A, a branch of the filbert tree; *a*, healed wound caused by the introduction of the egg of the nut weevil; *b*, extremity of the nut; *c*, exit hole of the grub. B, the grub of the nut-weevil. C, the pupa of the same. D, the perfect insect, *Balaninus nucum*.

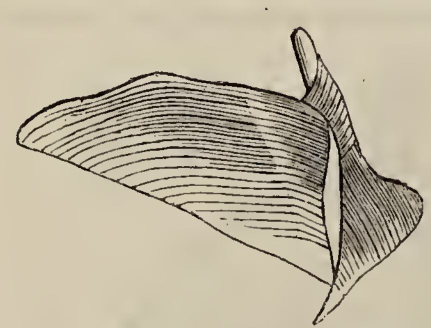
the shell and pushes itself through the aperture thus made, which, although it appears too small to have admitted of its passage, is easily effected, from the softness and contractile powers of the body, and not by the assistance of claws, as stated in the work above referred to, for the simple reason that the insect in this state is not armed with claws. The maggots then descend into the earth, where they remain all the winter, changing to pupæ, according to Rosel, in June, and appearing in the perfect state in August. There are about a dozen British species of the genus, which feed upon various vegetables: the *Curculio nucum* of Linnæus, whose proceedings are above described, being the type; it is about one-third of an inch long, and of a rich brown colour.

BALANOPHOREÆ. A natural family of monocotyledonous plants, containing only a few genera and species. By some authors the term *cynomomeæ* is applied to the order. Its essential characters are: flowers monoecious, collected in dense, roundish heads. Barren flowers, supported on stalks; calyx deeply three-parted; stamens one to three, epigynous, with the filaments and anthers united. Fertile flowers, ovary, inferior, one-celled, one-seeded, crowned by the limb of the calyx; one filiform, tapering style; stigma simple; fruit a rounded, one-celled, thick pericarp, closely united to the seed.

This is a curious order, having little affinity with any other. In some respects it resembles the arum tribe, but differs from it in possessing an inferior ovary. The plants included under the order may be said to be like the mushroom tribe in appearance. They are leafless, parasitic plants, provided with fleshy, horizontal roots, and having their stems either naked or covered with scales. They are found in warm climates, as in the West Indies, South America, and the Cape of Good Hope. Little is known in regard to their properties. The *Cynamomum coccineum*, a plant found in Malta, was formerly much used in medicine under the name of *Fungus melitensis*. It acts as an astringent, and was employed successfully in dysentery and hæmorrhage.

BALANUS (Lamarck). *Lepas tintinnabulum* (Linnæus). The arrangement of these mollusks will be seen under the article BALANIDEA, in which the general characteristics of the animal are also given.

Lamarck, and modern naturalists, have only classed in this genus such shells as appeared univalve by the connection of their valves in a peculiar manner,



One of the valves of the B. gigas.

Valve of the Acasta.

their lower part closed with testaceous matter, and the operculum consisting of four pieces. These shells are usually of a conical form, more or less elevated, sometimes narrower at the base, in the form of a tulip, irregularly shaped, from the circumstance of their being crowded together, in large clusters, on the substances to which they are affixed. Their aperture is subtriangular or elliptical; the base closed by a solid testaceous termination, firmly fixed to various bodies, the four pieces forming the operculum inserted internally near the base, forming a kind of pyramid at the upper opening of the tube.

B. Gigas.

B. spinosus.

B. spongites.

Three species now form this genus; the first is that in which there is no support, or merely a membranous one, as in the *Balanus spinosus;* the second includes those whose support is rather irregular, but usually very considerable, as in the *B. gigas;* and the third is that whose base or support is conical, hollow, nearly regular, patelliform, and found inclosed in sponges. From the form of this species, and their not being able to stand upon their own basis when detached from the substance inclosing them, Dr. Leach separated them from the genus *Balanus*, and constituted his genus *Acasta* of them. De Blainville, however, does not admit of a sufficient reason for separating them, in which opinion many modern naturalists concur.

These singular shells give rise to much interesting speculation as to the mode of their structure, which differs from all other shells; their increased growth in height and circumference is easily perceived in each of its stages, the one on the conical part, and the flake, or testaceous separation at the bottom, exhibiting the other; it may therefore be conjectured that the animal, when necessity obliges it to increase the size of its habitation, possesses the faculty of detaching the parts forming its exterior, and, after having added a given uniform portion to each, of fastening or soldering them together again, like the sutures of the human and other skulls.

Balani are named as one of the dishes at the famous gastronomic feast given by Lentulus, on the occasion of his being named "Flamen Martialis," a priest of Mars; and some species are now eaten by the northern nations. Their flavour nearly resembles that of the common mussel, but the substance is more stringy or tough. The name of this genus is derived from an acorn, *balanus*, which many species closely resemble in form.

As this genus is now circumscribed, it still includes a considerable number inhabiting all seas. Lamarck characterises twenty-nine of the two first sections, of which three or four are fossil species, and four of the second. De France enumerates sixteen fossil species, some of which are found in this country; they are, however, by no means common.

A further arrangement of this genus might be made with propriety by separating the species having six valves in the operculum, and a due consideration of the internal portion which some of the species possess double.

BALISTES (File Fish). A genus of fishes belonging to Cuvier's order, *Plectognathes* (soldered or united jaws), and to the second family of that order, *Sclerodermis* (hard skin). The name *balistes* has been given in consequence of the length of the dorsal spine, by which the fish appear to move like the arm of a cross-bow. The characters of the order will be explained under PLECTOGNATHES, and that of the family under SCLERODERMES. But it may not be improper to mention here that all the order are intermediate in their general characters between the bony and the cartilaginous fishes, their skeletons being formed of matter which is partially flexible, and the different portions partially soldered together. This is not so much the case as in the cartilaginous fishes; and it is more conspicuous in the bones of the head, more especially those connected with the upper jaw, than in any other part of the body.

It is a general law that those fishes which have a deficiency of bony matter in the skeleton have it precipitated, or accumulated, in some form on the surface of their bodies, as in the thorns on skates, the tubercles on sharks, or the plates upon sturgeons.

They are thus as it were intermediate between vertebrated and invertebrated animals, having the skeleton of the former, and partially also the shell, crust, or other form of covering, of the latter; and the condition of these two parts appears to be pretty constant as a whole, but to fluctuate in the two, sometimes going more to the one, sometimes more to the other.

In the two families of *Plectognathi*, the disposition of the osseous matter, though it is to the surface in both, is very distinct in each, so as to form a leading character. In the one division it goes to the jaws, and covers them with plates of ivory, which may be considered as continuous teeth, or teeth soldered by nature into one piece, though they have been styled *gymnodontes* or "naked teeth." In the division which includes the genus *balistes*, it goes to the external covering of the body, in osseous granulation over the skin, in strong spines to the fins, or in both. The latter is the case with *balistes*, which gets their common English name of "file fish," from the skin being granulated like a file, and the name *balistes* from the dorsal spines, or long rays in their first dorsal fins, which are not only much produced, but articulated to a peculiar bone, which enables them to perform much more motion than the dorsal appendages of many other fishes; but what function that motion performs in their economy is not known.

The general characters of the genus are, the muzzle long and conical and the mouth small (though these are rather characters of the order), the body compressed; each jaw furnished with eight teeth in a single row, the points of which are often trenchant, or partially chisel-shaped, and thus fitted for biting sea weed. Their skin is scaly or granulated, and the scales are of more consistent matter than those of the bony fishes, but they cannot be considered as absolutely bony, like the tubercles and plates on the cartilaginous fishes. The first dorsal fin is composed of one or more spines, articulated to a peculiar bone, and that bone is connected with the bones of the cranium.

The first dorsal fin is more or less moveable in the direction of the mesial plane of the body. The second dorsal fin is soft and generally large; but it varies in the different species: it is, however, in general, placed immediately above the anal fin, and the two very often resemble each other. The caudal fin varies very much in its form, being in some crescent-shaped, with long projecting points at the terminations; in others it is nearly square; in others again it is rounded, and on some it is nearly lance shaped. Many of the species are without ventral fins; but all have bones in the sides of the cavity of the body, which are articulated to the shoulder-bones. These bones are, in some of the species, capable of a very considerable degree of motion; and sometimes they are armed with spines at their extremities, and may perhaps be considered as the rudiments of ventral fins, and be in some way auxiliary in the process of swimming.

The gill-opening of these fishes is a mere slit, without gill-lid, or gill-flap; so that in this respect, as well as in some others, they approach the character of the cartilaginous fishes.

The species are very numerous, and generally inhabitants of the torrid zone, and invariably of the warmer parts of the ocean, none of them being found near the poles, or in very high latitudes; but there is at least one species in the Mediterranean, the one from which the genus was at first named by Artedi. They are usually found in the shallow water near the rocks, where their colours, which in many of the species are bright and finely contrasted with each other, have a very brilliant effect. They are said to feed upon sea-weed, and also upon the polypi by which the coral rocks of different sorts are formed; and when they feed upon the latter, their flesh is said to be poisonous, or at any rate unwholesome. It is probable, however, that their principal food is sea-weed, at least in those which have trenchant teeth; and Cuvier mentions that as being the substance he found in the stomachs of those which he dissected. The flesh of none of the species is valuable as an article of food. It is dry and tasteless, and in many of the species it is to be suspected, if not actually unwholesome.

The sizes, shapes, colours, and other external characters, which, from the very imperfect knowledge we have of their habits, are almost the only ones of fishes, vary so much that they have been divided into four subgenera,—*balistes*, properly so called, *monacanthus*, *aluteres*, and *triacanthus*; but, so far as is known, their habits all resemble each other.

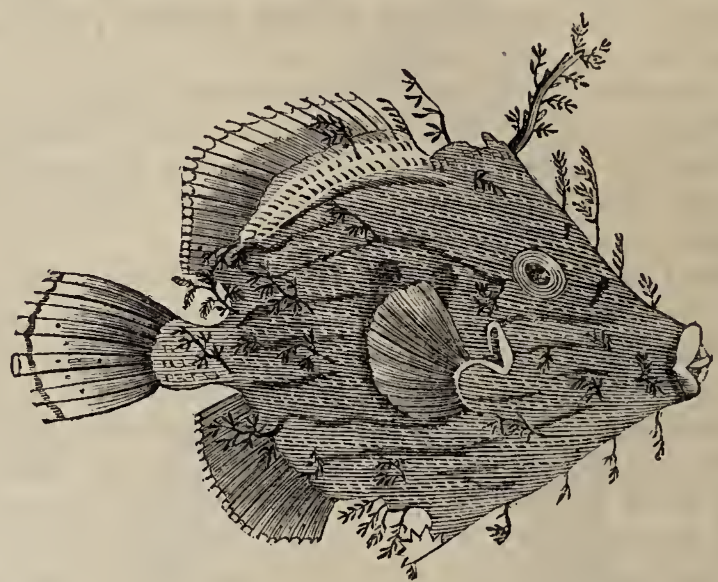
The *balistes*, properly so called, are those which, from the texture of their skins, more immediately merit the name of "file fish." They are covered with moderately large tubercular scales of a rhomboidal form and very hard texture, which are not imbricated or overlapping each other, like the scales of ordinary fishes, nor are they, as is generally the case with these, free at their posterior edges; but adhere closely to separate portions of the skin, with channels between.

There is here one point worthy of remark: the more that the scaly appendages to the skins of fish resemble bone, they are the more persistent; and when they attain the bony character it is doubtful whether they are ever shed; whereas, the imbricated scales, which have great part of their posterior edges free, often adhere so slightly that they can be rubbed off by a mere touch, and are probably shed every season, like the hair in most of the mammalia, and the feathers in most of the birds. In those species which have the scales deciduous, the colour is principally or wholly in the scales, and is subject to a change of bloom or lustre, being most bright in the breeding season. When the scales are osseous, again, the colour, in part at least, is in the skin, and the scales have not so much bloom in the breeding season. Scales of this structure and arrangement cannot be so efficient in the act of swimming as free scales; and hence the fishes which have them are either supplied with an extraordinary development of the fins, a peculiar form of body which facilitates their motion, or they are local and do not range far. Length, strength, and power of motion in the rays, are the general attributes of these fins. The body is either elongated or it is compressed laterally, the last of which is the case with the balistes. The bones of the ribs may also be considered as in some way contributing to the act of swimming; and, besides their motion, they are often accompanied by a power of extending the cavity of the body to a great extent by distension. But the balistes generally have not that power to such an extent as some of the analogous genera. In almost all cases, however, in which a fish has the power of inflating the cavity of its body, the part which it inflates is in some way armed with projecting members; and therefore one may conclude that it assists in some way or other in their motion through the water.

The first dorsal fin of the true balistes consists of three spines, of which the first is by much the longest; the last very small, and directed to the rear. The extremity of the cavity of the body is projecting and rough; and there are at the hinder part of it produced spines, which may be considered as the rudiments of ventral fins,—at least there is little doubt, that, aided by the action of the bones and the general roughness, they in so far answer the same purpose. Some of this subdivision have spines on the sides of the tail, and others have large scales or plates behind the gill-openings; but, in general, those which have the one of these characters are without the other.

Monocanthus have, as the name imports, only one conspicuous spine in the first dorsal; but they have one, or indeed two, rudimental ones, the last of which is hardly visible above the skin. The single spine is toothed on its posterior edge, the teeth being recurved like barbs; and the spine itself is much longer in proportion than in the first subdivision, having more the appearance of a barbed horn than of part of a fin.

Some of the species of this subdivision have the bones in the sides of the cavity susceptible of much motion, and the extremity of the abdomen provided with a rayed apparatus, capable of being folded and unfolded like a fan; nor is there any doubt that this apparatus aids them powerfully in their swimming. These have also spines on the sides of the base of the tail. Other species have the sides of the tail furnished with rough bristly appendages. Indeed, it is not possible generally to describe the appendages which the species in this subdivision have to the covering of their bodies. Some have their bodies beset with tubercles or little peduncles or stalks, and others have them branched, as if they were small sprigs of some kind of aquatic plant. One of the species, *pencilligerus*, of which the following is a figure, will illustrate that character.



Balistes pencilligerus.

Of *Aluteres*, which has also only one dorsal fin, the species are not so numerous, or, at all events, so well defined. See ALUTERES.

Triacanthus differs from all the other subdivisions, in having ventral fins, and the termination of the cavity of the body not prominent or bristly. These ventral fins are supported each by a large spine, which, however, does not stand out, but is united to the abdomen. Indeed, the fan-like apparatus in which the abdomen of some of these fish terminate, may be considered as two ventral fins joined together. The name of this subdivision would imply that the first dorsal fin has three spines; but it often has more (and there is but one known species) though the first spine is much larger than any of the others.

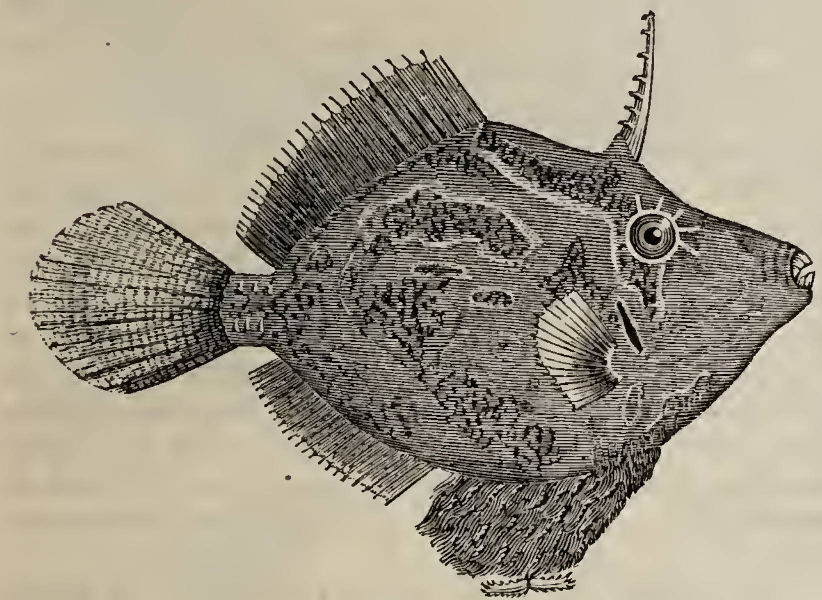
Though, as has been said, of little or no use as food, fishes of this genus attract attention by their singular shapes, and also by their bright colours; and they are known to British sailors frequenting the seas which they inhabit by the general name of "Old Wife."

An enumeration of all the species would be a long list, and it would be far from a popular one, as many of them are but little known. We shall therefore notice only a few of the more interesting—that is, of those that have been observed with most attention. We shall notice them all under the generic name balistes; and add the names of Cuvier's subgenera in parentheses where necessary.

Balistes capriscus (*balistes, C.*) is the one which has been longest known. It is the only one which inhabits the European seas, being found in the Mediterranean. The general colour of this species is brownish-grey, with blue or green stripes or spots. It is found in the Mediterranean, and also in many parts of the tropical seas. It appears to vary considerably both in colour and in size, and hence different authors have described it under different names,—which has indeed been the case with several others of the genus. The skin is smoother, and the depth of the body less than in some of the other species.

Balistes niger (*balistes, C.*) is altogether black, excepting a portion round each eye, and a bar on the basal part of the second dorsal, the anal and caudal fins, the last of which has the exterior rays produced forming two points. It has also some of the lateral teeth in the upper jaw produced, and in part resembling the canine teeth of mammalia. The dorsal fin consists of two rays, or spines, quite detached from each other; the first large, the second very small. The head is also much shorter, and the gape of the mouth much wider than in most of the other species. Instead of ventral fins, it has one large ray at the caudal extremity of the abdomen, covered for the greater part by the skin, or at all events united to it. The skin is very rough, in lozenge-shaped tubercles; most of the rays of the fins are branched at their terminations; and there are, on each side of the base of the tail, seven rows of spines curved forwards, which lacerate the fingers, if the hand be drawn from the head to the tail.

Balistes geographicus (*monacanthus, C.*) is one of the most remarkable species. Some notion of its form may be obtained from the following figure.



Balistes geographicus.

The name *geographicus* is given from the markings, which bear some resemblance to a map, the lighter part the sea, and the darker the land, with its mountains. The body is dark but compressed, the muzzle produced, the mouth rather small, the eyes large; the spine of the first dorsal prominent; and, in short, it has all the characters which have been enumerated in the short paragraph on *monoceros.* It is found both in the Atlantic and the Pacific, but only in the warmer parts.

Of *Balistes pencilligerus* (*monoceros, C.*) the figure has been already given. It is still deeper in proportion to its length, and more compressed than *geographicus.* The rays of the second dorsal, the caudal, and the anal fins, are, as in that species, bare or free from the connecting membrane for some distance at their points; and they are also more conspicuous by being farther apart from each other. The appendage at the hinder part of the abdomen is not so decidedly a ventral fin, though there is no doubt that it acts as such when the fish swims. The most singular part of its appearance, however, is the branched appendages, which are not only attached to the fins but scattered over the body and head. The first, or large dorsal spine, is very much branched, and so is the second one, which is much smaller and placed considerably to the rear of the first. The produced termination of the cavity is fringed with these appendages, and there are some of them on the forehead and cheeks. How they may act in the water is not very well known, nor is it easy to be imagined, as they appear to be singular appendages to swim with. One would imagine that, like barnacles on a ship's bottom, they would impede its progress through the water; and there is no doubt that such would be the case if the body of the fish had no flexibility, and if, like a ship, it were impelled by a force acting not in the water. But in the case of a fish, where both the moving power and the fulcrum from which that power gets the resistance to enable it to act, are in the water, the difference must be very material, so much so, indeed, that we can hardly institute any comparison, as we are not acquainted with any one mechanical contrivance which, acting wholly in the water, and equally both ways, as the fin of a fish does, which can impel itself forward. The three efficient fins of this species, the second dorsal, the anal, and the caudal, are all near each other, and they are also powerful for the size of the fish. It seems therefore that in order that a portion of their action may not be lost by throwing the head of the fish into alternate vibrations, a greater power of "holding on" is necessary; and thus these branched appendages may produce that steadiness of the body which is essential to the proper action of the fins. When we examine the lateral appearance, we find that the second dorsal and the anal extend forward nearly to the centre of gravity, and that the long spine answering to the first dorsal, and the projecting and fringed part of the abdomen, are nearly on the same line. The dorsal spine is connected with the bones of the head, and the fringe at the end of the abdomen is connected with the lateral bones of the cavity of the body, which are connected with the scapular bones.

It will readily be seen that, while the spine and the fringes prevent lateral motion at the line of which they form the terminations, the stiffness produced by the connections of bones must assist in keeping the anterior part of the fish in the line of its career steadily, while the lateral motions of the tail impel it forwards. Thus, by a careful examination of the parts, and a due consideration of the way in which, according to the known doctrines of motion, the one can react while the other acts, we may arrive at some understanding of the use even of those parts which at first sight appear to be redundant and even absurd.

The whole of this genus, and indeed, generally speaking, the whole of the order to which it belongs, are inhabitants only of the warmer seas; few or none of them are, from the form of the mouth, fitted for existing upon other fishes; and their structure is, in general, not such as that they can find their food in substances floating on the surface. It does not appear that the present genus has much of a pelagic habit; they do not range the depths of the ocean, but are found near the rocks, especially the coral reefs, which, even after the little creatures which formed them are gone, appear to abound more in living productions, both vegetable and animal, than most other rocks. Some of the fishes of this order (which appear to be among the grand destroyers of the surplus of small life on these reefs), are fitted for cutting off, with their trenchant teeth, the fronds of the fuci, while others appear to be more fitted for breaking the crusts and shells of the smaller crustacea, the young of which in particular are found in myriads among the seaweed on these reefs. Their economy in the general system of nature will, however, come better under the article on PLECTOGNATHES.

