with their economy as animals that breathe the free air; as it gives them the opportunity of breathing at the top of each of their leaps, without any other muscular exertion than that which is required for their progressive motion through the water. We know by experience that the respiration of all animals requires to be increased in the proportion of the exertion which they make; and it is a beautiful instance of adaptation to find that those air-breathing animals, which find their food in and generally inhabit the water, come naturally upon that element in which they breathe, whenever greater exertion renders more frequent respiration necessary.

Fishes again, which breathe water, have no tendency from the mere action of swimming either to rise or to descend, their tails strike the water right and left, and of course they strike against exactly an equal pressure both ways; and thus, when they either rise or descend in the course of their progress, they do it by an additional effort, and they are fatigued by it, and also have their peculiar kind of respiration impeded rather than assisted by it.

This can be very well observed of the common porpoise and the salmon, in the estuaries of the salmon rivers. The porpoise is very fond of salmon, and pursues them with great assiduity as they ascend the rivers. This is best seen, when it clears up after a heavy summer rain, which has brought a good deal of "fresh" into the estuary. The salmon always swim upon the "fresh," whether on account of its being there an additional supply of food, or for some other physiological cause, is not very clearly known; but any one who has paid any attention to the habits of salmon must be aware of the fact.

The salmon hold on their straight course, not far from the surface, for, as we have said, they swim upon, that is, they swim to meet the fresh; but while they are able to keep at a safe distance from the pursuing enemy, they do not appear above water. The porpoises tumble along, in the manner above described, not only showing the fin, but, in their eagerness to catch their prey, springing partly, or even altogether, out of the water. This is, by the way, far from the worst time for striking porpoises with the harpoon, or even with the spear, if they are very eager in the chase, and they generally are so, and also not singly, but in packs.

At length the salmon begin to get fatigued and exhausted; for there is nothing to renovate them in the same way that the ascent to the air renovates the porpoises; and when they are all but in the formidable jaws of the enemy, they leap into the air; but that is a means of fatigue to them, and not of relief: it is only another tumble forward on the part of the porpoise, and the salmon falls exhausted into its mouth. If both animals are in numbers, on a summer evening, when the sun is low, and the sky has just cleared of the rain, this chase is a very beautiful sight. The scales of the salmon show prismatic colours, and, as their leaps are taken with great rapidity, they seem as if they were little rainbows, rising momentarily out of the water. We shall now notice a few of the leading species of dolphins.

Delphinus phocœna (the common porpoise). This species, the common name of which in most European languages means "sea-hog," is the most abundant and the best known. It is plentiful in all the European seas, and especially so upon the coast of North America. Though a thick and apparently unwieldy animal, it is exceedingly active in the water, and even playful, frisking and even gamboling about, as if fond of amusement. There is a good deal of "speculation" in its eye, as compared with the eyes of fishes; and it shows an attachment to its kind, of which there is no known instance among the cold-blooded inhabitants of the deep. Many of the fishes assemble in shoals, but there does not appear to be any principle of society among them; and there are at least many of the species, in which the large ones prey on the little as readily as on any other kind of food; but it does not appear that any of the cetacea are cannibals; and the porpoises certainly imagine each other as members of the same society.

They accompany all the smaller species of shoaling fish upon their migrations; and where these are abundant, the porpoises often appear in very numerous packs, darkening the surface of the sea as they display their fins, and the upper parts of their bodies. When they are more playful than common, the sailors usually regard it as a sign of bad weather; and it is probable that they are correct. The storm at sea is a time of want for many of the fishes, more especially those that find their food near the surface; and we may suppose that, according to the general law of nature, that there should be a natural provision against the period of natural want, corresponding in some degree to the continuance and severity of that period. Nor is there any doubt that at those times, when the porpoises gambol much at the surface of the water, the surface fishes are generally near the top, the water being then quiet and transparent, and also considerably affected by the diminished pressure of the atmosphere which usually precedes storms, as is indicated by the fall of the barometer.