BALM. A well-known medicinal herb, the *Melissa officinalis* of botanists. Linnæan class and order, *Didynamia gymnospermia;* natural order, *Labiatæ.* Generic character: calyx upper lip flat, a little reflexed, three-toothed, the lower lip two-parted;

corolla upper lip vaulted, margined, and two-cleft, lower lip three-lobed, middle lobe largest, margined, and inversely heart-shaped; stamens, anthers kidney shaped, two-celled; style divided at top.

This plant is in every garden; a decoction of the leaves is recommended in cases of severe colds, &c.

BALM OF GILEAD. An under shrub of highly aromatic scent and qualities; the *Dracocephalum canariense* of botanists. This plant is in every green-house; and with little protection bears the severity of our winters.

BALSAM. One of our favourite green-house annuals. The beauty and variety of its flowers are very attractive; and though scentless, a specific mode of culture has been laid down for bringing them to perfection. The seed is sown, and the young plants are reared in hot-beds during the spring months, viz. in March, April, and May. About the middle of the last-named month, they should be, by frequent shiftings from small to larger pots, and from one hot-bed to another, advanced to the height of eighteen inches or more; and then are fit to replenish the green-house stage now empty; or for the decoration of halls of mansions, and the plots in flower-gardens. The balsam is one of those plants which by nature is destined to exist only one summer; but by art may be perpetuated from year to year, by the expedient of raising new plants by cuttings of the old. This, however, though practicable, is seldom practised; as they can be much more conveniently raised from seed. The seed-vessels of this genus have a remarkable property, they burst instantaneously on being touched when mature, scattering the seeds to a considerable distance: botanical name, *Balsamina hortensis.*

BALSAM APPLE. A climbing annual, native of India; the *Momordica balsamina* of botanists.

BALSAMINA (Rivinus). A genus of ten species of green-house annuals, chiefly natives of India. Linnæan class and order, *Pentandria Monogynia;* natural order, *Balsamineæ.* Generic character: calyx two-sepaled, deciduous; corolla four-petaled, unequal, the fifth abortive, two nearly united, the lower with a spur; anthers cohering, filaments short; stigma sitting, of five sides; capsule five-celled, five-valved, partitions thin; valves bursting by an elastic power, curling up; placenta like a central thread; tuberculis alternately seed-bearing. The common balsam, of which some account is given above, is the type of this genus, and was called *Impatiens* by Linnæus and others, but has been separated from the *Impatiens* family by Rivinus, a German botanist.

BALSAMINEÆ. Balsam family. A natural family of dicotyledonous plants, containing two genera and upwards of thirty species. The characters of the order are: sepals or phylla of the calyx five, irregular, deciduous, the two upper ones united together by their bases, the lower provided with a spur; petals four, hypogynous, united in pairs; five hypogynous stamens, with awl-shaped filaments and two-celled anthers; ovary single; stigmas divided into five parts; fruit capsular, with five elastic valves and five cells; seeds numerous, suspended.

This order has a great affinity to the geranium tribe, and is only distinguished from it by the spurred calyx, many-seeded fruit, and unsymmetrical flowers. In its flower it resembles the fumitory tribe, and in its seed-vessel, the wood-sorrel. The plants included in this order are chiefly succulent annuals, growing in moist situations, generally within the tropics. They are remarkable for the singularity and varied colouring of their flowers, as well as for the elastic force with which the valves of the capsules open and expel the seeds when ripe. They are propagated by seeds, and sometimes by cuttings.

Their properties are scarcely known, but they are looked upon as diuretic; some of them are said to be acrid.

The *Balsamina hortensis,* formerly *Impatiens balsamina,* or common garden balsam, was originally a native of the East Indies, but is now generally cultivated in Great Britain, on account of the beauty and showy appearance of its flowers. The numerous red and white varieties of this species which are met with in green-houses and drawing-rooms, must be familiar to every one. By care and proper cultivation, some balsams have been reared, four feet high, fifteen feet in circumference, and covered with large double flowers. The juice of the balsam, mixed with alum, is used by the Japanese to dye their nails red.

The *Impatiens noli-me-tangere,* yellow balsam, or Touch-me-not, is the only species of the order which is found native in Europe; it grows wild in several parts of England. It receives its name from the elasticity of its seed-vessel, which bursts, on the slightest touch, when the seeds are ripe. Its leaves are said to expand during the day, and to droop at night. Goats eat the plant, and a particular insect, the *sphinx elpenor,* lives on it. The *Impatiens biflora,* the American Touch-me-not, resembles the European species, but is handsomer. *Impatiens fruticosa* is remarkable, as being the only species which is not annual.

BALSAM OF CAPEVI (Linnæus). A genus of two species of South American trees; one of which is the *Copaifera officinalis* of botanists, producing the drug so called.

BALSAM PLANT. See POPLAR.

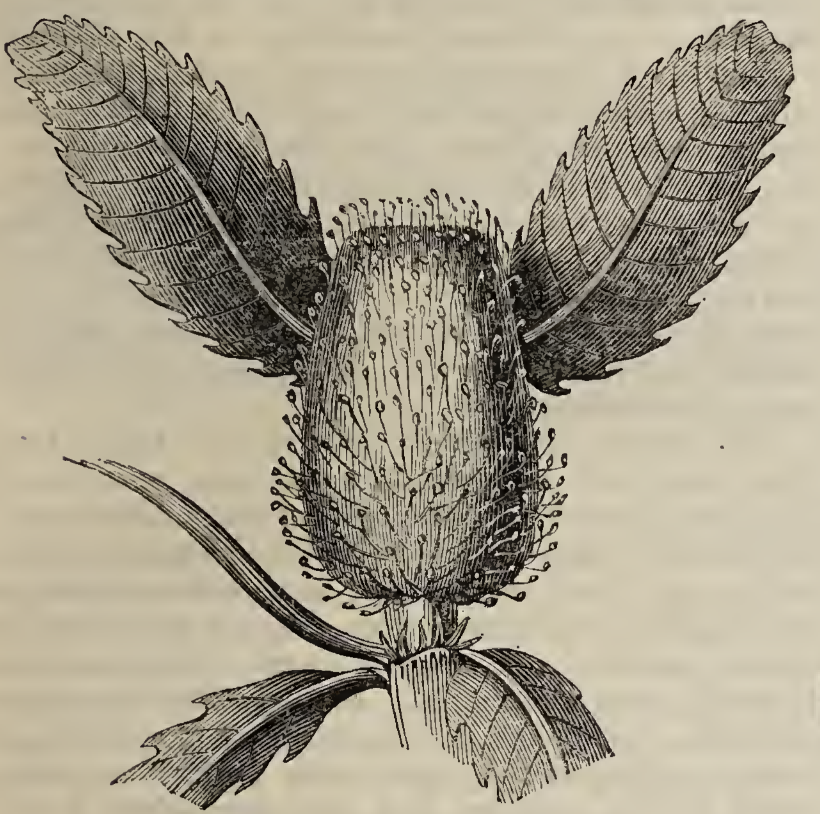
BAMBOO is the *Bambusa arundinacea* of botanists. It is a tree-grass, and one of the most useful vegetable productions in the countries where it is indigenous. Many stems rise, and continue to rise, closely together, from the same root. Their elegant jointed and tapering growth, to the height of forty or fifty feet; their regular form, high polish of the bark, toughness and durability of the wood, are circumstances which render the bamboo a most useful plant for the construction of huts, fences, household furniture, implements, and carriages; many kinds of vessels for liquids are made of the hollow stems. The young shoots are so succulent when they have just risen above ground, that they are cut like asparagus, and used as a pickle.

One of the species, the black bamboo, is often seen in Chinese scenery, and at a little distance has all the elegant pensile character of our weeping willow.

BAMBUSA (Schkuhr). A genus of eight species of shrubs and trees, natives of India. Linnæan class and order, *Hexandria Monogynia;* natural order, *Gramineæ.* Generic character: flowers in a spike or panicle, distinct, many flowered; inferior flowers hermaphrodite, upper ones males; calyx valves several, inner small, upper valves of the corollas are small likewise; corolla two valves, the lower one leathery, the upper membranaceous, margins turned inwards; squamæ, two below; style, bifid; caryopsis involved in the valves of the corolla. For some account of these trees, see article BAMBOO.

BANCHUS (Fabricius). A genus of hymenopterous insects, belonging to the *pupivora* and family *Ichneumonidæ*, or cuckoo-flies. The antennæ are long and thread-like, the abdomen is very much compressed at the extremity, and the ovipositor is not extended. Like the remainder of this great family, these insects are parasitic in the larva state, feeding upon the bodies of other insects. There are five British species, of which the *B. pictus* of Fabricius is the type.

BANKSIA (Robert Brown). A remarkable family of thirty-two species of Botany Bay plants, named in



Fruit and leaf of Banksia.

honour of the late sir Joseph Banks, president of the Royal Society. Linnæan class and order, *Tetrandria Monogynia;* natural order, *Proteaceæ*. Generic character: flowers in spikes, three single bracteated flowers, persisting; calyx four parted; stamens united to the top of the concavity of the calyx; squamæ four below the germen; folliculus woody, two seeded; seeds upper corner of winged. The great numbers and variety of this genus of plants, intermixed with thousands of others, which struck the view of Mr. Banks, Dr. Solander, and their companions, on their first landing in New Holland, under the guidance of the celebrated captain Cook, gave the name Botany Bay to that portion of the coast. The banksias, like a great majority of the plants from the same quarter, are as much unlike the plants of previously known parts of the world as are the distances between. Their physical habit, texture, and regular forms are only similar to a few found in southern Africa; but wholly different from the plants of the old world. Botany Bay is a source whence numerous new plants have been received, and a source which is not yet exhausted.

BARBADOES CHERRY. The genus *Malpighia* of Linnæus. There are twelve species, all stove evergreen shrubs. Class and order, *Decandria Trigynia;* natural order, *Malpighiaceæ*. Generic character: calyx, hemispherical, five cleft, bearing ten stipitate glands; corolla, five roundish petals, clawed, spreading; stamens below the germen; filaments cohering at the base; anthers roundish; style simple; stigmas capitate or like a nail; drupe tripyrena. This order of plants is generally handsome; and is known by their being furnished with stings upon their leaves, which causes a violent itching when applied to the naked hand.

BARBEL (*Barbus*, "bearded"). A genus of soft-finned fishes, with abdominal fins, belonging to the carp family, and having its name merely a contraction of "bearded carp." The generic characters are: the dorsal and anal fins short, a strong spine in the second or third ray of the dorsal, and four filaments of beard, one at each of the angles of the upper jaw, and two at the point of the muzzle. Barbel is a fresh-water fish, inhabiting the larger rivers of clear water, especially in stony places. In Europe they are not found in the very cold countries, as, for instance, in those to the northward of the Baltic; and in Britain they are found only in England. They are gregarious, are found inhabiting the same places in shoals, and are understood to be very voracious and indiscriminate in their feeding.

There is an ancient prejudice, that both the flesh and the roe of barbel are unwholesome, which Bloch found to be without foundation, by eating both without any bad consequences. The flesh is not, however, of very good flavour, neither is it understood to be very nutritious; and there is little doubt that, when out of season, that is, after spawning, it is not wholesome, as few fish are wholesome when in that condition. There are various species in the rivers of different parts of the world; and some of them, in their characters, approach the carp on the one hand, and the gudgeons on the other.

The common barbel (*Cyprinus barbus* of Linnæus) is the principal European species. It has the body and head both elongated, and the muzzle advanced considerably in front of the mouth, which gives that the appearance of opening on the under side. The upper jaw is strong, and tinged with red at the lip, as is also the under one. The two filaments of beard, which are dependent from the anterior part of the snout, are much smaller than those at the corners of the mouth. Each jaw is armed with ten teeth, placed in two rows, and recurved. The head is greyish olive, with some streaks of a yellowish tinge, extending from near the gape to the gill openings. The nostrils are placed near the eyes, and the last have the irides of a bright brown colour. The pectoral fins contain each seventeen rays, the ventral nine, the anal eight, the caudal nineteen, and the dorsal twelve, of which the third is armed with a spinous point. The pectoral, ventral, and anal fins are entirely of a reddish colour, rather paler at the base; the dorsal is reddish, with a portion at the base blue; and the caudal, which is forked, is bluish, with a portion at the base red. The back, which is rounded, is of an olive colour, passing into bluish toward the lateral line. Below that line the colour is yellowish, with a tinge of green, and the throat and belly are white. The lateral line is marked by a row of regular blackish spots, and the sides are bound obliquely with blackish brown, of greater or less brightness, according to the age and condition of the fish.

The favourite parts of the rivers for barbel are the currents of moderate rapidity which flow over gravelly bottoms, and especially among large stones. The fishes do not, unless when they are actively feeding, hold themselves in the stream, but rather lurk among the stones and under the banks. They are, however, easily brought out upon most occasions; but their most active time is, when moderate floods, which do not tinge the water too much, bring abundance of the substances on which they feed. The food which these floods bring them consists of snails, leeches, and other small animals, which are on these occasions either washed from the land, or lose the command of themselves in the water; and to these they have no objection to add the fry of other fishes, or indeed any living or recently dead animal which is small enough for their swallowing it. Some allege that they use their prominen snout for poking in the bottom of the water for food; but that is not very likely, neither is it very well ascertained.

Bloch mentions that they are fond of the flesh of the larger animals, and even of that of human beings. In corroboration of this, he mentions a feast of Turks and Turkish horses which the barbel of the Danube had, when, in 1683, the renowned John Sobieski of Poland raised the siege of Verona, which had been invested and all but taken by the Turkish army under Kara Mustapha. The valour with which Sobieski, with his Poles and Germans, set upon the Turks was somewhat unexpected; the rout was in consequence rapid and disorderly, and men and horses dashed or were driven pell-mell into the river. Their bodies, says the ichthyologist above-named, were in great part eaten by the barbel; and he adds: "*Avec un nourriture si variée, il n'est pas étonnant que le barbeau croisse fort vite*;" and unquestionably a much more formidable fish than a barbel might have grown very fat, if it had had a Turk and his horse every morning for breakfast.

There is only one objection to this story, and that is, it does not appear to be very possible. That a barbel, which is, as we have said, very indiscriminate in its feeding, will eat any animal which it can swallow, without inquiry as to whether it be beast or man, Turk or Christian, there is not the least doubt. But then, that a barbel could swallow a Turk and his horse, or any of the two singly, is rather too much for the reader to swallow; at least, if he swallow that, he may swallow any thing. Yet, if the barbel did not swallow the carcases upon that occasion, it is not easy to see how they could grow fast and fat upon them. The teeth of the barbel are not in any degree trenchant, so that it can neither bite nor masticate. The teeth, like those of most fishes, are merely prehensive; they catch food entire, but cannot divide it; and therefore, before John Sobieski could have fattened barbel for the epicures of Vienna with Turks and Turkish horses, he must have literally hewed them to mince meat before he drove them into the Danube. That the small animals upon which barbel feed should have attacked the dead bodies—that the barbel should have attacked them in return, and thus eaten the Turks and Turkish horses at second-hand—may have been true, because not impossible; but the eating of the Turks and horses at first-hand not being the one, could not be the other.

Barbel are ground or bottom fishes, and as such, they spawn in the warm season, and in the places which they inhabit. April or May, or even later in the season, according as the warm weather is longer in setting in, is the time for them. They are said not to be productive till four or five years old; and it is probable that the same individuals spawn only once in three or four years. There is no direct evidence of that being the fact, because we know very little of the habits of fish; and when we speak about their bringing forth their millions of young every year, we speak from what we know of land animals whose young are few. There is evident proof, however, of the fact, that, in those rivers where they abound, barbel may be had in season at all times of the year, though they are best about a month or six weeks before the time of spawning.

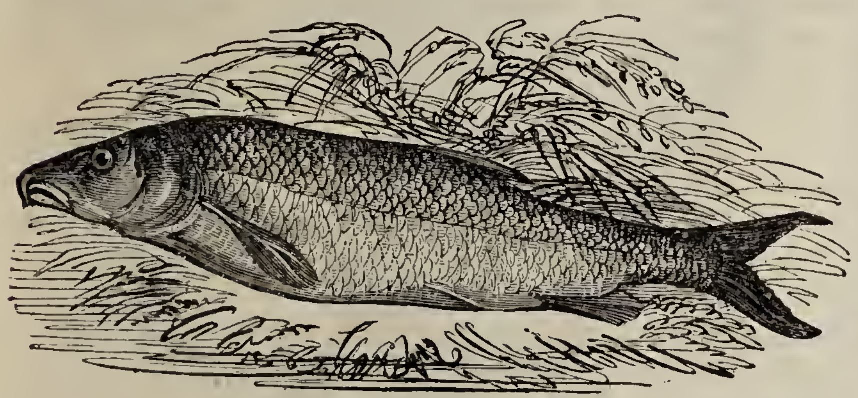
One must naturally suppose that the summer sun has much less influence upon barbel, and other bottom fishes, than upon those which come nearer to the surface—upon trout, for instance. Now, it is not clearly ascertained that trout spawn every season; and though they do, it certainly takes the whole action of the summer's heat to bring their roes and melts to maturity; for although, according to the different condition of the individuals, the operation extends over a considerable period, yet autumn is the average; and the eggs are placed in the shallows, so that they have the action of the sun early in the season. Barbel, on the other hand, deposit their eggs in the early part of the summer, and deposit them at the bottom. They are no doubt placed among stones or currents; but they are never placed where the water is very shallow, and it is not very well known at what period the young make their appearance.

The season of repose in barbel, or whether even they have such a season, has not been ascertained. Eels, which are much more ground fishes than barbel, hybernate by burying themselves in the mud, but eels are at all times mud-fishes; and, unless when, as passengers on their migrations, they are not found on those gravelly and stony bottoms which are the favourite resorts of barbel. But eels, like barbel, are much more abundant in temperate countries than in cold; and when they hybernate, they, if possible, resort to the estuaries, and bury themselves in the mud there.

The size which the barbel attains depends a good deal on the climate which they inhabit, and especially on the length and severity of the winter in that climate. They are said not to attain so large a size in the rivers of the north of Germany as in those of England; and not so large in England as in countries farther to the south. Three feet, and from fifteen to eighteen pounds weight, is a large barbel in England; but in the south of Europe they grow to the length of six feet, and are heavy in proportion. Like all the ground fishes, they are much more tenacious of life than those which inhabit nearer the surface; the action of their system appears to be slower, and their flesh is whiter. In these respects, however, they are inferior to the eel, though they approximate so far as to show that there is a diminution both in action and in the colour of the flesh, as well as more tenacity of life, in proportion as the fish inhabits at a greater depth in the water.

They are taken with nets, or with a line and barbed hook; and leeches, earth-worms, or small fishes, do for bait; they bite readily, and are in consequence easily caught. Bottom fishes, indeed, of all genera and species, bite more readily, are caught with more certainty, and appear to be much less capricious than those which inhabit nearer the surface, and sport and play in the water. But the probability is, that what we regard as the caprice of the latter, is their liability to atmospheric changes; from which the bottom fishes are defended by the deeper stratum of water which is habitually between them and the air.

Barbel, like eels, are very subject to intestinal worms, much more so than fishes which feed near the surface; and it is probable that the same extends to all or most of the bottom fishes. It does not appear, however, that, at any period of their history, the same mistake was fallen into in the case of the intestinal parasites of barbel as in those of eels. Subsequent inquiry has proved, what analogy pointed out, and inquiry would have showed at any time, if it had been made, that eels are spawning fishes, and remarkably prolific ones; but it was long said and written that they brought forth their young alive, and the worms were mistaken for the young. Barbel was always accounted a spawning fish. It is not one of the most prolific, neither is it one of the least so.



Barbel.

There are many species of barbel in the rivers, both of the eastern continent and the western. Some of the Italian species approximate to gudgeons, but retain the filaments at the mouth. There are one or two species in the Nile, and two or three in the Ganges; nor is there any doubt that, if sought for, they even would be found in most of the rivers of the warmer parts of the world. Their habits are, however, all nearly the same, so far as is known; and the chief distinctions are those of form, size, and colour, so that the description of one may in some measure serve as the description of all. They are nowhere first-rate or favourite fishes, and in some places they are despised, partly, no doubt, on account of the prejudice respecting their poisonous quality, but chiefly because the same rivers produce fishes of much better quality. See Cyprinoides.

BARBICORNIS (Godart). A very singular genus of butterflies, considered as belonging to the family of the *Polyommatidæ*, having the antennæ feathered throughout the whole length, and not clubbed at the tip. The genus consists of a single Brazilian species.

BARIDIUS (Schonherr). A genus of coleopterous insects, of the section *Tetramera* and family of the weevils. Schonherr enumerates fifty-two species, all of which are exotic.

BARIS (Germar). A genus of coleopterous insects, of the section *Tetramera*, and family of the weevils. They are of small size and reside in decaying wood; the fore-legs are inserted at some distance from each other, the antennæ are twelve-jointed. Curtis gives twelve British species, some of which, including the *Curculio lignarius* of Marsham, Mr. Stephens places it in the genus *Rhyncolus*.