The common porpoise is generally about six or seven feet long, very thick in the fore part of the body, and tapering gradually towards the tail. The upper part is bluish-black, or sometimes very dark brown, and the under part whitish, but not bright in the colour. The muzzle is short and broad, though the snout does project a little beyond the opening of the mouth. Each jaw contains about forty-eight teeth, which are small, sharp-pointed, and slightly moveable on the gum. The tongue is flat, zigzag on the sides, and united below to the under part of the mouth. The eyes are small for the size of the animal, though not nearly so much so as in the whales, especially the spermaceti whales.

When the porpoise is in good condition, the blubber of it is very thick, and furnishes a considerable quantity of very good oil; a large sized one yielding as much as a hogshead. The flesh is also tolerably well tasted; and in former times, when dishes were prized for their size, the porpoise was a leading dish at feasts. It is still eaten in some parts of the world, though we believe that our English epicures do not now have porpoise, and porpoise-sauce made of crumbs of bread and sugar, in the list of their dainties. Indeed the animal is far from being a favourite even with the fishermen, who look on it as a formidable rival in their trade, alleging that it drives the fish off the coasts, and injures their quality by hunting them about, as well as thins their numbers. It is also very apt to break and otherwise injure their nets.

It is generally understood that it does not, at least at all seasons of the year, confine its labours to surface fishing; but that it descends at least into the shallows, and not only captures flounders and other species which inhabit near the bottom, but even ploughs up the sand and mud with its snout, in order to capture those species of fish which burrow in these shallows. This is not improbable, as it is generally understood that even the salmon catch eels something in this way.

The skin of the porpoise, when properly dressed, makes neat, and very compact and durable leather, only the inner or fleshy side of it has to be much curried down, in order to remove all the cellular tissue. There are many anecdotes told of the modes of capturing these animals, especially on the American coast, where they are much more abundant than on that of Europe. We may quote one of these as throwing some light on the character of the animals. "The inhabitants of Canada, about the river St. Lawrence, adopt an amusing method of taking porpoises. They collect together a considerable number of slender branches of sallows, willows, or similar trees, and stick them firmly into the sand banks across the banks of the river, which are commonly left dry at low water, so as to form a long line of twigs, having the upper end connected with the shore, and an opening left next the sea, by which the porpoises may enter. As the tide rises the water covers the twigs, so as to keep them out of sight, and the porpoises, entering the river in quest of their prey, get within the line, where they continue the chace till they find, by the ebbing of the tide, that it is time to retreat into deep water. They now make towards the sea, but then the twigs coming into sight, and being all agitated by the current of the tide, form such an alarming spectacle, that they retire in great fright from this tremendous rampart. The tide continuing to ebb, the porpoises return from time to time, but not being able to conquer their dread of those terrific twigs, they flounder about till they are entirely deserted by the tide, when the inhabitants, watching a favourable opportunity, commence the attack, and soon overpower the defenceless animals. In this manner more than one hundred porpoises, each yielding about a hogshead of oil, are sometimes taken at a single tide."

Delphinus Delphis—the common dolphin. This species is considerably longer than the last mentioned, but it is not nearly so thick in proportion. The usual length is about nine or ten feet; the nose long, narrow, and pointed, with a transverse furrow across the skin towards the upper part; though there are none of the characters usually given to the imaginary dolphin of painters. The gape is very deep, reaching nearly to the articulation of the head; and the teeth, though variable in number, are said usually to be about forty in the upper jaw, and thirty-six or thirty-eight in the lower. The dolphin is more an inhabitant of the wide seas than the porpoise, and it is also found in lower latitudes, often accompanying ships for a long way on their passage to the East and West Indies, but is of rare occurrence on the British shores, and appearing there only as a straggler. The dorsal fin is even higher than that of the porpoise; and as the upper part is blacker, and the under part much whiter than in that animal, it makes a much more conspicuous figure in the water.

It is much more discursive than the porpoise; but still it is like that a gregarious animal, and very sportive, leaping entirely out of the water, with the back sometimes a very little arched, and the tail a little curved, during their leaps, but nothing at all as compared with the fanciful representations. It must be borne in mind, that, as the principal action of cetaceous animals is in the vertical plane, while that of fishes is in the horizontal, we might expect some flexure either upwards or downwards, in the posterior part of the spine, just as we find lateral flexure toward either side in the spines of fishes. There is, however, an optical deception in the case of an animal leaping from the water, and falling down again, which makes one imagine its back to be much more curved than it really is. Thus, when even a salmon leaps, it seems bent so far like a bow; and yet we know that the spine of a salmon bends little at all, either upwards or downwards. The cause of the deception is in the eye following the general curve in which the average mass of the body is carried, during the leap; and as the real shape is not very well seen while the animal is in motion, it is readily, and indeed necessarily, associated with this curve.