BARK is the name given to the outer covering of trees and shrubs. This member of the stem is visible as soon as the plumelet escapes from the seed, and exists on the roots as well as on the stem; it is then called the cuticle, and ever after remains (on the generality of trees) on the exterior. Immediately beneath the cuticle there is a bed, or layer of greenish cellular matter, called *parenchyma*, and which, in the early stages of the growth of the tree, appears to be of much service in the conduction of the fluids of the system. The bark is thickened by new layers annually added to its inner surface, which layers are called *liber*, because, in the early ages of the world, it was used as a substitute for paper to write upon. In some instances these layers of liber are so distinct as to be easily separated from each other, and numbered, and by which the age of the tree may be known—a new bark being added in every year. The inner bark of many plants, as the lime, or linden tree, is made into packing mats; that of the *Laurus cinnamomum*, is the rich spice of commerce called cinnamon, and the whole bark of many trees, shrubs, and herbs, is useful either for the filaceous texture, or the concentrated qualities of the plant which it contains.

As the annual growth of the stem takes place within the bark, the first formed layers are consequently either stretched horizontally, as in the beech, or irregularly rent into vertical fractures, as is that of the oak. As the growth increases, the rents become wider and wider, and, on close inspection of the fractured parts, the annual growth may be distinctly seen. From the circumstance of many trees discharging their bark every third or fourth year, as the grapevine, the plane, *Arbutus Andrachne*, &c., and being rejected when useless by the oak, elm, &c., we may safely conclude that bark is an excrementitious member of a tree; each layer having only a temporary function, and which, when performed, is cast off, if not actually, at least virtually, from the living parts. Indeed, we know that, if not cast off, or rent, or sufficiently stretched to make room for the vital part within, it actually becomes a constrictive burden, insomuch that fertility ceases, health is injured, and the very life endangered. To save a tree so circumstanced, incisions should be made with the point of a pruning knife from the top to the bottom of the stem, quite through the bark; thus assisting nature, in her own way, to overcome an unnatural induration of the outer layers, caused, perhaps, in the first place, by an unusually warm summer. So well understood is this practical expedient in the culture of fruit trees, that old stunted individuals are sometimes entirely stripped of all their rough scabrous bark, to the manifest relief and renovation of the vigour of the tree. The last formed layer of liber is all that is absolutely necessary to be preserved in disbarking a hide-bound tree. Nor is any danger to be apprehended from such an expedient, unless it be performed in the winter, and on trees having a resinous or gummy sap.

The bark of some trees is remarkably thin, as the beech; others remarkably thick, as the cork tree. It is said that, in Spain, where the cork trees abound, they grow the better for being disbarked; and that, so quickly is the bark renewed, that it is, or may be, stripped off every seventh year.

Whatever may be the predominating quality of the tree or shrub, a considerable portion of it is generally found on the bark, and hence the many kinds of bark used in medicine and in the arts.

BARLERIA (Linnæus). A genus of twelve species of evergreen shrubs, natives of India. Linnæan class and order, *Didynamia angiospermia*; natural order, *Acanthaceæ*. Generic character: calyx, four parted, equal, the fourth segment often bifid; corolla, funnel shaped; limb five cleft, segments deeply cut; stamens, anthers oblong, erect; the lower ones frequently divided at the base; style protruding, filiform; stigmas thickish; capsule four angled, two celled, two seeded.

BARLEY is the *Hordeum vulgare* of botanists. Of this most useful plant eighteen species are described. Some of these are probably only varieties, because a plant so extensively cultivated, and one which has been for so long in use, must necessarily undergo changes, which, however physically different, may still be only variations. The most approved kind for the purposes of the maltster, distiller, miller, and farmer, now in cultivation, has the two opposite sides of the spike fertile, and the two intermediate ones sterile. This is a sign that the favourite sort is only a variety.

Cultivation.—Barley is the most tender of all kinds of corn; it requires a light, rich, warm soil. The land cannot be too fine for its reception, as it will not vegetate at all if laid among rough clods. Every care should be taken by means of the plough, harrows, and roller, to reduce the surface to the finest state possible; and though it may be reduced to the condition of dry dust, the seeds will rise more readily. The forwardness of the season, and particularly the dry mellowness of the soil, determines the time at which barley may be sown. Any time between the 1st of March and 1st of May is the usual seed-time. The ground should be rather too dry than too moist; and as soon as the furrow falls loosely from the plough, it is time to begin. Two ploughings may be necessary, and for this crop an extra ploughing had better be bestowed than that the seed be laid in roughly. It is not only necessary that every seed should vegetate, but that the whole should rise together. An even sample is always the most valuable, especially to the maltster; and this cannot be had unless the crop rise simultaneously, as nearly at least as the means and power employed will allow.

Barley is usually sowed after turnips. The ground having been fallowed and manured for this green crop, is in excellent order for barley when the turnips are off, as well in respect of richness as freedom from weeds, From two and a half to three bushels of seed are sowed to the acre, usually broad-cast, the surface being first harrowed down. Late sowed barley is sometimes ripe in nine weeks; early sowings require a longer time of course; and the crop is usually heavier, provided March and April have been favourable. Barley is either reaped, and bound into sheaves, or mowed with the sithe, and carried unbound to the barn. The produce is according to the quality of land and style of culture, and varies from three to six quarters per acre. Grass seeds are usually sown with barley, and as this rises, and is cut with the crop, if got up in a favourable time, it makes excellent winter fodder for live stock.

BARNARDIA (Lindley). A Chinese bulbous plant, introduced in 1819. Linnæan class and order, *Hexandria Monogynia;* natural order, *Asphodeleæ.* Generic character: corolla, six-petaled, spreading, persisting; stamens inserted into the base of the petals; filaments dilated at the base, fringed; anthers erect, oblong; style simple; germen three-celled, each cell one-seeded.

BARREN WORT. The *Epimedium Alpinum* of Linnæus. Class and order, *Tetrandria Monogynia;* natural order, *Berberideæ.* Generic character: calyx four-leaved; corolla four-petaled, with four pouch-like nectaries; stamens pressing on the style; pod oblong; seeds oblong, many. This plant has blood-red flowers, and is very rare in Britain.

BARRINGTONIA (Forster.) A beautiful tropical tree, very common on the islands in the Straits of Malacca. Linnæan class and order, *Diadelphia Pentandria;* natural order, *Myrtaceæ.* Generic character: calyx above, two-cleft, persisting; lobes obtuse, concave, leathery; corolla four large petals, thick and tough; stamens longer than the corolla, standing on a thickish ring; filaments like hairs; anthers roundish; style thread-like, embraced at bottom by a cup-like sheath; berry large, four-sided, and somewhat pyramidal, crowned with the calyx, one-celled; seeds pendulous, without albumen. This is a very ornamental evergreen tree; the foliage, flowers, and fruit are all large. The flowers are magnificent, and may be seen at the distance of half a mile from the tree.

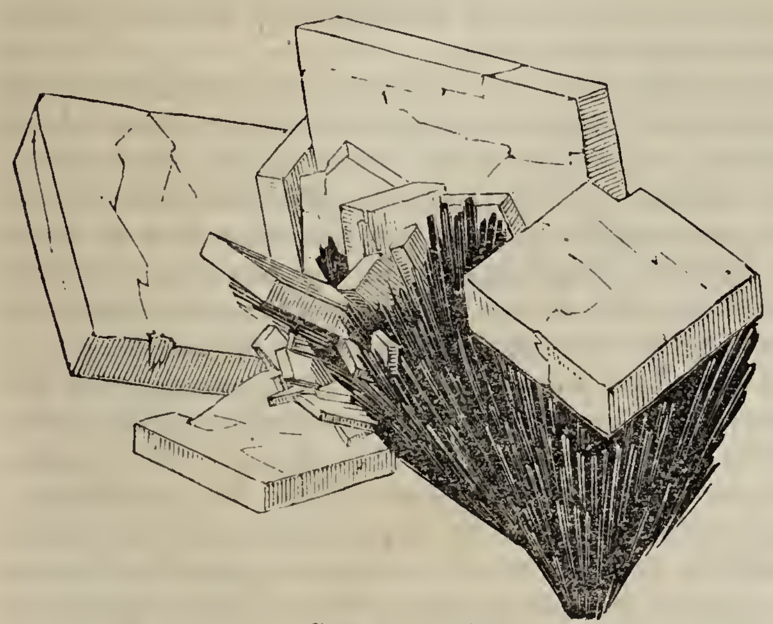
Barringtonia speciosa.—One-fifth the natural size.

BARTHOLINA (Robert Brown). A tuberous-rooted plant introduced from the Cape of Good Hope. Linnæan class and order, *Gynandria Monandria;* natural order, *Orchideæ.* Generic character: sepals gaping, connected interiorly with the base of the lip; labellum spurred, in three parts, multifid; retinaculo elongated, joined to the cup, glands distinct, exterior lobe half cut. This plant was formerly called *Arethusa pectinata,* by Linnæus.

BARTSIA (Linnæus). A genus of four species of annuals, three of them being indigenous to Britain. Linnæan class and order, *Didynamia angiospermia;* natural order, *Scrophularinæ.* Generic character: calyx tubular, edges four toothed, tips coloured; corolla gaping, upper lip erect, entire, concave; lower lip three lobed, a little reflexed, lobes equal; stamens under the upper lips; anthers incumbent, bifid behind; style with an incurved top; stigma headed; capsule compressed, two-celled, two-valved, dissepiment contrary to the valves; seeds oblong, ribbed. These plants resemble the common eyebright; and the *B. odontites* is easily mistaken for it.

BARYOSMA (Willdenow). A family consisting of six species, evergreen shrubs cultivated in the greenhouse; native country Cape of Good Hope. Linnæan class and order, *Pentandria Monogynia;* natural order, *Rutaceæ.* Generic character: calyx turbinated, unequally divided; the two upper segments like wings, the lower, smaller; standard erect, keel of two petals; pod thick, compressed, two-valved, one-seeded. These are ornamental plants, and nearly allied to *Diosma.*

BARYTES. A very heavy earthy mineral, which is not found pure in a natural state, but combined either with sulphuric acid, forming sulphate of barytes or heavy spar; or with carbonic acid, forming carbonate of barytes. Some of the salts of barytes are violent and certain poisons, destroying animals by inflaming the intestines, and are often used for the destruction of vermin.



Sparry Barytes.

The barytes, of which we give a representation in the above figure, is usually divided into a variety of sub-species, they are not, however, of sufficient general interest to be separately enumerated,

The radiated heavy spar is remarkably phosphorescent when heated. This property was first observed in the year 1630, by a shoemaker, named Vincenzo Casciarolo, during his search after the philosopher's stone. When the mineral is calcined, pulverised, and made into cakes, it acquires a strong phosphorescent property by exposure to light; the phosphorescence is visible, upon taking it into a dark place. When rendered phosphorescent it is known under the name of Bolognian phosphorus.

It may be proper to state that the columnar heavy spar has been frequently confounded with white-lead spar, but is distinguished from that mineral by the following characters: white lead spar has an adamantine lustre, its fracture is conchoidal, and its specific gravity rather more than six; whereas columnar heavy spar has a pearly lustre, distinct cleavage, and a specific gravity of less than five. See CELESTINE, STRONTIANITE, and WITHERITE.

BASALT. A term employed by geologists to describe a rocky compound, which furnishes some of the largest and most beautiful columnar masses which are to be found in the whole structure of our globe. Natural architectural edifices of this description are now existing, which far exceed in magnitude the Titan grandeur of Egyptian art; and it is gratifying to know that some of the most beautiful specimens of these temples, reared by the Creator as illustrations of his power, are found within the circle of the British isles. The singular tendency which basaltic formations evince to assume a columnar form, is familiar to the commonest observer: and no constituent material of the solid globe has more frequently been an object of geological speculation in recent times; theorists of nearly equal ingenuity having contended as vehemently for its igneous as its aqueous origin.

Although various parts of Europe and Asia abound with examples of basaltic columns, yet the island of Staffa and the Giant's Causeway appear to be the most extensive and striking in the known world. It is extraordinary that the former should scarcely have been known previous to the year 1772, when it was admirably described by sir Joseph Banks, on his visit to the Scottish Hebrides. The latter was better known by the previous description of the bishop of Ossory.

The island of Staffa will, in the first instance, engage our attention; and its extraordinary basaltic characteristics have been so accurately described by Dr. Macculloch as to render any further comment superfluous. The principal beauties of Staffa are to be found on its iron-bound coast, and our plate, BASALTES, will serve to convey a good notion of the character of one of its greatest basaltic ornaments.

If we commence with the landing place, the columns in this quarter are placed in the most irregular directions, being oblique, erect, horizontal, and sometimes curved; while they are also far less decided in their forms than the larger vertical ones which constitute the great face. When they reach the grassy surface of the island, they gradually disappear; but are sometimes laid bare, so as to present the appearance of a geometrical pavement, where their ends are to be seen; in other places displaying portions of their parallel sides.

At the Scallop, or Clamshell Cave, the columns on one side are bent, so as to form a series of ribs not unlike an inside view of the timbers of a ship. The opposite wall is formed by the ends of columns, bearing a general resemblance to the surface of a honeycomb. This cave is thirty feet in height, and sixteen or eighteen in breadth at the entrance: its length being 130 feet, and the lateral dimensions gradually contracting to its termination. The inside is uninteresting. The noted rock Buachaille, or the herdsman, is a coniadal pile of columns, about thirty feet high, lying on a bed of curved horizontal ones, visible only at low-water. The causeway here presents an extensive surface, which terminates in a long projecting point at the eastern side of the great cave. It is formed of the broken ends of columns, once continuous to the height of the cliffs. This alone exceeds the Giant's Causeway, as well in dimensions as in the picturesque diversity of its surface; but it is almost neglected among the more striking and splendid objects by which it is accompanied. The great face is formed of three distinct beds of rock, of unequal thickness, inclined towards the east at an angle of about nine degrees. The lowest is a rude trap tufa, the middle one is divided into columns placed vertically to the planes of the bed, and the uppermost is an irregular mixture of small columns and shapeless rock. The thickness of the lowest bed at the western side is about fifty feet; but, in consequence of the inclination, it disappears under the sea, not far westward of the great cave. The columnar bed is of unequal depth; being only thirty-six feet at the western side, and fifty-four where the water first prevents its foundation from being further seen. To the eastward its thickness is concealed by the causeway. Thus, at the entrance of the Great Cave on this side, the columns are only eighteen feet high, becoming gradually reduced to two or three, till they disappear. The inequality of the upper bed produces the irregular outline of the island. The inclination of the columns to the horizon, in consequence of their vertical position towards the inclined plane of the bed, produces a very unpleasing effect whenever it is seen from the south-west: the inclination of nine degrees conveying the impression of a fabric tottering, and about to fall. Fortunately, the most numerous and interesting views are found in positions into which this defect does not intrude; and many persons have doubtless visited Staffa without discovering it. Although the columns have a general air of straightness and parallelism, no one is perfectly straight or regular; in this respect they fall far short of the Giant's Causeway. Very often they have no joints; sometimes one or more may be seen in a long column; while, in other places, they are not only divided into numerous parts, but the angles of contact are notched. They are sometimes also split by oblique fissures, which detract much from the regularity of their aspect. These joints are very abundant in the columns that form the interior sides of the Great Cave, to which, indeed, they are chiefly limited; and it is evident that the action of the sea, by undermining these jointed columns, has thus produced the excavation: as a continuation of the same process may hereafter increase its dimensions. The average diameter is about two feet; but they sometimes attain to four. Hexagonal and pentagonal forms are predominant; but they are intermixed with figures of three, four, and more sides, extending even as far as to eight or nine, but rarely reaching ten. It is with the morning sun only that the great face of Staffa can be seen to perfection. As the general surface is undulating and uneven, great masses of light or shadow are thus produced, so as to relieve that, which, in a direct light, appears a flat insipid mass of straight wall. These breadths are further varied by secondary shadows and reflections arising from smaller irregularities; while the partial clustering of the columns produce a number of subsidiary groups, which are not only highly beautiful, both in themselves and as they combine with and melt into the larger masses, but which entirely remove that dryness and formality which is produced by the incessant repetition of vertical lines and equal members.

The Cormorant's or M'Kinnon's cave, though little visited, in consequence of the frauds and indolence of the boatmen, is easy of access, and terminates in a gravelly beach, where a boat may be drawn up. The broad black shadow, produced by the great size of the aperture, gives a very powerful effect to all those views of the point of the island into which it enters; and is no less effective on land, by relieving the minute ornaments of the columns that cover it. The height of the entrance is fifty feet, and the breadth forty-eight; the interior dimensions being nearly the same to the end, and the length 224 feet. As it is excavated in the lowest stratum, the walls and the ceiling are without ornament; yet it is striking from the regularity and simplicity of its form. But the superior part of the front consists of a complicated range of columns, hollowed into a concave recess above the opening; the upper part of this colonnade overhanging the concavity, and forming a sort of geometric ceiling; while the inferior part is thrown into a kind of secondary mass of broad but ornamental shadow, which conduces much to the general effect of the whole. The Boat Cave is accessible only by sea. It is a long opening, resembling the gallery of a mine, excavated in the lowest rude stratum; its height being about sixteen feet, its breadth twelve, and its depth about 150 feet. Upwards the columns overhang it, so as to produce a shadow, which adds much to the effect; while they retire in a concave sweep, which is also overhung by the upper mass of cliff, thus producing a breadth of shade, finely softening into a full light by a succession of smaller shadows and reflections, arising from the irregular groupings of the columns. The upper part of this recess, catching a stronger shadow, adds much to the composition; while the eye of the picture is found in the intense darkness of the aperture beneath, which gives tone to the whole.

The Great Cave is deficient in that symmetry of position with respect to the face of the island which conduces so much to the effect of the Boat Cave. The outline of the aperture, perpendicular at the sides, and terminating in a contracted arch, is pleasing and elegant. The height, from the top of the arch to that of the cliff above, is thirty feet; and, from the former to the surface of the water at mean tide, sixty-six feet. The pillars by which it is bounded on the western side, are thirty-six feet high; while, at the eastern, they are only eighteen, though their upper ends are nearly in the same line. This difference arises from the height of the broken columns which here form the causeway; a feature which conduces so much to the picturesque effect of the whole, by affording a solid mass of dark foreground. Towards the west the height of the columns gradually increases as they recede from the cave, but their extreme altitude is only fifty-four feet, even at low water. The breadth of this cave at the entrance is forty-two feet, as nearly as that can be ascertained, where there is no very precise point to measure from. This continues to within a small distance from the inner extremity, when it is reduced to twenty-two; and the total length is 227 feet. The finest views here are obtained from the end of the causeway, at low water. When the tide is full, it is impossible to comprehend the whole conveniently by the eye. From this position also the front forms a solid mass of a very symmetrical form; supporting, by the breadth of its surface, the vacant shadow of the cave itself. Here also, that intricate play of light, shadow, and reflection, which is produced by the broken columns retiring in ranges gradually diminishing, is distinctly seen; while the causeway itself forms a foreground no less important than it is rendered beautiful by the inequalities and the groupings of the broken columns. Other views of the opening of this cave, scarcely less picturesque, may be procured from the western smaller causeway; nor indeed, without bestowing much time and study on this spot, is it possible to acquire or convey any notion of the grandeur and variety which it contains.

The opposite points of Scotland and Ireland on the Antrim coast correspond exactly in geological structure. Of the basaltic group of hills in Ireland, Knocklead, in the northern extremity of the eastern chain, offers the highest summit, rising 1820 feet above the level of the sea; but its basis is occupied to the height of 500 feet by primitive rocks, leaving 1320 feet for the thickness of the overlying strata. Divis Hill, near the southern extremity of the chain, is wholly composed of these strata, and attains an elevation of 1475 feet above the level of the sea. Cragnashoack, at the southern extremity of the western chain, has a height of 1864 feet. The basaltic covering seems to acquire its greatest thickness on the north, where the basaltic cap of Benyavenagh, the most northern summit of the western chain, measures more than 900 feet. The average depth of the basaltic superstructure may be safely estimated at 545 feet, and its superficial extent at the prodigious area of 800 square miles.

The Giant's Causeway consists of three piers or moles, projecting from the base of a stratified cliff, about 400 feet in height: the principal mole is visible, for about 300 yards in extent, at low water, the others not more than half that distance. It is composed of polygonal pillars, of dark-coloured basalt, so closely united, that it is difficult to insert more than a knife-blade between them ; and the formation of a continuous surface at each point in the pavement, by polygons, whose angles vary considerably. Towards the centre of the whole mass the pillars ascend ; and, from the peculiar appearance of the surface, this vertex is usually called the Honeycomb. The pillars are irregular prisms of an uncertain number of sides, varying from three to nine : there is one of three sides near the centre of the Honeycomb, and several of nine have been detected, but the hexagonal form prevails most generally.

Each pillar is in itself a distinct piece of workmanship ; it is separable from all the adjacent columns, and then is itself separable into distinct joints, whose articulation is as perfect as human exertion could have formed them, the extremities of each joint being concave or convex, which is determined by the terminations of the joints with which it was united. But there is no regularity as to the upper or lower extremity being concave or convex ; the only law on this point is, that the contiguous joints are, the one concave, the other convex. In order to secure stability to this piece of architecture, the angles of the inferior joints frequently overlap those of the superior so closely that the force required to dislocate them occasionally fractures the joints. The geological scenery east of the causeway is truly sublime : the dark precipitous cliffs, which rise regularly in gradually retiring strata, certainly suggests the idea of their having been deposited age after age, as Werner thought ; and the extraordinary appearance of the various colonnades might, for a moment, seduce the fancy of the visiter, and lead him to imagine that here whole palaces had been overwhelmed in ruin. These successive capes, which are visible from the causeway, are but a part of one great headland, called Benmore, the rival of Benmore or Fair-Head, and all of them similarly formed. As an illustration of this part of the basaltic coast of Antrim, we may take a graphic sketch from the very remarkable detached mass of Carrick-a-Rede.