As might be expected from its more discursive habits, the flesh of the dolphin is inferior to that of the porpoise. Formerly, it was more highly prized than that animal, probably on the account of its greater rarity; but now it is not sought as food, or considered valuable for any purpose to range the sea without molestation. It is a voracious animal, and will feed upon any garbage which is thrown overboard by the crews of ships, and it is probable that this kind of food is its chief inducement for following them; but it does not appear that this species attacks any sort of prey but fish, though it has sometimes been said that it assails the whalebone whales.

The common dolphin is of little or no value as an oil animal, as the seas which it inhabits supply it with abundance of food at all seasons, while the width of its range, and its being pelagic, rather than a frequenter of the bays and banks, keep it thin, from being constantly in exercise.

Delphinus orca (the Grampus) is one of the largest and most powerful of the genus. It attains the length of twenty-five feet, and when it does so, it measures not less than twelve in circumference, and its dorsal fin is at least five feet in height. The upper part is black, the under white, the sides mottled, and there is generally a white spot upon each shoulder. The lower jaw is broader than the upper, and each of them is furnished with about thirty teeth; three are in the front part of the mouth, slender and blunt in the fronts, but farther in the gape they are larger and conical, with sharp points. The grampus is found in most seas,—the Atlantic in almost every latitude, the Mediterranean, and even on the coasts of Britain, though it is rare. There appear to be several varieties, at least in so far as the colours and the height of the dorsal fin are concerned; but their habits appear to be all very much alike. They are very active and voracious animals, preying not only upon fish, but upon seals, porpoises, and dolphins, though it does not appear that they, as is sometimes alleged, attack and bite the Greenland whales.

In their general habit they are pelagic animals, and seldom remain for any length of time on the surface; and this habit is sometimes the cause of stranding to them, as, when they come into the shallows, they are apt to get grounded. When attacked, they make a powerful resistance. The females are much attached to their young, and can hardly be made to abandon them even by personal danger. The great activity and strength of the grampus, and the perfect uselessness of its carcass after it has been killed, cause it to be little sought after. Even when it gets stranded, the labour of putting it to death is considerable, and all that is got for the labour is a great mass of flesh, which speedily becomes putrid, and renders the place where it lies unpleasant and unwholesome. It does not appear that much fat is ever accumulated upon these animals.

Delphinus gladiator (the gladiator dolphin, or sea-sword) is another large species, rivalling the grampus in length, but not quite so thick in the body. It gets the name of sea-sword from the shape of the dorsal fin, which is about five feet long, one foot and a half in breadth at the base, and tapering to the front. The upper part of the body is blackish-brown, the under pure white, and there is a black stripe on the side extending from the tail to near the articulation of the swimming paces.

It differs from all the varieties of the grampus, in having the snout much rounded, all the teeth strong and sharp-pointed, the jaws of the same length with each other, and the dorsal fin situated much farther forward.

This is an animal of great boldness and strength. Like the rest of the genus, it is gregarious, at least to a certain degree; and though we must not implicitly credit all the marvellous stories which are told of it, yet it is possible that several of them may make a joint attack on a Greenland whale. The tongue of that large animal is said to be the part at which they aim; and there is little doubt, that if one once gets a hold, others will endeavour to follow the example.

They are said not to be so fond of meddling with the full-grown whales; but the pack will readily attack a young one, bite it in various parts, and even catch it by the lobes of the tail. If they can once fasten in this part, which, from its length and fibrous texture, gives them a very firm hold, the power of the whale is at an end, as it cannot shake off the enemy, which hangs as staunchly by this part as a bull-dog does by the nose of a bull, or a lion by the muzzle of a buffalo. The others then bite with impunity, till they throw their victim into an agony of pain; and when it lolls out its tongue, which it does when severely hurt, the others are on the alert to seize that organ.

Instances have been mentioned of these animals carrying off, in the Greenland seas, the entire carcass of a whale, which several boats were in the act of towing, and that, in spite of all the efforts of the rowers, they bore it off in triumph.

This powerful animal is chiefly found in the north-west parts of the Atlantic, near the whale-fishing ground in Davis' Straits, but it occasionally ranges farther to the south; although it does not appear to be nearly so discursive in its habits as the grampus.

In the year 1793, one gave a specimen of its strength in the water in the Thames. This is not the only individual that has come into that river; but it was attacked by four men in a boat, and struck with three harpoons, and made fast. Still it drew the boat with the four men twice from Blackwall to Greenwich, and once as far up the river as Deptford; and, as this one was astray, out of its natural beat, we may naturally suppose that it was exhausted, and not so powerful as it would have been in its native seas.

Hyperöodon. There is only one species of this genus, the beaked whale, or bottle-head (*Hyperöodon*, Butskopf), which, in the structure of its teeth, is the most peculiar of all the marine cetacea. It is most abundant in the cold latitudes, but has been met with occasionally in many parts of the North Atlantic and North Sea. It is about twenty-four feet long, and fifteen in circumference at the thickest part, which is at the articulation of the swimming paws. The body thence to the tail has the form of a cone, and the lobes of the tail, which are concave at their margins, measure about six feet from tip to tip. The general colour is a deep blackish-brown, relieved by paler streaks and blotches on the under part. The depth and length of the head are nearly the same, but the mouth is lengthened out in the form of a sort of beak. In the lower jaw there are only two teeth, situated on the anterior part, conical and pointed; but the upper jaw and palate are beset with small sharp teeth, which vary considerably in size. The jaws are nearly of equal length; the tongue adheres to the lower jaw, and is toothed on the margins. The blow-hole externally is single, and crescent-shaped, with the cresses directed to the rear. The eye is placed over the corner of the mouth, and appears nearly in the middle of the head. The skin is very thin, the blubber yellowish, and the flesh of a much darker red than that of almost any others of the order.

Such are a few points in the outline of some of the leading species of this very remarkable order of animals, at least of those which are inhabitants of the sea. They vary in their modes and means of feeding, but they must all be considered as animal feeders; for, though the whalebone whale neither does, nor can bite any animal, but lives by filtering the water through the fringes of its plates of whalebone, yet the substances which it procures by this filtering are animal, not vegetable; and, though that portion of the sea in which it is chiefly found is technically called the "green water," yet the greenness arises from animal matter, not from vegetable. There still remains one subdivision or group of the order which are wholly or chiefly vegetable feeders. They are inhabitants of the warmer parts of the world, and are found in the rivers and their estuaries rather than in the ocean.

Herbivorous Cetacea. These differ much from the carnivorous cetacea both in their appearance and in their habits. Their teeth are flat on the crowns, and adapted for dividing and bruising vegetable substances; and some of them often quit the rivers to crawl about and graze on the banks. They have hairs in the form of mustachios, and the females have two pectoral mammæ. Hence, as Cuvier very justly remarks, they may have given occasion to the ancient fables of tritons and sirens, and also to the modern one of mermaids, though the mermaids of the Scotch, and of the rest of the north of Europe, to which these herbivorous cetacea very seldom, if ever, come, have most probably been albino seals, unfortunates which the rest of these wily animals are said to drive from the common society, and compel to sit solitary among the rocks.

In their general characters, these animals appear to be intermediate, between the cetacea of the ocean and the seals, though they partake more of the general characters, especially of the structural and physiological ones, of the former. They have the stomach divided into four separate sacs, of which two are lateral, and the intestine is furnished with a very large cæcum. The breathing holes are perforated in the upper part of the skull, as in the other cetacea, but they are continued in the soft parts to the termination of the muzzle. The lips are thick, the upper one usually divided in front, enlarged at the sides, and beset with bristly hairs. The external openings of the ears are very small, and concealed by the epidermis; the eyes are also small, but have the expression of those of land animals. The swimming parts are larger and rather more developed than those of the marine cetacea. The fingers are larger, though they are included for their whole length in the membranes, and some of them at least terminate in rudimental nails. They are rather ungainly walking apparatus, but they still enable the animals to make a sort of progressive motion along the banks, to which they resort to traverse the herbage.