Carrick-a-Rede.

The island is nearly of the same elevation as the adjacent mainland, rising about 350 feet from the surface of the ocean ; and in the adjacent cliffs is a very beautiful cave, about thirty feet in height, formed entirely of columnar basalt, of which the bases appear to have been removed, so that the unsupported polygonal columns compose the cave. Carrick-a-Rede is separated from the coast by a chasm of sixty feet in breadth. Vast iron rings are morticed into the rocks on each side, to which are fastened two ropes running parallel to each other, connected together with cross bars of rope at equal distances. A series of planks are added ; and over this species of primeval bridge, men, women, and children, are daily in the habit of passing to the basaltic mass.

Of the nature of the several mineral productions to be found about the Causeway it may be said, that where the basalt is not formed into columns, the masses possess a considerable variety of texture as well as colour ; in colour, they are to be found from various shades of grey and brown to a dull red. All these varieties are attributable to the iron contained in the mass under various circumstances of chemical influence. The basalt often approaches in its general character to amygdaloid, the cavities being sometimes very considerable, and either coated or filled entirely with various minerals. In the former instance, the interior surfaces have always a crystalline character, which, when entire, not uncommonly constitutes a hollow sphere, to which the name of Geode has been applied. This is principally the case with such as are of a siliceous nature. Zeolite occurs here in every known variety ; and that which is usually termed fibrous, or mealy zeolite, is particularly deserving of attention, from its extreme delicacy and brilliancy of character, resembling the fine down of a thistle. Calcareous spar is exceedingly common ; steatite and green earth are occasionally found ; chalcedony, approaching to opal, and agates, are not rare. On the side of Mount Pleaskin, or Placekin, near the Giant's Causeway, there is a remarkable appearance of imperfect crystallisation between the principal ranges of pillars, much resembling the diverging figure of radiated zeolite. The varieties of zeolite are well known to abound in basaltic regions, particularly the most northern, and that alluded to impresses the idea of a rapid crystalline process. Intense cold and frost most frequently produce a figure more or less resembling it.

On the islands of Staffa and Rathlin, curvilinear prisms of basalt present themselves, which, as we have already stated, much resemble the ribs of a ship. Near the Cascade of Vestena, in the territory of Verona, where a similar appearance exists, irregular aggregated bodies (some approaching to a sphere and some to an imperfect prism) rest within the uppermost segment of the circle. The influence of the laminated sphere seems no less applicable to the various degrees of inclination exhibited by basaltic columns in several other parts of the world.

Great quantities of basalt are likewise found in the vicinity of Mount Etna in Sicily, of Hecla in Iceland, and of the volcano in the isle of Bourbon. These three are the only active volcanoes in whose neighbourhood it is to be met with ; but it is found adjacent to many which are extinct, particularly the silent craters of Italy.

The rocks of the Cyclops, in the neighbourhood of Etna, exhibit magnificent basaltic columns, which at first view greatly resemble the Causeway pillars ; but on a closer inspection, a very remarkable difference will be found to exist. The cyclopian pillars are divided into distinct families or groups, of six or seven in number, assembled round a larger and central column, which they appear to be connected with; while the causeway pillars are not observed to respect any point or centre, but are each independent and complete. The basalts of these rocks also abound in small crystals, not unlike rock crystal, but much softer, and which yield to the action of the air.

The promontory of Castel d'Iaci, which terminates the basis of Etna, is almost entirely composed of basalts; but of a different kind from what has been just described. It consists of a number of cylinders, whose diameters vary from six inches to twenty feet. Some of these are solid, others hollow like a cannon; some extended in layers, others compressed like rolls of tobacco, some are like globes inclosed in the rocks, while others are bent in a variety of forms.

A general view of the various theories illustrative of the origin of basaltic formations, will be given under the head of TRAP-ROCKS, called by geologists "unstratified superjacent;" and we must content ourselves, in the present place, with briefly adverting to one or two hypotheses, which are essential to the illustration of our present article. Mr. Hare, who devoted a considerable deal of science and industry to an examination of the Antrim formations, says, that where basalt does not divide itself precisely after the manner of prismatic columns, or evince a tendency to that figure on a great and general scale, it often forms laminated spheroidal bodies, which, varying in their diameters, constitute, by aggregation, rocks of considerable magnitude.

The latter circumstance, in addition to the occurrence of basaltic fragments, in which a sphere appears to be enveloped by a polyhedral figure, suggested the idea that a compressible laminated sphere must be the primitive figure of each prismatic articulation, composing a common basalt; and that the lateral plane surfaces, as well as the corresponding concavity and convexity of the horizontal surfaces, the trihedral processes of the lateral edges, and the corresponding truncations of the superimposed joint, result from the assemblage of spheres under the influence of gravitation while the component particles are in a yielding state; their laminated structure being a mechanical accommodation to the filling of those interstitial spaces, which must result from an aggregation of spheres.

Basaltic Columns.

These ideas may be in some degree elucidated by the accompanying engraving, in which the first figure represents a basaltic fragment from the vicinity of Belfast, where the sphere is developed by a partial decomposition of the prism; while the group shows the prevailing character of basaltic columns in general, two of the constituent prisms being detached, to show the alternate concavity and convexity of the horizontal surfaces, with the angular surfaces and truncations of their edges.

The Rev. William Conybeare thus describes his view of the basaltic formations:—"I would observe, then, that this formation is distinguished by characters so directly opposed to those which all rocks undoubtedly of aqueous origin possess, that no hypothesis which ascribes both to a common origin, can be otherwise than contradictory, and at variance with itself. For,

"1. Of all other formations, the least ancient are the least elevated; but this, the most recent of all, yet rivals the primitive mountains in height.

"2. Of all other formations, the degree of consolidation decreases together with their age, their texture passing from crystalline through the several gradations of sub-crystalline, compact, coarse, and lastly earthy; while in this formation, even where it rests on chalk, the crystalline texture of the oldest rocks frequently occurs.

"Whin dykes, which are indisputably connected with this formation, differ from all other mineral veins in the circumstance of their traversing all rocks indifferently; while of other veins, particular classes are exclusively associated with particular rocks. Such being the negative evidence against the Neptunian hypothesis, I proceed to that which is positive in favour of the Volcanists; as,

"1. The identity of chemical composition in basalt and lava.

"2. The constant occurrence of trap-rocks in volcanic districts.

"3. The confessions of the Wernerians themselves, that the basalt of Auvergne is one of igneous origin.

"4. The testimony of those best acquainted with districts still exhibiting active volcanoes. Such persons as Dolomieu and Spallanzani, have uniformly maintained the igneous origin of basalt, while those who have contended against it, have generally been practically unacquainted with countries of this description."

Whether, with the above distinguished geologist, we regard the basaltic masses we have described, as of igneous formation—relics of those tremendous volcanic operations which shook the whole world, and ultimately, by breaking up the foundations of the great deep, assisted in producing the deluge recorded in Holy Writ; or, whether we adopt the less assuming theory of an aqueous origin, the contemplative philosopher must see in their exquisite symmetry of arrangement and magnificence of architectural proportion, a new cause for reverential gratitude to the great Architect of all things.

> Who not content
> With every good of life to nourish man,
> By kind illusions of the wondering sense,
> Hath made all nature beauty to the eye,
> And music to the ear.

BASIL. The *Ocymum basilicum* of Linnæus. This is an extremely sweet-scented garden pot-herb, and being an annual is sowed every year on a warm border, thinned and kept clean, is ready for gathering when in flower, and then, gradually dried, is tied in small bundles and hung up in a dry room for use.

BASILISCUS (basilisk lizard). A genus of Saurian reptiles of very harmless character, though by some means or other inheriting a most formidable name. The application of the fabled names of antiquity, such as the cockatrice, the dragon, and the basilisk, to the realities of modern natural history is not only absurd, but must in some instances be attended with bad consequences. Men read with horror, in their boyish days, of the terrible powers of dragons, and the deadly venom of cockatrices and basilisks,—venom so deadly, that it not only killed all else upon which the terrible creatures looked, but if they happened to meet the reflection of their own withering glances from a mirror or a pool of water, they could not escape the death-stroke of their own looks. These terrific qualities make a deep impression upon the youthful mind; and as the name is the index to all the terrors, the repetition of it naturally suggests them. Thus there must be a most curious conflict between memory and present perception, when the dragon is found to be a creature that can hurt nothing stronger than a fly, or that the basilisk is a harmless and pretty little creature—for although peculiar in shape it is pretty—that lives upon small vegetable seeds, and neither hurts nor is capable of hurting a single living creature. The reality which addresses itself immediately to the senses must, in the end, get the victory, how hard soever the impression on the memory may plead. Thus the fable is discarded, and takes along with it all which it in any way holds linked by association. The school and scholarship, and all that is connected either with the one or the other, come in for their share of the doubt, disbelief, and derision; and that which, but for the discovery, would have continued to afford excitement, and therefore pleasure, becomes the foundation of self-humiliation and reproach. Either, therefore, the fable should be given up, or the name which turns it into a mockery should cease to be used. The fable has its use in attracting the mind, at an age at which it could not be attracted by reality. Boyhood, when the hopes are full of the joys of years unborn, is a time of romance, and all the Utilitarians that ever lectured will never make it otherwise. And it is well for us that they cannot; for the reality of life is the painful portion of it, and the romance the pleasurable. Not only so, but that which utilitarians call the reality is the sensual, the animal, the material part of life; and the romance is the mental or intellectual part. If the former is made the sole object of consideration, then the result is misery in the present life and no hope hereafter. There is consequently an immediate and utter extinction of all that is pleasant in life—of all that is endearing in society; because there remains no value but *money* value; and "Thy money perish with thee" is the denunciation, which takes effect both here and hereafter.

We are not pleading for fables, or attempting to recommend that which is not true at the expense of the truth. But in "the youth of life," it is vain to refer to that which in after life is called "utility," as the only or the chief incentive to study. You cannot, at every step of a boy's education, draw his attention to his book, or his other study, by the allurement of "the price that it will bring him in;" and if you could, what a mean and sordid creature, nay, what an immoral and dishonest creature you would make of him! If we labour to impress upon the young mind, the idea that there is no value but in possessions, and no reward but in pecuniary payment, we absolutely, in express terms, teach fraud and theft, destroy all the better feelings of the heart, and make man no better than a beast. We take the very worst view of the worst conduct of human beings as the foundation of character; and then we need not wonder that our pupil ripens into crime, and as the law is not abolished, the feeling which we thus inculcate, that law and justice are evils, because restraints upon *utility*, renders him obnoxious to punishment. Little romantic extravagancies appear to be as necessary for young minds as they are for young nations—among which they have ever been found; and though they are only "play" in after life, both with the one and the other, yet the period when they cease altogether is the dotage of senility—the sad condition from which earthly hope has for ever departed.

It is, therefore, always to be regretted when the reality spoils a fable which gives pleasure; and the instructor who preaches truth in this wise, is exactly the counterpart of him who should go about to make a man zealous and enterprising in his business, by disclosing to him at the outset, all the failures, impositions, frauds, and misfortunes, to which he should be subjected in the course of it.

Applying the fabulous names of the ancients to the real productions of nature, is but one form of this mode of making knowledge the destroyer of happiness; but it is one which brings no good to compensate the evil. It destroys the marvel of the boy, but enough of that marvel remains to turn into ridicule and contempt the knowledge of the man. The withering power with which the eyes of the fabled basilisk were endowed, gives point to some of the choicest passages in poetry, and to persons of fine feelings these passages give more abundant and exquisite pleasure than they could purchase in the 'market,' even if they had the wealth of the Indies to lay out in the purchase of it. Now, if along with these passages there come always the conviction that the said basilisk is equally frail and harmless as a butterfly among the flowers, there remains no more pleasure,—derision, contempt, is the natural feeling. It is of no use to plead that it is a different basilisk altogether, for there is identity in the name; and if the fabled name has been bestowed upon a reality which has not the attributes of the fable, then the bestower of that name has been guilty of a falsehood.

Any one who wishes to judge how much of poetic enjoyment may and must be destroyed by this misappropriation of names that had their meaning before, may turn to the second scene of Richard III., and read on to this line, spoken by Lady Anne:—

> "Would they were *basilisks*, to strike thee dead!"

Substitute the word "butterflies" for "basilisks;" read the line thus:—

> "Would they were *butterflies*, to strike thee dead!"

and then feel the power of the scene if you can.

Yet the butterfly of natural history is quite as likely to strike one dead as the natural history basilisk; and thus while the application of the fabled name destroys the force of the fable, the memory of the fable turns the real animal into ridicule. The application of sounding names, where there is no analogy to warrant their use, has done much mischief in all the departments of natural history, and also in all the other subjects from which these names are taken.

The basilisk of antiquity (and it was gravely described by Pliny and Galen among the ancients, and has been so by Lobo, Prosper Alpini, and Aldrovandi, among the moderns) was a terrible creature. Among the pools and lakes of that land of marvels which gave source to the mighty flood of the Nile, it reigned in terrible majesty; but it reigned in desolation. Its name was derived from the Greek word βασιλιζομαι, "to reign." It had eight feet, two large scales for wings, was of a golden yellow, and its head

"The likeness of a kingly crown had on."

The taint which it communicated to the air was more deadly than that fabled of the upas tree, and believed by Dr. Darwin (though the Doctor was rather a sceptic in some other matters, the proofs of which were open to him); for no animal could breathe the same air and live, and its glance was instant death, even to the lion himself. Nature could not, of course. form such a creature in the ordinary way; but, like the cockatrice—the dread of which has, perhaps, not yet altogether ceased in this country—it was hatched by a serpent out of the egg of a cock!

Though adopted by the naturalists above mentioned in the plenitude of their credulity, and continued by their copyists, the basilisk of the ancients was purely a poetical creation—the emblem of regal tyranny, in short; and its origin was made unnatural, and the scene of its dominion laid in the desert, because to have spoken more plainly at home might not have been altogether safe. It does not follow, however, that the ancient poet who imagined the fable believed in the material existence of the basilisk, any more than Milton did in that of his personifications of Sin and Death, or Shakspeare in those ghosts which he conjured up with such matchless skill, and upon which the poetic beauty and the moral grandeur of some of his best passages are made so much to depend.

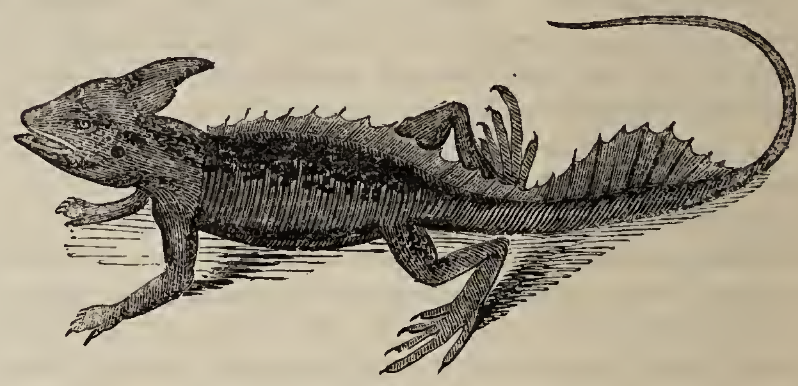
We have deemed it advisable to notice, in this the first striking instance of it which has occurred in the regular order of the alphabet, the prostitution of poetic or allegorical names to subjects in natural history; and having done so once for all, we shall shortly notice those basilisks which come more properly within the scope of our pages.

Basiliscus is a genus of the lizard family, and the characters are—the body rather thicker in proportion to its length than in most of the order; the head short, and rather pear-shaped; the legs thick and strong, with five toes, armed with a claw on each foot; and the tail very long, and compressed or flattened laterally. The back and upper part of the tail are furnished with a crest, supported on rays something resembling those of the fin of a fish, and capable of being folded or expanded. The rays of this crest are articulated to the spinous processes of the vertebræ. The whole surface, including that of the dorsal crest, is covered with small imbricated scales of a rhomboidal form; but there are no pores on the inner sides of the thighs. The tongue is broad and fleshy, and not protrusile, but rather united to the under-jaw for the greater part of its length. There are small teeth both in the palate and the jaws.

The structure of the mouth shows that these animals do not lie in wait for their food, but go in quest of it. They are nimble and lively, as well as harmless and gentle. They jump with much agility from branch to branch, in which they are assisted by the dorsal crest, and probably also by the inflation of the throat, which they have the power of doing at pleasure. Some of the accounts state that they can fly, but that is a mistake. They leap far, but they have no means of giving themselves a fresh impulse when in the air, which is the essential operation in flying. It is probable that they can swim, and that they then use the crest on the tail in the same way as a fin. But their habitation is on the dry land and in the forests, to which their lively motions give a cheerful air.

There are two known species, the one an American and the other an Asiatic, but the places where they are found are local, and bear some resemblance to each other.

The Mitred Basilisk (*Basiliscus mitratus*) is the American species, and the following figure will give a general notion of its form.



Mitred Basilisk.

This species has a long mitre-shaped crest on the back part of the head, from which it gets the specific name, and probably the generic one was given on account of the same; but it is not generally accurate, as the Asiatic species has no crest. The crest is membranous, with a cartilaginous support. This species is of considerable size; its general colour is blue, with one white band behind the eyes, and another behind the gape, the last with points inclining to the shoulders.

The Amboyna Basilisk (*Basiliscus Amboinensis*) differs from the former chiefly in wanting the mitre-shaped crest on the head, and having that on the back and tail pectinated or toothed like a comb; the tail also is less pointed than in the American species.

These harmless and lively little creatures are natives of those parts of the several continents which receive the trade winds [see the article Atmosphere]; and are, in consequence, not only abundant in all kinds of life, but have more variety both of plants and of animals, and more species which are peculiar and unknown in any other region than any other portions of the globe. The north-east coast of South America, and the south-east of Asia, and particularly Guiana and the lower part of the valley of the Amazon in the former, and the Oriental islands in the latter.

The vegetation which the peculiar climates of these lands, the most highly favoured by nature on the whole surface of the globe, furnish as the foundation of support for all the varied living tribes in which they abound, is not a mere carpeting—a surface vegetation, such as we find in the meadows of the more temperate lands: it is a forest vegetation, one in which many races of animals can take up their abodes in the same trees, the one race inhabiting above the other—some among the roots of the trees, some on the stems, and so on till we come to those that inhabit the small twigs at the very top. All classes of animals are found there; but the peculiar inhabitants are chiefly climbers,—climbing mammalia, climbing birds, and climbing reptiles. The first of these have not much beauty to boast of; but in colour the second and the third are among the gayest of nature's living productions. The ground reptiles, the serpents, and the frog tribe, which live under the shadow of those thick and perennial forests, are seldom beautiful, and the former are often poisonous; but the tree saurians rival the birds in the brilliancy of their tints; and in the more lively ones, among which may be counted the basilisks, it is not very easy to distinguish reptile from bird when they are in motion among the trees.

BASSIA (Linnæus). A genus of three species of East Indian trees. Linnæan class and order, *Dodecandria Monogynia;* natural order, *Sapoteæ.* Generic character: calyx of three sepals, leathery, persisting; corolla bell-shaped, tube swollen; limb eight parted, erect; stamens inserted on the tube of the corolla; anthers linear, arrow-shaped, hairy within; style awl-shaped, longer than the corolla; berry fleshy, five-celled; cells one-seeded. The *Bassia butyracea* is celebrated for yielding a great quantity of useful oil from its seeds.

BASSUS (Fabricius). A genus of hymenopterous insects belonging to the division *Pupivora* and family of the cuckoo flies, *Ichneumonidæ.* As originally constituted, the genus contained insects of different genera, and Mr. Curtis has much increased the confusion by figuring one of the *Ichneumones adsciti*, the *Diplozon calculatorius* as a Bassus. As defined in Gravenhorst's great work upon this family, it is distinguished by the abdomen being depressed and sessile with the first joint flat, and comprises thirty-five species, and three sub-genera. The species are all parasitic upon other insects.

BASTARD TOAD-FLAX. The *Thesium linophyllum* of Linnæus. Class and order, *Pentandria Monogynia;* natural order, *Santalaceæ.* Generic character: calyx five cleft, with intermediate notches; corolla none; style cloven; drupe crowned by the calyx. There are six species of this family, all, except one from the Cape of Good Hope, herbaceous. One is found in England, on high open chalky pastures.

BATRACHIA (frogs and frog-like animals). An order of reptiles, the last of the class in Cuvier's arrangement of the animal kingdom; and very properly so placed, as they may be considered as the connecting link between the other vertebrated animals and fishes. This is not to be taken so much from the haunts of the animals as from their structure. They are indeed all more or less aquatic; and if they do not live actually in the water, they are found only or chiefly in moist places, and they come most abroad in humid states of the atmosphere. There are aquatic animals of all the vertebrated classes; and many of the others live more habitually in the water than some of the batrachia; but the organisation of the batrachia approaches more nearly to that of fishes, than even the organisation of the water tortoises.