The posterior termination of their bodies is a tail, as in the cetacea, and not the union of a tail and two imperfectly formed swimming paws, as in the seals; but in some of the species at least there are rudiments of the bones of a pelvis imbedded in the flesh of the flanks; and, imperfectly developed as these bones are, they no doubt assist the animals in maintaining their vertical position—that is, preventing them from rolling over on the side as they attempt to advance the swimming paw, as is the case with the whales and dolphins.

There are several species, the history of some of which is not, however, very clearly made out. They have been hitherto found only in the waters of the warmer latitudes; and those of the Atlantic, and of the Indian and Pacific Oceans, are described as different genera. When we say of the oceans, we principally mean the shores, and estuaries of rivers emptying themselves into the oceans; because we are not to expect that any vegetable-feeding animal can be pelagic, and keep out in the open sea. As there are, however, many fishes and some reptiles—turtle, for instance—which live in great part upon the vegetable productions of the tropical seas, it is by no means unlikely that animals of this group may do the same.

So far as these animals are known, they are all very wild in their dispositions, and their flesh is much better flavoured, and more eagerly sought after as food, than that of any of the other cetacea.

The Manati (*Manatus*, Cuvier). By the older naturalists this animal was very incorrectly classed with the mouse (*Trichechus*), which belongs to the seal family, and has not the structure of the habits of the cetacea. The name *Manati* is said to have been given to the animal on account of the slight hand-like form of the swimming paws, and has been somewhat strangely metamorphosed into *lamantine*, by the incorporation of the article *la* with the original name.

These animals have been found only in the great rivers of South America and of Africa, which discharge their waters into the Atlantic within the tropics; the Amazon and its branches especially on the American side, and the Senegal and Gambia on the African. In the Niger, and its continuation to the bight of Benin, and the Quorra, these animals are not known to any great extent, but it is most likely that they may also be found there, and probably in the river of Congo, though the current of that may be too rapid, and its banks too steep and rugged for animals whose powers of motion upon land are so limited. Those which are found in the African rivers are described as differing from the American ones, so that there may perhaps be two species, *Americanus* and *Africanus*, and probably varieties of one or of both. At present, however, our information, especially as respects those of Africa, is rather vague.

In America, on the other hand, they are well known; and along the whole valley of the Amazon, up almost to the mountains, their flesh forms a considerable part of the food of the people.

The characters of the manati are: the body oblong when seen on the side; the tail fin oval and rather elongated; the grinders eight, with square flat crowns, marked with transverse ridges; but the adult animals have neither incisive nor canine teeth. The young are said, however, to have two sharp and pointed teeth in the intermaxillary bones, but these disappear at a very early age. The paws have the rudimental nails which have been mentioned, but they are seldom complete on all the fingers; still they give some support to the termination of the paws.

These animals are locally known by the name of *vacca marina*, or sea-cow, and certainly they form in many respects the nearest approach to the genus *bos*, which is to be met with among animals frequenting the water. Among the native mammalia of South America they are the ones whose flesh is most abundant in quality, and also most palatable for human food, and for these reasons they are the most valuable to man.

In the course of the present work we have frequently had to remark upon the very peculiar characters of this part of the world—in particular, that many parts, especially of the great tropical valleys, are alternately parched land and fresh-water sea. Such a state of things is perfectly inconsistent with the existence of browsing animals—with the ruminantia, which are found in most other parts of the world. It is, as it were, the extreme of vegetable feeding, where not only the semi-aquatic buffalo, but even the hippopotamus, must give way, as they would be subject to starvation at one season, and to drowning at another; for, when the rains come, there is too great a breadth of the country laid under water for allowing any animal which walks the bottom to subsist. This is farther increased by the quantities of weed and sludge, in which the feet of a walking animal would stick beyond the possibility of extrication.

We have this partially in the tropical parts of Asia and of Africa, but nowhere to the same extent as in South America. We have, accordingly, herbivorous cetacea in those places, but they are nowhere so numerous, or so exclusively the herbivorous animals of the valleys, as in the case of South America, where the principal grazing animal is committed to the water as its general habitation, and its means of transport from place to place. The power of swimming which these animals possess not only renders them quite safe from those casualties to which ruminant animals would be subjected when the rains and inundations come, but it gives them a facility and a range in their migrations in quest of food which not even the fleetest of the antelopes, or any of the mammalia which walk upon the earth, can possess. These last are hemmed in by the mountain ridges, by the deserts, and even by the larger rivers, and their march is laborious, and their food often scanty. The manati, on the other hand, launched upon the water, buoyant, and at home in that element, can, without any fatigue, migrate for thousands of miles whenever such migrations become necessary. In these extended marches they are not restrained even by the sea; for although, as we have already said, it is not very probable that vegetable feeders shall range the breadth of the ocean, yet it is certain that these animals often pass along the shores to very considerable distances.

They also have this advantage, that they are far more certain of provision by the way than the walking animals which migrate on land. In tropical countries there is never any barrenness if there is water, whether that water be a lake, a stream, or the sea; and thus the animals in question can always approach the bank, and feed whenever a supply is required.

When full grown, in places which are favourable for them, these animals are very large, generally more than fifteen feet in length, and sometimes twenty or upwards. They are gregarious, and often found in numerous herds, especially on the low meadows by the banks of the Amazon, where the soil is humid and the vegetation rich. They are gentle in their dispositions, and it does not appear that they offer violence to any creature; and when they are threatened with danger they move off for the water. The females have generally two at a birth, and the period of gestation is said to be about twelve months. The largest of these animals, that is to say, those which are about twenty feet in length, weigh between three and four tons; the swimming paws are rather less than a fourth of the whole length from the point of the muzzle; the skin is of a deep blackish grey colour, slightly granulated on its surface, and having a few scattered hairs here and there, though very few, with the exception of those which form the mustachios.

The manati of Africa is smaller than that of America, being seldom more than about eight feet long and seventy or eighty pounds in weight. Its colour is blackish ash, with the iris of the eye blueish. The bones of the head are said to be shorter in proportion to the length of the animal, and the different parts are said to be more marked. The differences are, however, comparatively small, and the habits of both are nearly the same.

The Dugong (*Halcione*—daughter of the sea). This is much more a marine animal than the manati; and though it ascends the larger rivers to some distance, it is chiefly found in the salt water, and its principal food is understood to be sea-weed. It is found chiefly on the south-east of Asia. The name "dugong" is said to be Malay, and to have much the same meaning in that language as "sea-cow." Illiger's generic name *Halicore*, of which "sea-lass" is perhaps the best English translation, is not very applicable; but the animal certainly claims to be made a distinct genus from the manati.

There are some differences in the skeletons, as for instance, the dugong has a pair of ribs more, a greater number of vertebræ in the tail; the rudimental pelvis rather more developed, and also the clavicles. The principal differences, however, occur in the teeth; the cheek teeth of the dugong consist of two cones united together, and with their tips flattened and formed into small tubercles, and the teeth in the fore part of the jaw do not perish early in life like those of the manati; they continue and become true tusks, firm and sharp-pointed, but concealed by the thick and fleshy upper lip. These lips are granulated in their appearance; the upper one projects so far over the lower as completely to cover the opening in front, and the extremity of it is, in part at least, prehensile. The whole animal is covered with a thick skin of a blueish grey colour, with spots of a darker tint on the flanks, and white spots on the belly. The muzzle is beset with hairs intermixed with horny spines, those on the lips being about an inch long. Those parts of the jaws with which it seizes the sea-weed and other plants on which it feeds are beset with horny tubercles; and it is probable that it also uses the tusks of the upper jaw in loosening the sea-weed from the rocks. The eyes are very small, and covered with a third eyelid; the ear-openings are exceedingly small, and the nostrils are on the tip of the muzzle, so that the animal can breathe freely with the whole of the feeding apparatus under water.

This animal is found in the greater part of the Indian ocean, and the south and west of the Pacific. Its head quarters may be considered the oriental archipelago; but it is understood to shift with the monsoons, being more abundant on the east of the

Limdel islands during the north-eastern monsoons than during the opposite one.