There is one habit which may be considered as the sign of this organisation. All the birds and other reptiles which inhabit the waters are produced upon the land. In the breeding season the parents seek the shores and banks, and deposit their eggs there to be hatched by the action of the dry atmosphere. They even, in general, protect them from the moisture of the atmosphere—the rain and the dew. The eggs even of the most aquatic bird—of those species which cannot fly, and which walk with great difficulty, and may therefore be said to have no element but the water, would be rendered abortive if they continued wetted even for a very short time. It is probable that the eggs of the other aquatic reptiles would suffer from the same cause; for though these animals do not incubate, or sit upon their eggs like birds, yet they deposit them in holes of dry banks, or in the beach above flood-mark, and carefully cover them up from the weather. The batrachia take no such precautions, or, to speak more in accordance with the facts, they do not require the heat or the protection to bring them to maturity.

It is a universal law, holding not merely in the operations of nature, but in the works of man—even in his mental exertions—a law to which there is not one exception—that, if the work is done with equal skill, the result—the superiority, or perfection, or at all events, the elaborateness of that which is produced, is always in proportion to the quantity of labour bestowed upon it, estimating that labour both in energy and in time. This is a most important principle in the study of natural history, because of its perfect universality; and we can apply it better in natural history than in human action, because nature's workings, as far as they go, are all equally skilful.

Now we find a very striking difference in the apparent care with which the young of different races of animals are brought to maturity. Those of the perfect mammalia are cherished and defended in the internal matrix—defended from all action of the weather, and enjoying the temperature of the mother, till they are fully formed. But even among these there are considerable differences;—as the kid bounds and the lamb sports almost the instant of birth; while the young of the carnivora are dropped blind, and remain utterly helpless for some time. The young of the marsupialia remain in the matrix only for a time: that of the large kangaroo, which may be regarded as the *type*, or most perfect example, of marsupial animals, being about forty days, at the end of which period the young one is received into the marsupium (abdominal pouch), and there partially exposed to the action of the atmosphere. The labours of birds in forming nests for their broods, and the assiduity with which one, and in some instances both of the parents bring the eggs to maturity, by the heat of their own bodies, are well known. In them too there are differences, from the female that sits constantly, to the one which leaves her eggs for the greater part of the time. Then we come to the oviparous reptiles which are not batrachian; all of which lay detached eggs, or at most they are slightly formed into strings, and they consist, with the exception of the shell, of materials not very different from the eggs of birds, only they contain more gelatine and less albumen, and do not (at least so easily) "boil hard." But all these take some means of protecting the eggs from the direct action of the atmosphere, as if the naked action of that were too much for the power of life which is in them,—or, as if that life required for its development something more than the common working of the elements.

Among the mammalia, wherever the mother is, the young, in the fœtal state, is also there, whether uterine or marsupial. But of animals that are oviparous, or have the undeveloped young separated from the mother, all those which have been enumerated may be considered as *natives* of the land, and produced or evolved by a higher temperature than they could find in the water in its ordinary state: requiring also that temperature to be more uniform than could be obtained in the open air, with even the common alternation of day and night. In all of them there is a natural provision for the bringing about of those circumstances which are necessary for their development; an animal action, opposed to or counteracting the natural operations of inorganic matter, and the only measure that we have of this animal action, is the extent to which it counteracts them. We find that gradually diminishing in the order in which we have taken the animals, till we come to that of the reptiles, which is simply burying their eggs in the earth; and when we look at the animals themselves, we find a corresponding diminution in the development of life, and the energy of all its functions. Some of the saurian reptiles are remarkable for their agility; but it is known that most of them, and it is probable that all, spend no inconsiderable portion of their time in a state not merely of ordinary sleep, but of dormance; that, whether the *winter* to which those powers of activity yield be the natural winter—a season of cold—or whether it be deluging rain or burning drought, they all, to some extent or other, *hybernate*, and during that time, the functions of life in them are very nearly suspended.

But in their hybernations, animals pass to the place of their birth, or to one bearing an analogy to it; and there is not, in all the races which have been mentioned, a single instance of one which hybernates in the water. The alligators and water tortoises make the entrances of their retreats often under the surface of the water; but the chamber of their repose is always above the height of ordinary floods. They received their animation upon the land, and it is upon the land only that they appear to be capable of bearing these long pauses of its action.

But when we come to the batrachian reptiles, we find the beginning of life and the powers of its action in a new element. We find, at the same time, less animal action in the development of the egg, and a simpler and less energetic organisation resulting from it. There are no doubt differences of degree in the different genera which make up the batrachia; but a kind of action, structure, and economy, and even of locality, is common to them all. Generally speaking, they are developed in the water; and if there are any exceptions, it is only the damp earth instead of the absolute pool.

Yet though water is, thus, an element in the developing of the batrachian reptiles, they are not children of the waters in the same sense or to the same extent as the fishes. They come not from the depths; and the eggs which produce them are not aërated by air derived from the water, as is the case with the spawn of fishes, but by air derived from the atmosphere, as in that of the other orders of reptiles.

Among the fishes, we find the spawn deposited at different depths. The bottom fishes lay it deeper than those which play through the waters and find part of their food at the surface. The carp family do not seek the shallows as the salmon do; and eels are produced still deeper than carp. But in all true fishes there is some depth of water over the eggs when the action of life begins in them; for those which are committed to the sea and float there, are, in general, more developed ere they are so committed, than the eggs which are buried in the sand or glued to the stones; and besides, they do not "float out," till they float as the empty tunics out of which the young animals have escaped—as in what are called the "purses" of sharks and rays. If the oviparous animal breathes water through life, the egg is also aërated by means of water when it is in a state of development; and the spawn of no fish can be quickened and matured in dry air any more than the egg of an oviparous land animal can be hatched in the water. The proper distinction is not land and water animals, but animals which breathe the free air, and animals which breathe through the medium of water; and, with the exception of the batrachia, all the vertebrated animals are, from the first action of life in the germ to the last moment of their living existence, true and constant to the one or the other of these. The degree differs, for many air animals seek their food in the water, and some water animals pass part of their time in the air; but still, with the exception of the batrachia only, the vertebrated animals all continue as they begin; and egg or animal, is equally deprived of life, if exposed to the wrong element for a longer time than it can exist without breathing, or being acted upon by that element which is natural to it.

So also, in all these there is no change of form at any stage. There are certain parts of all animals which are not required in the infancy of their lives, and those of course are not then developed; but the animal is substantially the same from the time that it comes out of the egg till its final dissolution.

Thus we have, independently of the ordinary classification of natural history, two grand divisions of vertebrated animals: those which cannot live without air, and those which cannot live without water. Intermediate between these, we have the batrachia, partaking of the characters of both; and although more decidedly reptiles than any thing else in the systems of vertebrated animals, as at present arranged, yet perhaps requiring, in a perfectly natural system, to be formed into a separate order—as should also be the case with the marsupial animals, though even these, in their general economy, do not stand so distinctly alone as the batrachia.

The batrachia may be said to be productions of the surface at which the air and the water meet; though as no animal can live in a mere surface, they find their food in the one or in the other, or in both alternately. In all those, of which the mode of production is known, the spawn or eggs are committed to the water, or to some humid surface, where they have the advantage of the action of water. But they "float out," and have the action of the air at the same time. We are best acquainted with the spawn of the common frog; and that is never deposited in deep water, in running streams which have much current, or in fountains which flow clear and transparent from great depths in the earth, and, consequently, with uniform temperature, or little affected by the state of the weather. Pools and ditches, in which the water is shallow, and which are tangled with weeds in the season, or which otherwise show that they are under the influence of the sun and the atmosphere down to the very bottom, are the places which the frogs select. There the eggs, floating in the water certainly, but still with one side of them exposed to the air, abide all the vicissitudes of the season. They are pelted by the rain at one time, heated by the rays of the sun at another, frozen at a third; and all these often alternately within a very short time. They are thus exposed, too, without any preparation by the parent animals, or any care during the time that they are in progress, being merely cast upon the waters, and abandoned to the elements. They are abandoned to these, too, at the place where their action is the most powerful and the most varied; for a little elevation in the air, or a little depression under the surface of the earth, would exempt them from much of the variable action of the weather.

No other vertebrated animals thus leave their eggs wholly unprotected, or place them on the plane of the greatest action of the weather. But the free air of the atmosphere, the action of light, and the water, are required for the development of the batrachia; and in order to enjoy all these, they must, of course, abide the viscissitudes of the weather. But it appears that they are tempered to the trial which they must thus endure; and though in cold places they are often frozen quite solid, it does not appear that they are thereby injured; for one may see the spawn imbedded in solid ice, and yet when the season comes round, the water of the same pool or ditch swarms with tadpoles. Some of the other species, as, for instance, the common toad, are much more retiring in their habits than the frog, and consequently much more obscure in all their economy. Among them, in the adult state, the principle of life is remarkably tenacious as well as sluggish; and we have instances of their being inclosed in growing trees and yet continuing to live. They also appear to require much more action of the sun to call them from their seasonal repose than the frogs do; and yet they even more habitually avoid the sun's direct action. They do not make their appearance till the earth has been heated by the action of the sun; and not then, till it has been, in some measure, cooled again. Still evenings after summer showers, or dewy evenings after sultry days, and when the sun has a little passed the summer solstice, are the favourite times for these harmless but generally hated animals. They also breed later in the season than the frogs, and do not deposit their eggs or spawn so decidedly in the water; but still humidity appears necessary for its development, as it is often found in showery weather where water has been partially stagnant, in the form of stringy masses of gelatinous or gluey matter, which are, by the rustics in some parts of the country, known by the odd name of "fallen stars." What may have given rise to this absurd name, and to the more absurd belief on which it is founded, it is not easy to say. Toad spawn does certainly appear as late in the season as that at which, in the colder parts of this country at least, the meteors called "shooting stars" are not unfrequent in the evenings; and as these meteors are very generally followed by rain, it is not unnatural that the meteor and the spawn of the toad should be observed in succession; but why the one should have come to be identified with the other, it is not so easy to determine.

The batrachia have not only this double action—the action both of water and of atmospheric air, in bringing them forward in the egg state, but they have a double life afterwards, or, more strictly speaking, they have two successive lives—a first one in the water, and breathing that fluid; and a second one in which, whether on the land or in the water, they breathe air. The last of these lives, or states of existence, must, however, be regarded with some exception or explanation; for there are some genera which retain both sorts of breathing apparatus, and thus are true *amphibia*, and indeed the only known animals which, in a physiological point of view, merit that appellation.

Every one must be familiar with *tadpoles*, or frogs in their first or aquatic state of existence. They are of a dusky-blackish colour; oval in the body, with long fleshy tails compressed laterally, and fringed with a sort of fin. Other than this tail they have no organ of motion, and as the whole of their bodies do not work so well in swimming as those of fishes, it costs them much wriggling of the tail in order to get along. When in this state their mouth can hardly be said to consist of jaws, but rather of two horny mandibles, forming a sort of beak. In this state they are very voracious, as is generally the case with insects in their larva state, or in that state in which they come immediately from the egg; and they eat indiscriminately animal and vegetable matters. How far they are able to go in the way of killing prey has not been clearly ascertained; but they can contrive to nibble with their mandibles till they pick the bones of a little fish perfectly clean.

While they are in this state they breathe water, and are incapable of breathing air. Their gills are placed on the sides of the neck, supported by arches of cartilage, and having their entrance from the mouth, but without any gill-lid to the openings for the escape of the water. Thus, though they breathe water, their breathing is not exactly similar to that of fishes of any kind, though it approximates more to that of the cartilaginous than of the bony fishes. Indeed, it is toward the cartilaginous fishes that the batrachian reptiles approximate in all the aquatic part of their economy. But they are less perfect water-breathers than even these; which would lead to the conclusion that their breathing, and all the functions are but slow even there, as the water has no ingress but by the mouth, and there is no peculiar apparatus by means of which its passage through the gills can be accelerated.

Tadpoles are, in those places which are favourable to their existence, a very abundant production of the season, apparently as numerous in proportion to full-grown frogs as the fry of fishes are to the full-grown of these animals. The pools and ditches in which they are bred also often get dry as the summer advances—although frogs do not deposit their spawn in the water which stagnates from an occasional shower, and which is certain to be dried up before the average season of the tadpoles being able to take to the land, and escape. This last circumstance, whatever may be the instinct which guides the parent frogs in the choice of the water, is what we might expect, because it is part of the general system upon which nature acts. Wherever the egg is deposited, or how completely soever it may be abandoned by the parent, it is always safe in nature's keeping; and upon the average, the egg is always placed in that situation in which it is most certain of being brought to maturity, and the young most certain of being fed until it undergo some change, or can otherwise shift for itself.

But still, though the spawn of the batrachia is deposited in such a way as secures the continuance of the race, the eggs and the tadpoles are, in the case of the frog, so very numerous, that they must answer some other purpose in the economy of nature; for in nature there is no selfishness, no production, which exists for itself only. Also, in the case of those which, like the frog, appear in more states than one, there must be a general use in nature for each state. The egg, the tadpole, and the perfect frog, must all have their part to perform—a purpose which they answer, besides keeping up the succession.

And this natural use of the creatures is twofold: they are useful in that which they consume, and in that by which they are consumed; and if there is a change of state, both uses change along with it. The same insect, as an egg feeds the titmouse in early spring, the warbling songster as a caterpillar in summer, and the bat as a moth in the full heat of the season. It is probable that, but for the tadpoles, the ponds and ditches which they inhabit would, against the torrid season, become rank to pestilence with the remains of small life. But while they are performing this operation, and it is far from an unimportant one, they are preparing the surplus of their own abundant array as subsistence for another race of feeders. The ducks, and all the other birds which nestle in the marshes or on the banks, and dabble for their food in the shallow waters, would, in many instances, fare but scantily, if the spawn of the frogs did not supply them in the early season, and the tadpoles when it is more advanced. Thus the abundance of these creatures in their early stages is not a waste, but a wise provision for other races; and if they were struck out, the blank which would thereby be occasioned in nature would be much greater than one would at first consideration suppose. Indeed, where drainage and culture have taken away the nursing places of the batrachia, the marsh birds also have departed; and there is no question that the one is, to a certain extent, the cause of the other.

And when they are full grown they still have their double use. In the water, or upon land, they restrain the superabundance of insect life under circumstances that do not readily admit of its being done by races differently formed. The leap, which is the prominent motion of the frogs, and which all the four-footed portion of the race can perform, is a motion of capture, as well as of mere progression. The habit varies, and some have more the character of liers in wait; but still they are all fitted for keeping within bounds the exuberance of something, which could not be so well kept down by creatures differently formed.

That over which they are thus set is seasonal, and also occasional, so that they hybernate at those times when the economy of nature does not require their action; and at other times they can endure the want of food long and patiently—to a degree which is utterly incompatible with the nature of animals having more ardent systems. All reptiles have this enduring quality to a very considerable extent; and on that account they may be called Nature's "extraordinary labourers." They remain torpid and quiescent till the season which requires them comes round, and then they are ready, and in action in an instant. One knows not whether most to admire, the perpetual activity of some other races of animals, or the perfect obedience to their time, which is displayed in these. In form and habit they are different, but in purpose and adaptation the one is every way as admirable as the other.

When the appointed season, during which the different species of the batrachia are to remain in their aquatic state as breathers of water, draws to a close, they undergo those changes, both of external and of internal structure, which are to fit them for their new state. But the development of the new parts rather precedes the shedding or absorption of the old ones. Tadpoles may be seen, with the feet pretty well developed, and the swimming tail still adhering; and there is also one period of their lives, however short, in which both sets of breathing apparatus can act. When the lungs assume the superiority, the characters of the land animal predominate throughout the whole structure; but in those genera in which the gills continue, the characters of the aquatic animal continue predominant. *Light* is, however, essential to the change.

The three genera which retain the double function in breathing are, the *siren*, *proteus*, and *menobranchus*. They are all inhabitants of the water; and hitherto they have been found only in America. Their economy in a state of nature is but imperfectly understood; and it is doubtful whether they use both systems either at the same time, or alternately with each other. They are very curious creatures, however; and the little that is known of each of them will be stated under the generic names.

The system of circulation in the batrachia bears some resemblance to that of the other reptiles, and also to that of the fishes. Red blood circulates to the remotest parts, though slowly, and in but small quantity; and the web of a frog's foot, in consequence of the transparency of the integument, and the slowness of the circulation, is one of the very best cases in which to observe the passage of the blood from the arteries to the veins, and thus establish that the grand mass which flows through the system is the same, however it may, in successive portions, be altered by substances with which it parts or takes up.

To observe the living tide at this "turn" of its course, when it has communicated all the nourishment which, at that passage over the body, it is capable of communicating, and when it is about to return, taking up the absorbed surplus and the prepared food on its way, is one of the most interesting points in the animal economy; but it is one which is very difficult to be seen, more especially in animals that have a quick circulation. Artery and vein never anastomose with each other; and, except through the heart, or that which answers the same purpose, they have no communication but through those capillary junctions, which are so small that they are not visible to the naked eye. It does not even appear that they bleed when lacerated; for the blood which is obtained from a wound is either arterial or venous, and never the intermediate blood of the capillary. This increases the interest which is felt in observing the living action; but that action cannot be seen without the aid of a microscope of high power, and that power of course multiplies the velocity as much as the lineal dimensions.

While the batrachia are in the tadpole or gilled state, the system of circulation is exactly that of a fish. The heart has but one auricle and one ventricle. The aorta proceeding from the latter divides into as many branches as there are gills, and thence it returns by veins to an arterial trunk situated on the spine. From this trunk the systematic arteries are ramified over the body, and from their extremities the veins originate, and bring back the returning blood to the auricle. Thus the heart of the tadpole is only a branchial heart, sending the blood to the gills by its contractions, and the systematic circulation is performed by the arteries alone There is thus little or no force or velocity in the systematic circulation, and consequently there is little or no heat produced in the system.

When the gills are absorbed, the arterial branches which carried the blood to them also disappear, only two remaining, which go to the two lungs. These two remaining branches carry to the lungs only a portion of the blood which the heart propels, the remainder going to the systematic circulation without being acted on by the air. The action of the air (or the water, according to the habit) upon the blood appears to be the grand or primary action which regulates all the rest, and the energy of the whole system of the animal is in proportion to the quantity of the blood thus acted on, and the rapidity with which the action takes place. In birds, it takes place not only by the whole current of the blood which passes through the heart passing through the lungs also, but along almost the whole course of the arteries, so that the bird is "lungs all over." In mammalia, the whole passes through the lungs, and in reptiles a part only, and in the case of batrachian reptiles only a small part; hence their coldness, and capability of enduring hunger and other privations.

The change which takes place in the batrachia from breathers of water to breathers of air, by a mere *structural* alteration, and without any change of *substance*, proves that, in principle, these two means of breathing are the same, and that the difference is merely one of mode. The animal which the one moment sends its blood to the gills to be acted on by water, and the next moment to lungs to be acted on by air, is one and the same animal, and the blood so sent is one and the same blood. Therefore, the action which it undergoes must be one and the same action; only the mode is different. As stated in the article Air, it is really *air* which is breathed in both cases, only, in the case of the gills, that air is mixed with water, but there is no decomposition of that water, and no change of it farther than that a certain volume of the air, which it contained in the state of oxygen, is converted into an equal volume of carbonic acid gas. Thus, that which is otherwise only a rational theory, is demonstrated to be truth in the case of the batrachia, and from them the application to all other animals becomes obvious, and even necessary.

There are some other very important points which receive elucidation from the study of the batrachia. Breathing by gills is a much less efficient process than breathing by lungs. There are in the tadpole of the frog tribe eight gills, four on each side, and there is an epual number of arterial branches which carry the blood to them; but there are only two which go to the lungs of the same animal, and they carry only a portion of the blood; consequently, a smaller degree of the action of lungs in breathing air suffices for the purposes of life in the very same animal. But the particular forms of the two kinds of breathing apparatus shows the different modes in which the two fluids act. Lungs consist of cells, into which the air is received, and over the walls of which the small vessels containing the blood are ramified. Gills consist of small fibres or filaments, over the surfaces of which the vessels are ramified, and these filaments are surrounded by the current of water. The air is thus received into the lungs; and the gills are immersed in, or surrounded by, the water. In the former, the action is the resistance of the walls of the cells, which, in animals of warm temperament, is increased by the expansion of the air in consequence of the heat,—and that, by the way, is one of the reasons why the lungs pant and labour when the body is much heated. The action upon gills is the pressure of the water, which, of course, varies with the depth, and explains why animals which inhabit at great depths breathe much more slowly, and are much more tenacious of life, than those which inhabit near the surface. Attention to these points enables us to understand many of the differences of structure, and explain many of the habits of different races of animals, without the labour of individual observation; thus greatly abridging the time and trouble necessary for acquiring that general knowledge of natural history which should be possessed by all who claim the character of being even moderately well educated, and rendering the science a source of pleasure to a much greater number of persons.

Even when the batrachia arrive at that stage in which they breathe air with lungs, their respiration is feeble, as well as limited to a portion only of the blood. They want the proper structure of respiring animals; for though their gills are (with the exceptions already mentioned) replaced by lungs, they have not the apparatus for working those lungs which are possessed by the mammalia, and for which birds have substitutes in their air-cells and air-tubes. They have no ribs nor breast-bone, and therefore the thorax does not act in breathing.