The Stellere (*Rytina*—wrinkled). This animal is found in much colder latitudes than any other of the herbivorous cetacea. Its chief habitat is the northern parts of the Pacific, where it occurs both on the coast of America and on that of Asia. The history of this animal was, for some time, obscure; but it is now tolerably well cleared up, and there is reason to believe that, in some parts of the north seas, stray specimens of this genus may have been the mermaids, of which the accounts are too numerous not to have had some foundation, however much of that which was raised on it may have been fabulous.

The most remarkable character of this animal is the teeth, of which there is, properly speaking, only one in each side of each jaw. These teeth are flat on their crowns, with many zig-zag ridges of enamel; but the intermediate matter, which forms the body of the tooth, is of a horny nature. They have no true roots, but are united to the jawbones by means of cartilage, in the same manner that the plates of baleen in whales are united to the bones of the head.

The head of the animal is obtuse, without any distinct appearance of neck; the body is thick at the middle part, but tapers off to the tail. The whole body is covered with a very thick epidermis, which is naked, or without detached hair; but it may be regarded as a coat of short hairs, all soldered into one compact mass, for it consists wholly of short fibres which stand perpendicular to the surface of the *epidermis*, or true skin. This structure of the epidermis is certainly curious, but it is in the structure merely that the curiosity consists; for, in all animals, the substance of the epidermis has a very considerable resemblance to that of hair, and, indeed, even hair and feathers are of the same nature as the epidermis, and, in fact, productions from it. The fingers of the swimming pores are closely united to their terminations by the membranes, and they have no distinct nails, though the tips of the pores are callous. The caudal fin is crescent-shaped, very broad, but not very long, and its two points are very sharp. The females have two mammæ on the breast, which are rather prominent.

The lips have the appearance of two great sausages; the mouth is small and below the muzzle; the eyes are, in great part, covered by a cartilaginous membrane, which forms a sort of third eye-lid; there are no external ears; and in the paws, the bones of the fingers are short and soldered together, so that this animal is not more powerful on land than the cetacea properly so called. Two of the vertebræ of the neck are so closely united, that some describers have stated them as being only six in number; but this is a mistake. There are nineteen vertebræ in the body and thirty-five in the tail. The rudimental bones of the pelvis are long and round, and attached to the tail vertebræ of the body by ligaments. The stomach is not so completely divided into compartments as in most of the other cetacea, but the intestines are very long; the cæca are large, and the colon is turned and partially divided by septa. The whole of the alimentary apparatus, indeed, indicates a very laborious digestion.

There is only one known species, an inhabitant exclusively of the sea, in which habit it differs from the rest of the group, more especially from the manati. The skin of the body is very rough and wrinkled, and was compared by Steller, the first person who observed and described the animal, to the rough bark of an old oak tree. The head is small as compared with the body; it is elongated, and diminishes down from the top to the muzzle. The mustachios are several inches in length, re-curved, and of a white colour. The nostrils are in the front of the muzzle; and the eyes, which are black, and about the same size as those of a shark, are placed in the same longitudinal lines with the nostrils, and separate mid-way between them and the openings of the ears. These openings are near the neck, and very small for the size of the animal.

The swimming paws are situated immediately under the neck, and they enable the animal not only to keep itself steady to the action of the tail in swimming, but to hold on upon the crags of the rocks, from which it bites the sea-weed. This animal attains the length of at least five-and-twenty feet, and measures about eighteen in circumference at the thickest part. The weight, when of this size, is between three and four tons.

These animals are gregarious, and assemble in numerous troops in the bays when the weather is calm, and they often enter the mouths of rivers. In their progress the old ones generally surround the young, in order to protect them from danger. They pair in spring, and bring forth in autumn, the period of gestation being understood to be nine months. They swim with about half the body above the surface of the water. In stormy weather they come near the shores; and in winter, when the shallow water freezes to a considerable distance southward, they are scantily fed, and by the time that the ice clears away they get very lean.

The inhabitants of eastern Asia, especially of Kamtschatka, the Aleutian Islands, and other adjoining parts, pursue these animals with great assiduity, esteeming them the most valuable products of the sea. Their tough hides serve them for boats, which are generally stretched upon ribs of bone or whalebone, and they are very light and buoyant. The flesh is much relished by some of these semi-barbarous tribes. In the old animals it is tough, and requires a great deal of cooking; but in the young it is something intermediate between veal and pork. The fat of the young very much resembles that of the hog.

These animals are exceedingly numerous in the part of the sea to which allusion has been made, more so perhaps than any cetacea are in any other part, if we except the manati in some parts of the rivers of South America. As they are surface animals, and do not frequent the deep water, except on their voyages from place to place, they are very conspicuously seen, and give a character to the seas in which they are found. It is said that bones, though no living individuals, have been seen in the Greenland seas; and if it be true, as it is highly probable, that the point of lowest temperature is the situation of the magnetic pole, it is by no means unlikely that they may pass from sea to sea further to the north.

CETERACH (Willdenow), is an English fern, called by Linnæus, *Asplenium Ceterach*, and *Grammitis Ceterach* by Swartz. It has been long used medicinally.

CETOCHILUS. A minute genus of crustaceous animals, belonging to the order *Branchiopoda*, section *Lophyropoda*, sub-section *Carcinoida*, and nearly allied to the genus *Cyclops*, from which it differs in having a pair of eyes. These little animals are about one-sixth of an inch long, of an oblong-oval form, and are furnished with two very long, and two short antennæ, a mouth, five pairs of short foot-jaws, and five pairs of swimming, bifid, and ciliated legs, with a small narrow five-jointed abdomen, the last segment of which is provided with several long setæ.

This genus was established by M. Roussel de Vauzème, in the Annales des Sciences Naturelles for the year 1834, and affords a most interesting instance of the great share which the minute tribes of annulose animals take in the economy of nature.

The little creatures of which this genus is composed inhabit the Pacific and Atlantic oceans, beyond the 42° of south latitude; where they swarm to such an extent, that, at certain seasons, they form dense masses upon the surface of the sea, to which, from their being of a bright red colour, they give a bloody appearance, serving also for food for the whales which abound in those parts of the ocean.

It had been long known that whales feed upon various minute animals. Fish also, and crustaceous animals, as well as medusæ, serve for their food; but, in general, direct observations upon the genera and species of these latter animals are wanting in the works of travellers—a want which we trust the establishment of those societies, which are peculiarly devoted to various branches of zoological knowledge, will tend to supply, by first showing the necessity for such observations.

M. de Vauzème, who accompanied a party of whale fishers to the southern ocean, has, to a considerable degree, made known various interesting circumstances respecting those animals, which are in various ways connected with the whale, including those of the *Cetochilus australis*. This expedition remained near the islands of Tristan d'Acunha for four months, occupied daily in fishing, and without discovering the animals upon which the whales feed. In passing, however, thence to Cape Horn, in the month of February, the surface of the sea was discovered one morning to be streaked as though with blood, in red lines many leagues long. The experienced fishers immediately announced that they were arrived at the station of the whales, and shortly afterwards some of these monsters of the deep were seen sporting in the midst of these bloody streaks. The sea also appeared to be in a constant ebullition from the rapid movements of these living masses, which gave to it so extraordinary an appearance. On examining the living animals whilst in motion, the hind legs were observed to be directed towards the head, and by a sudden movement thrown backwards, so as to give the body a progressive jerking kind of motion; the large antennæ were also curved in a semi-circle round the sides of the body, and appeared to assist in locomotion. Although conglomerated in the ocean in compact and regular masses, each animal in the space it occupies possesses sufficient liberty for all its movements. Sometimes during rough weather, whole shoals of these animals were lifted with the waves above the surface of the sea, falling upon the sails and other parts of the vessel. The whales devour myriads of them. The American fishermen term these red shoals of animals the food of the whale; and they informed M. Vauzème, that, during the months of October and November, they remain hidden in the depths of the ocean. Later in the season, and when they are ready to deposit their eggs, they come to the surface of the sea. This circumstance therefore is noted by the sailors as the sign of the departure of the whales, which shortly afterwards approach the bays. After the eggs are deposited, these red streaks upon the surface of the sea become yellow. The food of the whales is then technically said to be ripe, and the whales soon depart. This change of colour, produced by the presence of the eggs, M. Vauzème was informed by experienced fishers, takes place soon after the appearance of the animal, although he did not observe it himself.