The frogs, as the types of the order, will best serve for illustration upon this, as upon all other points. The frog receives the air which is to be conveyed to the lungs by the nostrils, but there is no vacuum or cavity formed by the expansion of the thorax, as in the mammalia, so that the mere pressure of the atmosphere, following the expansion, does not inflate the lungs as in these. An effort is required after the air is taken into the body, and that is performed chiefly by the tongue. When a frog is breathing with its head to the observer, it may be seen raising and lowering the skin between the bones of the under jaw, but with its mouth firmly shut all the time. The depressions of the skin of the lower jaw last much longer than the elevations, because, during them, there is a double operation to be performed—the expulsion of the air already in the lungs, and the readmission of fresh air into the body. When that skin first descends, there is a contractile action of the abdomen, by which the air in the lungs is driven out; and when that is all expired, the abdomen returns to the neuter or natural state; but being without bones, it cannot form a vacuum, and thus the lungs could not be inflated but by some other action capable of overcoming the resistance of their cells. It is for this purpose that the skin under the jaw is raised, but the motion of raising it is in the tongue. That first shuts the nostrils by pressure near the anterior part of the roof of the mouth, and then rising gradually backwards, it fills all the cavity of the mouth, and forces the air which it contained into the cells of the lungs, which constitutes the respiration. The depression of the tongue opens a passage by the nostrils, and the muscles of the abdomen contracting, force the air out by that passage after it has performed its office. So far is the frog from deriving any aid from the mouth in breathing, that it cannot breathe with the mouth open, as there is then no means of inflating the lungs; and if the mouth is forcibly kept open, the animal as certainly dies of suffocation as the mammalia when both mouth and nostrils are kept closed, though, from the slower circulation, and the fact of only part of the blood passing through the lungs, that catastrophe would not take place so speedily. So also, if the muscles of the abdomen are divided, or paralysed, or otherwise rendered incapable of acting, the air remains in the lungs, and by that means the animal is suffocated.

The skin or covering of the batrachia is in all cases simple, without crust, scales, hair, or any other appendage; and there are some of them that have even no nails on their toes. Those that have teeth have them very small, fitted rather for securing insects and larvæ, which they seize with the mouth, than for biting any animal or other substance. They have no weapon either of offence or defence; for though it is said that pores on the backs of some of the foreign species secrete an acrid poison, yet that is probably no better founded than the old stories of the venom of the common toad, or of the medicinal jewel which it carried in its head.

Taken as an order, they are among the simplest, and certainly the most harmless of animated beings. They doze out the cold season, or other season unsuitable to their habits, in holes of the earth, or at the bottom of the waters. The common frog is especially fond of hybernating in springs, no doubt because of their uniform temperature during the winter. But so far from doing harm there, it tends to render them sweet and pure, by making its first and last meals for the season upon any eggs or larvæ that may happen to be there. In the depth of its hybernation the frog does not eat, and therefore its mouth remains perfectly close all that time, and, from the general rigidity of the all but lifeless animal, it is not easy to be forced open. On this account it has sometimes been said that the lips of the frog adhere and seal up the mouth while it hybernates, an operation for which there could not be any possible use.

There is nothing which man cultivates, cherishes, or in any way sets a value upon, that is in the least injured or interfered with by any of the batrachia. The bull-frogs, indeed, are " horrible musicians," and the love songs of those of our own country are certainly not so tuneful as the songs of birds. Many of the species also offend against our notions of beauty, but in that respect the fault is more in the narrowness of our standard than in the animal. Both our notions and our vocabulary would require to undergo much alteration before we could call a toad " handsome;" but uncouth as the toad is in its general appearance, it has a beautiful and most expressive eye,—an eye by no means deficient in speculation; and it is not unsusceptible of attachment, or insensible to kindness. There have been instances of " pet toads," which, though they lived in retirement in the winter and during the heat of the day, according to the habit of the race, yet knew their master's voice, and came leaping from their hiding place at his call on the fine summer evenings.

The common toad, at variance as its appearance is with our usually-received notion of beauty, is not the most ungainly of the race. Some of the foreign species are much larger, and also more rough and warty in their appearance. One of the most singular looking is perhaps the Surinam toad (*Rana pipa*, Linnæus), which may be regarded as a sort of marsupial reptile. The eggs are placed by the male on the back of the female, much in the same way as if they were the tubers or seeds of vegetables; and after they are fecundated, the female betakes herself to the water. There she remains with the back partially exposed. The skin of her back swells or puckers up, and forms cells in which the eggs are not only hatched, but the tadpoles nourished till their feet begin to grow and their tails to drop off, after which the female returns to the land. This is perhaps the most singular mode of rearing a progeny which is found in the whole range of the animal kingdom. It is somewhat analagous to marsupial nourishment in form, but it is not so in principle; for the young of the marsupial animals are not only quickened, but advanced to a certain stage of their growth before they are deposited in the marsupial receptacle; whereas the eggs of this animal, when placed on the back, are only separate elements of the organic being, and would never advance to maturity, or become animated at all without the other elements.

It now only remains to mention the subdivisions of the order to which to refer for some notices of the more remarkable species.

There are two divisions or sub-orders—batrachia without tails, and batrachia with tails.

Of tailless batrachia, the genera are: TREE FROGS (*Hyla*), COMMON FROGS (*Rana*), and TOADS (*Bufo*); but by some these genera are united, and by others they are further subdivided.

Of tailed batrachia, the genera are: SALAMANDRA (*Salamander*); MENAPOMA; AMPHIUMA; AXOLOTL; MENOBRANCHUS; PROTEUS; and SIREN. These are by no means so common as those of the former division; the history of some of them is very imperfect; and there has been a little confusion produced by confounding them with the saurian reptiles, and calling them lizards.

BATS (*Vespertilionidæ*). A very numerous family of mammalia, belonging to the order or sub-order *Cheiroptera*, or animals with winged hands; that is with the skin between the fingers of the anterior extremities, between these and the posterior ones, and in some instances between the posterior ones including the tail, so much produced and capable of extension as to answer for flight.

Bats have, in all ages, been perplexing objects to systematic naturalists. They have been so on account of what appears to be their double character, the general structure of mammalia, and the motion of birds. With the ancients they were *aves non aves*, " birds yet not birds," and in the progress of natural science to something like a structural classification, they were sometimes arranged with one kind of animals and sometimes with another. Aldrovandi classed them with the ostrich, which, though it now appears absurd, was in accordance with the most striking, and therefore the first chosen ground of classification—the element in which the creatures moved. The bats were quadrupeds which could fly, but they could walk on the ground very imperfectly, or not at all. Ostriches were birds which could run well, but were altogether incapable of flight. Thus each had the structure of the one class and the motion of the other, which made them resemble each other as a sort of mongrels.

If, however, the action itself, or the organisation by which it is performed, be examined with even a moderate degree of attention, it will clearly appear that the motion of the ostrich along the ground is not the walk of the mammalia, neither is the motion of a bat through the air the flight of a bird. The ostrich balances a horizontal spine upon two legs, and a large portion of the middle of that spine is so inflexible, that it may be considered as a sort of beam or balance, poised on the articulations of the supporting legs. But the articulations of the vertebræ of the mammalia all (with the exception of some in the necks only of a few species), admit of motion; and, therefore, there is no part of their spine which can be balanced like a beam, upon two legs articulated at the same distance from the extremities. Consequently, they cannot stand or walk upon two legs but with the spine in an erect posture, so that each vertebra may support the portion above it.

The back bone of a bird, from the insertion of the neck to that of the tail, may therefore be considered as an inflexible beam or lever (at least it is nearly so), supported upon the articulations of the legs as a fulcrum, and, by the well known property of the balance, capable of being held in equilibrio at any angle, except perpendicularly to the horizon,—the flexible neck and tail, and the bendings of the joints of the legs, being the means by which it is kept in equilibrio. In as far as support is concerned, it is evident that if any body is supported on a point, that point may be moved, and the supported body along with it, in any direction and with any velocity, without in the least disturbing the equilibrium of the body. The point upon which the body of a bird is supported, is always in the line joining the articulations of the legs, in the middle where the bird stands equally on both feet, and nearer the supporting foot when it stands unequally; and the motions of the head and tail enable the bird to swing upon this point, without the least tendency to fall. If the bird had any other supports, these would prevent the motions of its body, and actually render it unstable. So that the two feet of the bird perfect its support in standing or walking on the ground; and when the habit of the bird is also to fly (which is the general one), its wings are left entirely free, or available for aërial purposes. When the bird flies, the point of support is transferred to the line of the wings, on which the balance is as complete and independent as that on the feet. The bird has thus *two* systems of motive organs, feet for the ground and wings for the air; and each of these is perfect in itself, and independent of the other. We shall show that the mammalia can have only *one* system; and, therefore, must be either walkers incapable of flight, as in the majority, or flyers incapable of walking, as in the bats. These are no doubt balancing wings, and partially also swimming wings, the structure and action of which will be explained in the article Bird; but it is not necessary to allude to them here, as they form no part of the structural distinction between a bird and a bat.

But if the spine of a bird resemble a *beam* or *lever*, which can be supported and balanced on *one* point, that of the mammalia resembles a *chain*, which unless it can be supported on end, as in the case with man, must have *two* points of support. A chain can merely hang across one support placed not at its extremity; and a certain degree of *tension* is requisite for keeping it in *any* form upon two, as, left to its gravitation, it would fall into the well known curve called the *catenary* (or chain curve). The system of muscles with which the spine of the mammalia is furnished gives this *tension*, and the spinous processes of the vertebræ, which have often so singular an appearance, are the levers upon which these muscles act in putting the spine into the position required. But still no action of muscles on the flexible spine could keep that supported upon a single point, unless nearly on end, as in man.

Therefore, it is not possible to give to the mammalia two sets of motive organs, one for walking and one for flying, as in birds; because both sets of extremities are necessary for supporting the body both on the ground and in the air. In all reasonings on the comparative structures of animals, man must be left out; because none other of the mammalia have only *two* walking feet, and none two hands of all work. Apes cannot walk long in the erect posture, and they walk awkwardly, while all the other mammalia, unless they use all their four feet in walking, merely shuffle along in a sort of sitting posture; and if they were to attempt to walk fairly balanced on their hind legs, the fore part of the body would fall down. So also, though they had wings in place of the fore legs, they could not use these wings for flying. They might assist in a leap, like a parachute; but the moment that the body were committed to them, the hinder part would fall down, in consequence of the flexibility of the spine; the body would turn on the axis of the wings till these were on edge; and then it would tumble to the ground with the head or the heels foremost, according as the one or the other weighed heavier from the axis of the wings. If the spine were inflexible, so that they could balance themselves on wings, they could not use four feet in motion, or turn round without much labour. Some of the saurian reptiles turn with much difficulty, on account of their stiff scaly coverings, though they have articulated spines.

Thus much of the general principles of animal mechanics is absolutely necessary, in order to have any thing like clear notions of the structure and motions of bats; for as all animals are made of matter, and subject to the laws of matter, no animal can act in opposition to those laws without an apparatus capable of overcoming them. A foot cannot walk, or a wing fly, unless it accord with the general organisation of the body; and two structures which are incompatible with each other cannot act at all. The winged horses, and the winged beings otherwise in human shape, which we meet with in paintings and sculptures are, on this account, incongruous combinations; and if the beings which they are meant to represent could not fly without the wings, they could not possibly fly by means of them, as the action of wings is perfectly incompatible with that of fore legs or arms.

It was similar ignorance of, or want of attention to, mechanical possibility and consistency, which led to the confounding of bats with birds; but as the principles of zoology began to be better understood, and animals were classed more according to their physiology, it was admitted that the bats were true mammalia; and in consequence of the pectoral mammæ of the females, and some other external appearances, Linnæus placed them in the same order with man and the ape tribe.

The faultiness of that classification is easily seen; but it would seem much more easily seen than corrected. Cuvier ranks them and the other cheiroptera as the first family of his great order *Carnassiers*, of which the *Carnivora* form another family. This is an instance of very defective nomenclature; for "*carnassiers*" is the literal French translation of the Latin "*carnivora*;" and thus the definition of the order and that of the family should be the same, and one of them useless, or else the same word is used in different senses. Cuvier had certainly too great a fondness for classing animals according to their teeth or other feeding instruments. His notion evidently was to include all animals which have digital extremities and the three kinds of teeth, with the exception of man and the quadrumana, in one general order. But if that order include the bats, it might also include the quadrumana; for the characters of these are not more different from those of the true carnivora. The quadrumana are separated on account of their organs of motion—organs adapted for climbing trees; and surely climbing the air, or floating along in that element, is as distinctly marked a character. If we take into account the whole character and economy of the animals, we shall find that the bats have fully as many in common with the quadrumana as with the beasts of prey. So that, though Linnæus proceeded more by general analogy and Cuvier more by anatomical dissection, Linnæus is in this instance not more incorrect than Cuvier. *Cheiroptera* should unquestionably be a separate order, if the system is to guide us to the affinities or relations of animals; and if not, we might as well be without any system. When we take the proper distinctive character of the cheiroptera—the flying membrane, and look for the affinity—the possession of the same character in an inferior degree, we do not find it in the *carnivora*, but in the *rodentia* and the *marsupiata*—in the squirrels, and the *phalangista* and *petaurista*; and with these there is the same relation in habit as in structural character. See Classification.

With the exception of a single genus, and that probably not consisting of more than one species—the genus *Galeopithecus*, the "cat-ape," or the "flying cat" of common language, all the *Cheiroptera* are called bats. That genus has pectoral mammæ, and the skin of the sides enlarged so as to form a parachute, extending nearly to the points of the toes; but it has none of the true bat characters. It does not fly, that is, it does not, by the action of the fore legs, give itself fresh impulses while in the air. It is a climbing and leaping animal, and its extremities are far better adapted for these purposes than for flight; whereas the bats can neither climb nor leap, at least they must, from their structure, be very awkward at either. The peculiarities in the structure of the bats receive no illustration from that genus, nor from any other animal, nor can they be used in explanation of any other; therefore, whether they are to be called an order or a family, the bats should stand alone; and doing so, they form a very well-defined natural group, a group no member of which can be mistaken if the characters of any one are well understood.

The *characters* of the bats as a group are: the skin of the sides produced into a broad and thin membrane, which extends to the points of the toes; the toes, or fingers, of the fore-legs very much produced, and united by a thin and broad membrane; the thumb separated from the fingers, generally very short, and furnished with a strong crooked claw, which the fingers are generally without; the membrane wholly or nearly naked, and having a leathery appearance. The hind legs are much shorter than the fore, the toes on them but little produced, and each of the toes furnished with a crooked claw. The length of the tail varies, being in some of the species merely rudimental; it is generally included in the membrane, but does not appear to be the efficient instrument of steering or keeping the course in the flight of the animals. That appears to be done chiefly by the motions of the hind legs, while the fore legs are the grand instruments of flight. The hind legs have not any peculiar muscular structure, by means of which they can be very efficient in moving the wings, and, when the animal is extended, the motion which they have is horizontal rather than vertical. The fore legs, on the other hand, have little horizontal motion, and cannot be moved much either in advance or to the rear; but their vertical motion is powerful; and, in order to give insertion to the large pectoral muscles which produce it, the sternum or breast-bone is provided with a prominent *crista* or ridge. The shoulder-joint, or articulation of the *humerus*, admits of a considerable range both of elevation and depression; but the joints of the elbows, wrists, and fingers, do not admit of being stretched beyond the straight line. The wings, or rather the "membranes of flight," for they are not wings either in the form of their bones or the nature of their covering, thus admit of partial flexure or folding when they are raised; and when they first "take the air," in their downward stroke, they are hollow, by which means they take a better hold, and this hollowness in some degree compensates for the want of feathers, the fibrous structure of which takes hold of the air without the assistance of hollowness, at least to the same extent, though all birds which fly with a fluttering or bat-like motion have the wings more or less hollow. The membrane of flight is very thin and light, and admits of being folded into very little space when the animal is in a state of repose. Such are the general characters as dependent upon the organs of motion.

The organs of nourishment have a general resemblance to those of the other mammalia which feed upon insects and other small invertebrate animals; but with a general modification to suit the habit of the tribe, and particular ones in the different genera. The gape of the mouth extends very far backwards, and also opens wider than in most animals of the same size. In these respects it has some resemblance to the gape of the bills of birds which catch insects when in flight, especially to the goat-suckers, which, like the bats, are nocturnal or twilight feeders. It is further worthy of remark, that these birds which, in their mode of preying, certainly resemble the bats more than any other animals, can make little or no use of their eyes in the catching of their prey. The front or incisive teeth vary in the different species, the canine are generally large, and the grinders have short protuberances. The intestinal canal is simple and without any cæcum, indicating food of easy digestion. This last character forms a very marked distinction between the bats and the galeopithecei, which have the cæcum large, and are more of vegetable feeders.

The organs of sense are variously developed. The ears are in general large, and in some of the species they have a duplicature or second concha, as if there were one ear within another. It is hence presumed that the sense of hearing is acute; and it *may* be that those which have the duplicature to the ears have the means of closing up the auditory passage, so that they may not be disturbed in their repose during the day. The nostrils and also the mouth are also sometimes surrounded by produced membranes, the use of which is not very well known. Perhaps they aid the sense of smelling, which is generally acute in nocturnal feeders; perhaps they assist in the capture of the insect prey; and perhaps they are in some measure organs of touch. The eyes are very small and deeply enfonced, something like the eyes of moles; and though they must have the power of vision, it does not appear that they are essential to the animal in finding its way, even when that is intricate. The well-known experiments of Spallanzani, which were verified by others, proved that when blindfolded, or even blinded, bats can find their way through between obstacles of which they could have had no previous knowledge; and indeed though we, reasoning from ourselves as the example, are very apt to suppose that what we call the caution of animals is a matter of experience, yet, prejudice and false analogy apart, experience appears to have little or nothing to do in the matter. Spallanzani suspended willow rods in the room in which he turned the blind bats loose to fly; but, though he shifted these so as to make the passage between them as varied and as intricate as possible, the bats never struck against one of them, though they kept flying about in all directions.

A question has hence been raised as to the means by which bats do contrive to avoid obstacles; and the same question may be extended to very many other animals. A horse in the dark pauses when he comes to a closed gate, though he never was the road before; nocturnal beasts do not more frequently fall into pits and over precipices, than beasts which are abroad during the day and have their eyes to guide them: and nocturnal birds do not fly against trees any more than day-light birds. People, too, will keep a *well-known* path though the night be pitch dark

In the last case we are in the habit of saying, that "the feet know the road;" and the saying is probably not very wide of the truth. "Feet" or "head," we know *that which we have learned*. Animals need no learning in the performance of their natural functions; and therefore they know all ways instinctively which their habits lead them to, and the nocturnal ones have no more difficulty in the dark than the diurnal ones have in the brightest sunshine: another proof of the wisdom and goodness of the Creator.

This, it will naturally be said, is not an answer to the question; but, though it would be easy enough to *write* more, it is in truth all that can philosophically be given. That the animals feel a different resistance in the air in time to avoid the obstacle, the pit, or the precipice, is evident; but *how* they feel it, or even what name we are to give it as a *sense*, is another matter. Of sensation we have no knowledge beyond the experience of our own senses; and what is said respecting them, even by those who are accounted the "authorities" in matters of physiology, is vague enough. The most rational theory on the subject is, that as the sentient animal is *one*, all the senses are essentially one also, only modified by different organs. And if modified by different organs in the same body, much more may they be modified by bodies which are specifically different, so that the sense which has apparently a similar organ, and to which (on that account) we give the same name, may be very different in two different animals. We are accustomed to say that a blood-hound, which follows upon the "slot," has a very exquisite sense of smell; but the hound cares nothing for roses or mignonette, or all the perfumes in the world; and the eye of the eagle, much as has been descanted on its power of vision, has no perception of beauty either in forms or in colours. The flying membranes of bats, thin as they are, contain a beautifully reticulated plexus or net-work of nerves, and the texture of them externally is of that description with which we usually associate a very delicate sense of touch. But still we cannot say that such a surface is absolutely necessary; for it appears that the whiskers of cats, the delicate fringes in which the wing feathers of owls terminate, and many other surfaces and substances in which there do not immediately appear to be any nerves, give indications equally delicate and certain. A blow on the horn of an ox appears to pain the animal even more than a similar blow on the hide; and treading on the toe is not a tittle the less painful for its being fortified by the mail of a corn.

Delicacy of sensation is rather a quality of the general constitution of animals than of any local organ; and the bats appear to possess it in a very high degree, not only as regards the contact of solid substances or the mechanical motions of the atmosphere, but as regards light and temperature. They cannot bear wind, they come not abroad during the day, and they hybernate in the winter. The temperature which suits their nature appears to be more limited than that of almost any other race of animals.

Their *habits* all tend to show this. They breed at the very hottest time of the year; and the young, which are usually two in number, are naked and helpless at their birth, capable only of clinging to the teats of their mother, which, however, they do with the greatest firmness and pertinacity. This habit in them is necessary, for the mother does not lie down or even stand on the ground when she suckles her young, as is the case with most of the mammalia. She hangs suspended, by the nails of her thumbs, or more generally by those of her hind feet, to the branch of a tree, or some cranny or irregularity in a ruin. There is no nest in which she can leave the young ones when she goes out to feed; and thus she must bear them about attached to her body till they are capable of flight. The female has no marsupium; but this habit resembles a little those of the marsupial animals—the young are very immature when produced; and their nest and place of safety and repose is the body of their mother.

Some of the species occasionally fly during the day, but that habit is by no means common, and is confined to some of the foreign species which are in part vegetable feeders. In temperate climates, they conceal themselves during the day, even in the season of their greatest activity. Caverns, holes of trees and walls, and ruined buildings are their retreats; and from these they issue forth as dusk begins to set in, flutter about in their laborious flight, and capture such insects as are then on the wing—gnats, mosquitoes, moths, and beetles; and their wide gape with its formidable teeth is an excellent trap for the capture of such prey. The service which they render to vegetation, by the destruction of insects which in the larva state prey upon it, is very considerable, even in temperate climates; and some of the hot countries in which they swarm by myriads, could not, but for them, be inhabited. In humid places on the margins of tropical forests, mosquitoes are troublesome enough as it is; but if the bats did not thin their numbers, they would be utterly unbearable. Those species too, which frequent the towns and settlements are useful in other respects. Most of the race are miscellaneous in their feeding, and not very delicate in their taste. They devour indiscriminately all animal substances, whether raw or dressed, and whether in a recent or a putrid state.

But though they are thus voracious in their feeding, they can endure hunger for a great length of time; and the waste of their system appears to be but small. When the weather is favourable for their feeding, they very soon get fat, and when they are compelled to remain longer in their retreats than usual, the fat is absorbed, and they get lean again.

In temperate climates, they disappear by the time that the cold evenings of autumn set in. Their retreats are the closest crannies which they can find, and there they are often clustered together in heaps. In high latitudes they remain in their dormant or hybernating state for a long time; but the short period during which they do feed is more favourable for them than in lower latitudes, as it is twilight all night long. While they are hybernating, the digestive functions are wholly suspended, and the circulation so nearly so that it cannot be perceived in the smaller vessels. The respiration, of course, is feeble in the same proportion as the circulation. There is thus very little waste in the system, and very little absorption of fat can supply it; but how long they could exist in the dormant state before they perished of exhaustion has not been ascertained. The lowest temperature at which, in our latitudes they come out, varies according to the species, from about 42° to 48° of the common thermometer.

The extreme sensibility to light and to touch, which has been already mentioned as not confined to any particular organ, is finely shown in the dormant state. Be that ever so deep, the creature shrinks from the touch, even before actual contact, and so does it from a candle or any other light; but these have no tendency to awaken it from its profound slumber, which shows that the sensibility is not in consequence of activity in the other functions of the animal.

When, however, the requisite degree of heat is applied they revive, and show themselves as obedient to it as ever. But in order to revive safely they must revive gradually; for if they are *forced* by a high temperature, such as exposure to the fire, they awaken only to perish; and the operation appears to give them pain, something similar to that which is felt when the frozen hands are held to the fire. The injury is probably the same—the rupture of the small vessels.

When they are awakened in that gradual manner which does not destroy them, their circulation, their breathing, and their appetite return; and if they have slept long, and their fat is nearly all absorbed, they must soon eat, or perish of hunger. Casual awakenings during the season of repose are, therefore, highly injurious to them; and it is to avoid these that they betake themselves to places which are so concealed as that the vicissitudes of the weather do not readily affect them; but they, of course, do not go into those which never during summer acquire the temperature at which they revive. But the more constant the winter, and the cooler the place of their retreat, they are safer; as the contrary circumstances are apt to rouze them before the season can supply them with food.

Though the bats are, upon the whole, useful rather than hurtful to man, they are creatures to which poetry and superstition have in all ages had recourse to deepen the feelings of loathing and horror. The bats are things of the doubtful light—the dim twilight, which, in ages of ignorance, converts white stones into ghosts, and bushes into spectres. They dwell in the ruined wall, or the rifted earth; and they also often found their way into the sepulchres and catacombs of the ancients. They were thus dwellers with desolation and with death; and it was but stretching the imagination a little further to suppose that they were in league with these loathed and dreaded powers. And the rapacity of the bats in their feeding during the twilight gloom, and the miscellaneous nature of the food, gave still farther colour to the supposition. Hovering about the temples, they ate greedily the blood and other remains of the sacrifices; when famine or pestilence, which were then of frequent occurrence, though fortunately known to us chiefly by name, strewed the earth with the bodies of the dead, and when night closed upon the horrors of the battle-field, the bats came to the nocturnal feast; and as in all cases they came fluttering and apparently formless, with wing most unlike any organ bearing the same name which is spread to the light of day or the sun of heaven, they perfected their claim of poetical alliance with the infernal regions, and the powers which held dominion there. As the peacock was the bird sacred to Juno, the queen of heaven, so the bat was the creature sacred (or accursed, if the word is better liked) to Proserpine, the empress of hell.

The use of them for these purposes is as old as Homer, who very skilfully manages them in heightening the graphic effect of the splendid passage in which he describes the shrieks and wailings of the ghosts in the regions of woe; and, after Homer, all poets and painters who have ventured upon similar delineations, have made use of the bats for the purposes of effect. Even to this day painters must borrow the wings of bats to their devils, in like manner as they borrow the wings of pigeons to their angels; and one has only to throw a deep Rembrandt shade over a piece of canvas, and show a bat's wing partly displayed from a cave, in order to give an infernal air to it, and make it, with very little painting, a good poetic representation of the gates of hell. It is easy to see how a race which is linked with such associations should have had but a scanty measure of justice meted out to it by the half superstitious naturalists of the middle ages; and a remnant of the same superstition is, no doubt, the cause of much of the horror which is associated with some of the larger bats of the warm countries.

In Britain, though there are several species, the individuals are no where numerous, unless where the whole colony of a country-side are found clustered together hybernating, or hiding themselves from the day in solitary and seldom-frequented caves. This occurs most frequently in the southern parts of our island; and there are some of the rarer British species which have been found only in such situations. No where, however, and of no species, are British bats so numerous as to form a striking feature in the natural history of the country. A few of the common bats may be seen flickering about villages and farm yards on the fine stilly summer evenings; and they stand accused of making small inroads upon the dairy and the larder; but still there is not sufficient interest about them for creating much attention, and they have rather to be sought out as curiosities than otherwise. The thinness of their numbers as compared with those in the nearly corresponding latitudes of continental Europe, may be accounted for by the nature of the climate, and the effect which, as already explained, it has upon creatures so sensitive. Taken altogether, the temperature of our year is too uniform for being favourable to this family of animals, and taken in the details, it is too variable and inconstant. Our summers have too much rain in them for making good bats' weather; and our winters are too mild—they keep them awake after their food has become scarce; and they not only awaken them again too early in the season for its reappearance, but they very frequently awaken them to certain destruction in the winter and the spring.

Common Bat.

But there are many countries where bats are far more numerous than any other species of mammalia, and where they are consequently very characteristic. These are the richer parts of the tropical countries, and some of the islands in the warmer seas. Such places are often crowded with bats, which fly in swarms, darkening the twilight almost to the gloom of night; and during the day coat over the larger caves and places where they hide themselves, as if they were stalactites. These places are also rendered offensive by them, for their forms are lurid and ugly, the odour which they give out is rank and offensive, and their cries when disturbed are harsh and disagreeable.

Of course they are not, from their habits, found in desert or in naked places; because there they would neither have shelter during the day, nor food during the twilight. Places where life, and especially vegetable and insect life, are rich almost to rankness, are most favourable for them. The banks of the Nile in Egypt, where they dwell in the palaces and sepulchres of forgotten kings, and the temples of forgotten gods, are particularly replenished with them, because the swelling and subsiding of the Nile cause a vast production of insect life. In India also, especially toward the western coast, where the monsoons first break, and rain and fertility are most abundant, they appear in great plenty, and swarm in the stupendous cave temples, which were formerly hewn out of the rock with so much labour, but which are now nearly abandoned to clustering bats suspended from the roofs, and crawling reptiles on the floors. In the fertile parts of New Holland they are also very numerous; and they are particularly so in the South Sea islands, which appear to be their head-quarters, at least in that part of the world. The prevailing species there is of large size; and yet Forster mentions that, at the Friendly Islands, he counted more than five hundred suspended from a single tree, hanging in all sorts of ways, some by the heels, and others by the thumb claws.

In some of these islands they stand accused of being a plague, barely less destructive than that of locusts. They do not confine their depredations to the twilight, or to animal substances, but come abroad at all hours, their numbers darkening the air and their ravages extending to fruits, flowers, the juice of trees, and in short to every thing consumable. In some places, however, the inhabitants make nearly the same reprisals on this species, as the Arabs do on the locusts; they eat them and consider them a delicacy. Even the French in the isle of Bourbon, follow the fashion of the Moors and Malays in this species of food; they make soup of the bats, which is said very nearly to resemble hare soup, both in colour and in flavour.

In America, especially in the northern, or richer part of South America, bats are also very numerous, and the larger species there equal in size, and far outdo, in uncouth appearance, the largest and worst looking of their congeners of the East. It is there where the vampire stands accused of sucking the blood not only of single individuals of the human race, and single animals of other species while asleep, but of cutting off in this way whole herds of cattle, when these were first introduced into South America by the missionaries. Many of these accounts are no doubt exaggerated, and not a few of them are, in all probability, utterly groundless; but still they have been so often repeated, that they cannot be altogether without foundation. The superstitions which we have mentioned as being continued from the time of Homer, must no doubt have done much to heighten the pictures of the American bats; but their effect could not have continued without at least some admixture of truth.

The details of the bat family are much too extensive for a single article in a popular work. There are not fewer than 140 or 150 species or varieties, forming many genera or subgenera. Several of these, however, are made up from museum specimens, of the manners, or the native localities of which, little or nothing is known. These, of course, do not come within the scope of popular natural history, as they are merely curiosities to look at, which have got "no story to tell." Of those which have a history, the more remarkable species can be more advantageously mentioned under the names of the genera—to a very brief analytical list of which we shall devote the remainder of this article.

The family admit of convenient division into two sections; first, those which have the grinders adapted for bruising vegetable food; and secondly, those which have not,—the last being the true bats.

I. *With teeth for bruising vegetable matter.* This group comprehends by far the smallest number. There are two genera, which differ in their characters, and the species are also subject to considerable variations, and often to local variations of size and colour in the same species. They are all natives of the south-eastern parts of the old world, especially the Oriental Archipelago, and the isles in the Indian and Pacific Oceans. The incisors or cutting teeth, are more or less chisel-shaped or trenchant, and the grinders have their crowns not exactly tuberculated like insect feeders, nor entirely flat like those that live upon vegetables, but formed into two ridges in the line of the jaw with a furrow between; but the ridges wear with age and the furrow becomes partially obliterated. The number of teeth is also either not constant in the same species, or they are liable to fall out with age. The following are the genera :—

1. Pteropus ("winged foot," called *Rousettes*, by the French naturalists, and having no general English name). Of these there are two subdivisions, one without tails, and the other with rudimental ones; the former being the most decidedly vegetable feeders in the structure of their teeth.

The members of this genus are the largest of the whole family, the body of the largest one being a foot in length, and the extent of the wings or flying membranes not less than five feet. The first or index finger of their anterior extremities consists of three phalanges of bones, and has a small nail, which is not the case in any others of the family. It is, however, much shorter than the middle finger, which is greatly produced, and gives the wings a pointed appearance. The third and fourth fingers consist of only two phalanges of bones, and are without nails. The flying membrane originates in the sides, and is much divided between the hind legs. The muzzle is simple, or without any appendages; the nostrils are apart from each other; the ears are of moderate size and consist of only one membrane; the tongue is covered with recurved hard papillæ; and the stomach is elongated, and varies in diameter in the different parts. They are in great part vegetable feeders, very numerous, gregarious, and destructive to the fruits and other crops; but they are also understood to prey upon birds and the smaller mammalia. One of the division with tails, and which has the tail rather longer than the others, and partially detached from the flying membrane, inhabits as far to the westward as Egypt, where it resides during the day in the caves or excavations near the Nile.

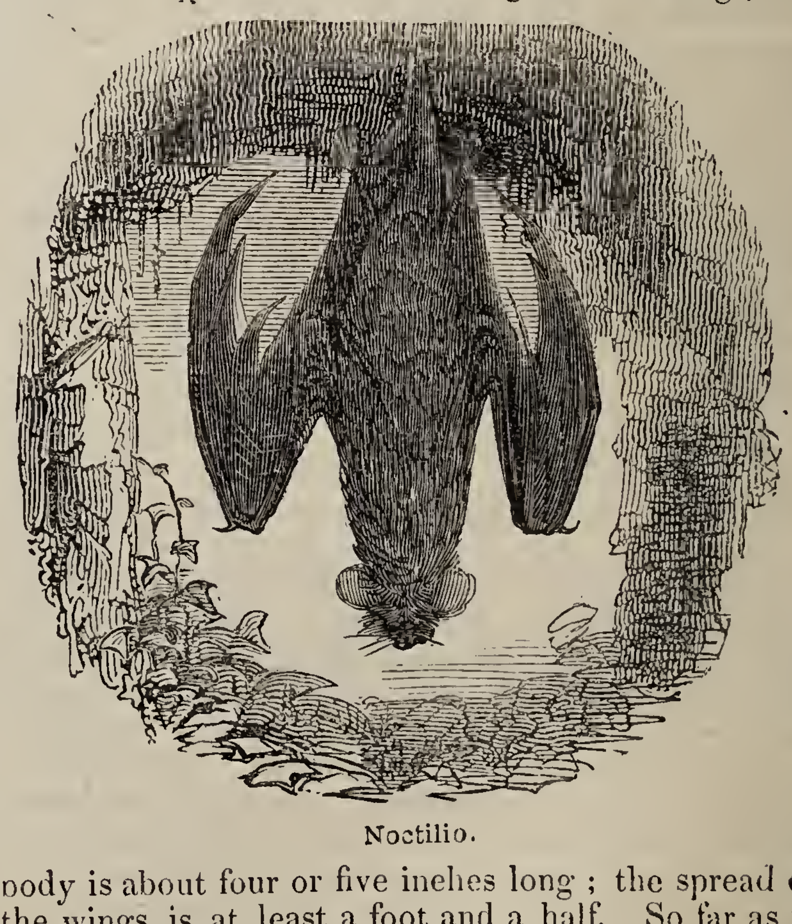
2. Cephalotus. The teeth in this genus resemble those in the former, but the flying membranes are different. Instead of originating at the sides, as they do in the former species, they meet at the dorsal line or ridge of the back, and are attached to the body at that line only. The fore fingers have three phalanges, but the last one is small, and has no nail. Some of the species are subject to the loss of their front teeth, which is, indeed, so common an occurrence in many species of the family, that a different number of those teeth cannot safely be taken as a positive specific difference.

II. *With insectivorous teeth*, that is, the crowns of the cheek teeth have prominent tubercles. These are the true bats. All the species of this division have three phalanges of bone in the middle finger, and only two in all the rest. They are far more numerous, varied, and generally distributed than the members of the previous section, though from the peculiar nature of their food, they are not generally found in such numbers in any one locality. There are many well authenticated genera of them, besides a number of rather doubtful ones, being founded entirely upon museum specimens, of the history of which in the living state nothing is known.

1. *Molossus*. This genus has the muzzle simple but the head large, the ears also large, united to each other at the base, and furnished with a small secondary membrane. From the form of the head some of them are called "bull-dog bats." They are wholly or chiefly confined to the American continent. They are subject to variations in the number of the front teeth.

2. *Nyctinomus*. These have two large conical front teeth in the upper jaw, and (generally) four small ones in the under. Their grinders, of which there are four on each side above and five below, are furnished with very sharp tubercles. The lips are deeply wrinkled, or with a furrow in front. The nose is flat, but without any membranous appendage. The ears are large, united at their bases, and have an external duplicature. The wings are very large, the hind feet covered with long hair. The body not exceeding three inches in length, and generally smaller. They are found in Egypt, India, the Oriental islands, and Madagascar; and also, as is said, in Brazil, and some of the West India islands, but their existence in the latter places wants farther confirmation.

3. *Noctilio*. This genus have four front teeth above, the two middle ones longer than the others; two front teeth in the under jaw, the canines large and strong, the cheek teeth four on each side of both jaws, with very sharp tubercles on their crowns. The muzzle is short, thick, covered with fleshy tubercles, and cleft with a furrow, in a manner similar to that of the hare, on which account they are popularly called hare-lipped bats, though some of them are also called bull-dog bats. The nose is without any membranous appendage, the ears are small, placed towards the sides of the head, and not united at their bases. The membrane between the hind legs is large, but does not reach entirely to the point of the tail. The claws on the hind feet are large and strong; the



Noctilio.

body is about four or five inches long; the spread of the wings is at least a foot and a half. So far as is known, they are all natives of South America.

5. *Phyllostoma* (leaf-mouth). This genus is so named from the leaf-like appendages which are attached to the mouth, or rather to the nose, one of which has very much the form of a leaf, the other more that of a horse-shoe. They have four front teeth in each jaw, and five cheek teeth in each side of both. The tail is wholly or partially detached from the interfemoral membrane. The ears are large, naked, and not united at their bases, but they have a second membrane in the form of a triangular flap notched at the sides. Their tongue is protrusile, and furnished with papillæ which adapt it for a sucking instrument; and the lips are also beset with fleshy tubercles. The body, even in the largest species, is not above six inches long, and the wings are short in proportion, which renders the flight fluttering and apparently laborious. It is to this genus that the vampire bat, of whose leech craft so much has been said and written, belongs. All the species are natives of the warmer parts of the American continent. They are usually divided into three sections: those which have no tail, those which have the tail united to the interfemoral membrane, and those which have the tail free.

6. *Megaderma* (large skin). So called from the great production of membrane about the nose and ears. Their noses have the leaf still more complicated than in the last genus. The inner appendage of the ear is also large and often forked. The external ears are united on the top of the head. Their tongue is smooth, and not adapted for sucking, as in the *Phyllostoma*. They are without tail; and the interfemoral membrane is entire. They have four front teeth in the lower jaw, but none in the upper; and the intermaxillary bone is cartilaginous. They are all natives of the hotter and more productive parts of the eastern world, especially of tropical Africa and the oriental islands.

7. *Rhinolophus* (crested nose). These are commonly styled horse-shoe bats. They have the nasal membranes very complicated, and extending toward the forehead in a shape which rudely resembles a horse-shoe. The tail is long and united to the interfemoral membrane. They vary considerably in size, but the largest does not exceed four inches in length. They are all of them natives of the eastern world; most abundant in the Oriental Archipelago, but in some of the species extending to Europe, including England.

8. *Nycteris*. These have a longitudinal furrow along the forehead, partly covered by duplicatures of the integuments, but no membrane attached to the nose. Their ears are very large, but not joined to each other; and their tails are included in the interfemoral membrane. They have a pouch on each side of the mouth, opening into a sac formed by a duplicature of the skin. They are of small size, with the wings long in proportion; and inhabitants of the eastern world, chiefly of Africa.

9. *Rhinopoma*. The nose long, blunt, or apparently truncated at the end, surrounded by a short membrane, and the nostrils capable of being shut, at the pleasure of the animal, by means of a membranous operculum or lid. The ears large, united at their bases, and the ends hanging over the face, containing an inner membrane. The interfemoral membrane narrow, and straight at the posterior edge, not extending to the extremity of the tail, which is long and slender. This bat is a native of Africa. There is said to be an American species, but it is, however, doubtful.

10. *Taphozous*. These have a rounded channel on the forehead; but are without any membranous appendages to the nose. Their head is of a pyramidal form; they have four front teeth in the under jaw, which are three-lobed; and in the upper they have only two, and sometimes none. Their ears are not joined to each other, and the tail is above the interfemoral membrane, and not attached to it. The males have a cavity placed crosswise, on the throat. The membrane is produced so as to form a small pouch on the wrist. They are found in various places in the warmer latitudes of the eastern world, especially in Africa, and it is said that there are some species in North America.

11. *Mormoops* (owl-eyed bats). These have a triangular membrane on each side of the face, extending from the nose to the ear, which forms a sort of shade to the eye. The form of the head is much more pyramidal than in the former genus; and there are four front teeth in each jaw, those in the upper one very large. They are found in the Oriental Archipelago.

12. *Vespertilio*. This genus comprehends the common bats, the species of which are very numerous, and generally distributed over the globe. They have no prolongation of membrane, save that which they use in flight. They have four front teeth above, the two in the middle pointed, and apart from each other; and they have six below, which are partly trenchant, partly tuberculated or lobed at their points. Their tail is included in the flying membrane. There are several species natives of England.

Pigmy Vespertilio.

13. *Plecotus* (long-eared bats). These are without any appendages to the nose, but the ears are very much produced, the external ones being as long as the head. The internal duplicatures are lancet-shaped, and there is an operculum or lid to the auditory passage. They are said to be found both in the eastern and in the western world, and one species is by no means of rare occurrence in England. See figure p. 320.

The best known British bats are,—two species of the horse-shoe bat, the larger and the less; three of the common bats, the common, the margined and the great, and two of the eared bat, the common and the barbastel. The habits of bats are, however, so obscure, that it is not easy to say that all the species in any country have been discovered; but as the habits of the animals is not migrant, all that are observed in any country may be considered as natives.

Long-eared Bat.

From this list of the genera, short as it is, and incomplete as not containing the numerous ones which have no history, it will readily be seen that the natural history of the bat family is no short or easy matter. Their vast number and variety, their being most abundant in those places where all natural action is the most energetic, and their being fitted for living on so many different kinds of food, show that the part which they perform in the economy of wild nature, must be an important one. It is true that they are preyers, as all animals are, whatever may be the kind of their food. But, in the economy of nature, preying is not destruction but preservation; and, in the animal kingdom, strange as it may seem at first sight, predation tends quite as much to preserve the races which are preyed upon, as those which are the preyers. Life is, in all its forms, too energetic for the means of life; because the one is an energy—a principle, not in its nature trammelled in by material bounds; the other is regulated by the quantity of matter which can exist in a particular form. It is this excess of productive power which keeps the system going; for if there were no more of each kind produced than were necessary for the continuation of that kind, all means of nourishment would be at an end, and the whole would speedily perish. But the caterpillar eats the superabundant leaf; the little songster eats the caterpillar; the omnivorous bird destroys in part the eggs of the songster; the omnivorous bird falls a prey to the rapacious bird. So in the mammalia, one eats the grass, a second the grass eater, and the series goes on, both in the animal and the vegetable kingdom, till fungi feed upon the ruins of the oak, and the larvæ of insects fatten upon the carcass of the lion. And if, by any contingency, the race to which it is given to regulate the numbers of another race or of other races should fail, nature still has its resource, so that those which have gotten the mastery, shall not keep it, to the destruction of others and ultimately of themselves; *epizooty* comes, as "the pestilence which walketh in darkness," and cuts off, one sees not how, those numbers which have increased beyond that wholesome balance which is the best for all. This is the beauty of the system of nature,—that which elevates it far above what we could conceive or imagine, if we did not derive our knowledge from the direct contemplation of the system itself. As there is implanted in every individual a means of repair and renovation, which works without foreign assistance during the average period which it is required that the individual should last; as there is implanted in every species a means of continuation, to which all the other propensities of that species must yield; so there is implanted in the whole a means of general preservation, by which one race is made to support and preserve another, and which, while it is plastic or obedient to those physical changes, to which the whole must ultimately be subservient, yet so acts upon the whole, that, under all the vicissitudes of place and of time, there is at all times, and in all places, the maximum of beauty and natural usefulness. Not only so, but the whole is given to man as a volume of instruction, which he cannot read with understanding without the full profit to himself from the reading. Go to what place of the globe he may, if he will but study the working of nature there, in the proper manner and without bias brought from other places which are different, he cannot fail in finding the means of turning all the capabilities of that place to his advantage, in the easiest manner, and with the greatest certainty of success.

All the productions of nature, animate and inanimate, are indices to this knowledge, if we give ourselves the trouble of finding out the mode of applying them. If we find any one species of production, whether animal or vegetable, predominant, we may be sure that that production is the most intimately connected with the active powers of the place—with those powers of which we must avail ourselves if we are to turn it to our practical advantage. If we do not attend to these means of instruction, we not only increase the quantity of our labour, but we, in many instances, labour in vain, and not merely in vain, but we actually defeat, by our ignorant exertions, the very objects which we have in view.

There are but few instances in which our science guides us to the right application of what nature has to teach; and in the case of animals so peculiar in their structure, and so obscure in their habits as the family of the bats, we may say that we are, hitherto, almost without the lesson of utility. They are, however, one of the races which should especially stimulate us in our inquiries. They are extraordinary animals, for they have the structure of one class and the habit of another; and whenever we find these extraordinary combinations in nature, we may be sure that they are for the accomplishment of purposes as extraordinary.

What the specific purpose in the case of bats may be, we have said that the present state of knowledge does not furnish us with data for ascertaining; but they afford us one instance of a very curious fact,—namely, that none of the elements in which animals can exist is confined to a single class; and as the mammalia are those which appear to have all the functions of life in the highest state of development, we find them seeking their subsistence in all the three elements,—on the earth, in the waters, and in the air, in the case of the bats.

BAUERA (Hortus Kewensis). A genus of two species of greenhouse shrubs, named in honour of Francis and Ferdinand Bauer, eminent botanical draughtsmen. Linnæan class and order, *Polyandria Digynia;* natural order, *Cunoniaceæ.* Generic character: calyx from six to eight cleft, persistent; corolla from six to eight or more petals; stamens below the germen;

filaments filiform; anthers oval, two-celled; styles two, diverging.

BAY TREE. The *Laurus nobilis* (Willdenow). This celebrated tree is a native of Italy, and among the Romans was the emblem of victory. It is scarcely hardy enough to bear severe winters, unless the situation be high and dry. It is beautifully evergreen, and grows like a great bush rather than a tree, and emits a very pleasant resinous scent like that of myrtles. The leaves are used by cooks and confectioners for flavouring dishes, &c.

BEAR (*Ursus*). A genus of *Plantigrade* mammalia, or those which apply the whole sole of the foot to the ground in walking; and by much the largest and most formidable of those which have this habit. The genus cannot be considered as strictly and exclusively carnivorous, but rather as one which is very miscellaneous in its feeding; and yet when goaded on by hunger, or roused by any thing irritating, there are few animals which show greater ferocity, or rend in pieces that which they overcome with more savage display. Animals whose general habit is predatory always kill their prey in what may be called a "business-like manner." They attack some vital part, so that their attack speedily becomes fatal; and those which are of inferior mechanical strength, very generally bleed their prey to death by a small incised wound; nor is there one among the habitual preyers on living animals which begins to eat till the prey has ceased to live. But when the bear "plays the butcher," he does it like one whom nature has not bred to the trade. He tears away at the part upon which he first seizes, and when he tears from hunger, the moment that he begins to tear he begins to eat. His feast upon a warm-blooded animal is thus the most sanguinary and savage to be met with in nature. But it is so far from being habitual to him, that he probably never has recourse to it if he can find food of any other kind. Wild berries and other fruits, in search of the last of which he can climb with great dexterity, honey, which he also generally finds in the trees, the eggs and young of birds, small mammalia, and, when it comes in his way, carrion, however putrid, are the ordinary food of the bear.

This must not, however, be considered as extending literally to the white, or polar bear; for that species, by inhabiting the margins of the polar ice, has to depend chiefly on the sea for food, and in that case he must feed upon animal matters—indiscriminately on what the sea casts up, and on those who come to feed upon it, but chiefly upon the former.

Bears of some species or other are found in every latitude, and therefore their habits must vary with the climates and seasons of these; but there is a very considerable uniformity of structure in the whole race; and the typical ones, or those which possess the character in the highest degree of perfection, are certainly the inhabitants of cold climates. The natives of the sunny lands—though there they are in the cave and the forest, rather than the sunshine—are feeble in body and subdued in temper, compared with the dwellers on the margin of the polar snow. Not a cold climate merely, but one in which nature has a long winter of repose, seems to be best suited for developing the character of the bear, or rather, it is the extremes of seasons which suit them, and not any particular degree of average temperature, for they live under the equator as well as in the polar circle.

Bears may be considered as animals of the northern hemisphere, in both continents of which they are found; but they do not appear to extend to the south of the equator, except, perhaps, on the Andes, where there is the temperature of every climate over a vast range of latitude; and there are none in New Holland, or even in Africa. It is not improbable that those which are found in the forests of the tropical countries may have originally migrated from the north, and been gradually changed by climate; and it is certain that, in Europe, they were much more abundant in former times than they are now. The diminution has taken place not merely on account of the breadth of surface from which they have been driven by thicker peopling and cultivation, and the destruction of them by hunting—for in western Europe they have become few in those wild forests which culture has never invaded; and where men begin to till the ground, and follow the other occupations of civilised life, they hunt much less than when, in far fewer numbers, they are wholly dependent on the wild productions of nature.

The improvement of climate, or, at all events, the approximate equalising of the seasons, of which the diminished number of bears is one of the evidences, does not appear to be wholly the result of culture. Much of Europe to the southward of the Baltic, and about the Black Sea, and also not a little of Asia to the northward and eastward of the Caspian Sea, has certainly, at some period of the world's history, been under water. Of this fact, science furnishes us with abundant evidence confirmatory of Holy Writ. At that period, also, there must have been much of it under forest; and from these circumstances we may conclude, that then the climate much more resembled that of the northern parts of America than it does now. The few facts which we are able to glean from history prove this, although all which we can regard as authentic refer to times much more recent than when this must have been the case. But the inhabitants of ancient Rome were certainly as familiar with snow as the inhabitants of modern London; and the Tiber was as often frozen over then as the Thames, even above the tideway, is now.

At these times it is highly probable that the bears of Europe ranged seasonally from the Baltic or from Scandinavia to the Mediterranean, just as those of America still range from the northern parts of the Stony Mountains to the shores of the Gulf of Mexico.

With us, therefore, the history of bears is a history of those whose day has gone by; and though we have no record of the more ancient races in history, we have indubitable monuments in the bones of the animals themselves, which are found in no inconsiderable numbers in plains much farther to the south than any which the bear now inhabits in Europe. The bones of the great extinct species (*Ursus spelæus*), the size of which must have been equal in lineal dimensions to that of the horse, and, from the different form of the animals, vastly more in solid contents and in strength, are found, though sparingly, in some of the caves in England; and although, unlike as the animals are to each other, there is some popular confusion in the names of the *bear* and the *boar*, yet there is little doubt that, even later than the time of the Romans, the common brown bear was to met with in both the southern and the northern division of Britain.

At present the line of its habitation is much farther to the northward in western Europe, though in the eastern part of the old continent it is more southerly. The numbers, also, increase towards the east; and are probably greater about Kamtschatka than any where else; though there, as well as throughout the rest of Siberia, they are very systematically hunted, but it is only by a very scattered population.

In considering the progressive history of the bears, we are, therefore, to regard them as on the decline in the eastern continent, in the north of Europe, and in Siberia, and when we turn to those parts of North America which have been settled by Europeans and their descendants, we find that, though the commencement of the decay be more recent, the progress of it has been much more rapid, though it does not appear that, in that part of the world, any species has become extinct. These few observations will, at least in part, show to what stage of the history of countries bears belong; and we shall now give a short descriptive notice of them as an existing race.

The generic characters of the bears are, briefly, these:—The incisive teeth are six in each jaw, those in the upper jaw have one large middle lobe on their points, and a smaller one on each side, and those in the lower jaw have two lobes. The canines are conical, slightly bent, and placed at some distance from the incisives. There are three false molars in each side of the upper jaw, and four in each side of the under. These are all of small size, and liable to decay or fall out. Then there is one carnivorous or tearing grinder, and three tuberculated ones in each side of both jaws. The carnivorous teeth are proportionally smaller than in the true carnivora, and they are not of quite so tearing a character,—the anterior point is wanting, and the central and posterior ones are rather small and blunt. The tongue is soft. Such is the structure of the feeding organs in the bears; they are by no means well adapted for feeding upon flesh in its recent state; and they accord with the fact, that the animals never attack when they can find food which is more easily managed.

The muzzle is variously produced in the different species, and terminates in a moveable cartilage. The sense of smelling is understood to be keen; and from the soft tongue, and the partiality of the animals for honey and other sweet substances, it is presumed that the taste must also be acute. The eyes are small, and, in the ordinary states of the animal, by no means ferocious in their expression. The ears are also small. The body is very thick and strong; and the length of the covering, which is intermediate between wool and hair, very thick and firmly planted in the skin, gives them a shaggy and clumsy appearance. This is in part increased by the mode of walking, and by the tail being so very short as to be with difficulty perceived. There are no clavicles to keep the shoulder bones steadily apart, and thus, as the fore legs are moved, the blade-bones "work" much more on the sides than in animals which have clavicles. The hind legs too, seem awkward, especially to us who are most familiar with four footed animals which walk on the toes, and have the first flexure of the leg with its joint projecting backwards. That joint, which is really the ankle-joint, is at the ground in the bears, and thus the first joint of their hind legs, bends the other way from that with which we are most familiar.

From these peculiarities of formation, we are accustomed to regard a bear as an animal which is "loosely put together," and that it must walk with pain and difficulty. Such, however, is not the case. The broad base which the foot of the bear forms, enables it to walk very securely, even in difficult paths; its progress is more rapid than we could suppose; and the firmness with which it can stand on the flat soles of the hind feet, enables it to use the fore-paws in grasping. The want of clavicles enables it to grasp and hug between the fore-legs, much more powerfully than could be done by a clavicled animal; and this power is of great service to it, not only in climbing, an operation to which it must often have recourse for its food, but in hugging its enemies, which it does so powerfully, that a strong animal is strangled by compression of the chest. Climbing is, however, the proper function of the want of clavicles, and climbing by grasping the bole of the tree between the paws, and not by grasping with the single paw, as the quadrumana do with their hands. And this mode of climbing answers uncommonly well in those places where the bears are most abundant. Pine forests are its haunts; and where pines grow close together, they have no lateral branches till a considerable height above the ground. Such trees could not easily be climbed by animals which grasped only with the hands. The paws of the bear have the claws long and strong, and moderately bent, adapted for digging, but capable also of inflicting very dangerous wounds; and while the animal hugs with the fore-paws, it is very apt to lacerate with the claws of the hind ones.

Bears live chiefly in dens and holes of the earth, though rather in natural ones than in those of their own forming; and they not unfrequently take up their abodes in hollow trees. This method of lodging is one reason for which they prefer places which are rough and wild, for they spend much of their time in their habitations. They hybernate less or more, according to the climate, and during the time of their hybernation they, like other animals which have that habit, cease to eat. They do not require the same shelter as most hybernating animals, in consequence of the almost impenetrable thickness of their winter coat, and of the quantity of fat which, at the time when they retire, they have accumulated under it. These protections prevent their temperature from sinking so low as that of most other hybernating mammalia; and the consequence is, that their functions are not so completely suspended—their slumber is not so profound. They do not move about, neither do they eat, but live upon the accumulated fat; and when the climate renders the time of their retreat long, they reappear again in a very lean and exhausted condition.

There is some difference in the hybernation of the sexes, at least in some of the species, and it is perhaps what we would not, upon a superficial view of the matter, expect. The pairing time is the summer season, a little sooner or later, according to the climate, so that the period of hybernation is that of gestation. One would at first suppose that there should be then a demand for nourishment in the female much greater than in the other sex; because, although her own system may be, in many of its parts, in a state of indolence, we must suppose that it must be active in so far as the bringing forward of her progeny is concerned. But the female retires much earlier in the season than the male, and her hybernation appears to be much more close and profound; nor does she again come abroad till her young ones are able to accompany her. We need hardly mention, that the old story of the cubs of the bear being perfectly shapeless until they are "licked into shape" by the tongue of the mother, is wholly without foundation. As is the case with the young of the genus *sus*, which, though it belongs to a different order, has many habits in common with the bear, the young are rather more handsome than the adult animals. The cubs are rarely, if ever, more than two, and often only one at a litter; they grow rather slowly, and follow the dam for a year, or at least for the whole season of her public appearance. She is a most attached and affectionate mother, bold beyond imagination almost, in the defence of her offspring, and they, even when very young, are ready to "show fight" in defence of her. This maternal affection must have been early noticed; for, in the Bible, a "bear bereaved of her whelps" is selected as the type of implacable and unrelenting vengeance. This is not confined to the land bears, but extends also to the polar or maritime bear, which, from its size, and the manner of its feeding, is a much more formidable animal than the common land-bear, and far more so than the bears of southern climates.

Such are some of the general characters; and we shall now proceed to notice the leading species. The most natural order, or at least, the most convenient one in which to take them, may perhaps be this: first, the land-bear of Europe and of the north of Asia; secondly, the polar or sea-bear, as connecting Europe and America, and being perhaps most abundant on the northern shores of the latter; thirdly, the bears of North America; fourthly, the bears of the more southerly regions of that part of the world; and fifthly, the bears of Southern Asia and the Asiatic isles.

European Bear.

1. *Land Bear of Europe and of Northern Asia.*—It is probable that there is only one species, though that species is subject to many climatal variations both in shape and in colour; and the readiness with which it undergoes these may be an argument for the original identity with it of the bears of the south. Of this, however, there is and can be no proof, so that we can include in the species only those which inhabit what may be considered as a continuous locality.

This species (*Ursus arctos*) is usually styled the "*brown* bear," and brown in various shades is, no doubt, the prevailing colour; but it is so far from being invariably brown, that there are specimens met with in all the shades of colour from black, or at least dark bistre, or soot colour, through brown, up almost to white, though the white retains that half straw-colour sort of tint which is found in the bristles of pigs. The colour is, generally speaking, darker in the summer, and paler in the winter, at which time the skin is finest, and most esteemed; but there is only a sort of bleaching by the weather, and not a change of colour, as in those animals which pass the winter in very cold countries without hybernating. The brown bear is said not to take up the whole of his fat by internal absorption, but to extract a considerable portion of it by licking from glands in the pads on the soles of his paws. This is the popular opinion; but it is certainly a singular mode of feeding, and it is at least as likely that he performs the operation alluded to in order to keep up the heat of those parts of his body. There are, no doubt, instances of animals eating their own hair or feathers, and even gnawing the flesh off their bones, but these have happened only in the very extreme of hunger.

Though the brown bear shows a great deal of spirit when hunted or otherwise attacked, and the female is always dangerous when she has cubs; and though when pressed with hunger either sex is ferocious enough, the habit of the animal is not to attack. The bears which are led about the streets for show are ferocious, but then they are made so by cruel treatment. They are blinded, muzzled, and then beaten, to make them play tricks; and they of course must resent such treatment, and resent it indiscriminately, as they are incapable of seeing the aggressor. When the barbarity of the age was such as to include bear-baiting among "sports," the bears kept for that purpose were naturally savage; but this again arose from the treatment they met with. Indeed, as in the case of many other animals, bears have been made the scape-goats of human cruelty, and have been doomed to bear to the wild forests, and hold there, as their native birthright, savage propensities which are of human origin.

Bears when taken young are not difficult to tame; and in that state they are playful and harmless, though, according to the general habit of animals which are domesticated solitarily, they probably get more ferocious as they grow older. On board vessels which trade to Russia tame bears are sometimes kept, which play about the deck and climb the rigging, but these are generally young ones; and though they do not attack, if duly fed, they are apt to "show fight" if annoyed.

In all countries which it inhabits, the brown bear is a favourite animal with the hunter; and it is among the most valuable of the wild ones. The flesh is, at all ages, wholesome; and in the young ones it is good. To the rude tribes which inhabit the north of Asia, the brown bear is an animal of no small value. "It would be difficult," says Tooke, in his *View of the Russian Empire*, "to name a species of animals, excepting the sheep, so variously serviceable to man as the bear is after his death to the Kamtschadales. Of the skin of this animal they make beds, coverlets, caps, gloves, and collars for their sledge-dogs. Those who go upon the ice for the capture of marine animals make their shoe-soles of them, which have this advantage, that the wearer is in no danger of slipping with them. The fat of the bear is held in great estimation as a very savoury and wholesome nourishment; and when melted, and thus rendered fluid, it supplies the place of oil. The flesh is reckoned such a dainty, that they seldom eat it alone, but usually invite a number of friends to partake of the repast. The intestines, when properly cleansed and scraped, are worn by the fair sex as masks to preserve their faces from the effects of the sunbeams, which here, on being reflected from the snow, are generally found to blacken the skin, by which means the ladies of Kamtschatka preserve a fine complexion. The Russians of Kamtschatka make window-panes of the intestines of the bear, which are as transparent and clear as those made of Muscovy glass. Of the shoulderblades they make sickles for cutting grass. A light black bear-skin is one of the most comfortable and costly articles of the winter wardrobe of a man of fashion at Petersburgh or Moscow; and even the small white hand of a belle is slipt into a huge bear-muff, which half covers her elegant shape."

In as far as the muffs are concerned, the females of this country are as fond of handsome bear-skin ones, and, no doubt, wear them as gracefully as they of the land of the autocrat. In the temperate latitudes, neither bears' flesh nor bears' grease is much used, or at all known as a culinary article; but the latter is in no small request as a cosmetic; and were it not for bears' grease, half the perfumers in some of our cities might close their bazaars. Thus, in some portions of its body, the bear becomes an article of export to the people of those countries of which it is a native; and where the grease is the matter in request, it is understood to be necessary to fetch the bear entire, and fatten it with offal in the cellar of the vendor. Hence there is a very considerable demand for live bears, as well as for the skins of dead ones; and though it is highly probable that one veritable bear may impart virtue and give currency to the lard of a hundred hogs, yet an occasional bear becomes necessary, in order to prevent the said lard from lapsing into its original state of simple emollient ointment, good for the skin when rigid, but perfectly inert and passive in the matter of ringlets in either sex.

Many stratagems are naturally had recourse to for the capture of an animal which is in so much request both at home and abroad. The direct methods are to attack him openly with clubs, spears, or fire-arms, according as the captor may be provided. In those parts of Siberia where wood is plenty, a trap of logs is formed by the side of his path, and a trigger placed, which he cannot avoid pulling to his own destruction. At other times he is snared in pitfalls, in the bottom of which sharp-pointed stakes are placed, and the mouth of the pit is covered with sods placed upon as slight a platform as will bear their weight. The bear is a cautious animal, and anxious to escape from anything which is novel in appearance. Thus the hunters place in his path an elastic "bugbear," which shall start when he touches a cord attached to it, and frighten him off in the direction of the pit. In case the bugbear should not succeed, other means of annoyance are placed in his path—such as "caltrops," or pointed double crosses of iron, which, toss them about as you will, always present a salient point—logs hung vibrating from the branches of trees—and other things of artificial contrivance with which the bear, in wild nature, is unacquainted. If these do not drive him to the pit-fall, they perplex him, make him stand still, and throw him off his guard, so that the hunter, who is generally lurking about, can approach sufficiently near for taking a deadly aim. At other times, again, they bend an elastic tree, secure it by a cord, and place on it an attractive bait, which the bear has no means of reaching but by ascending the bending tree. This he readily does; but before he can reach the alluring prize his neck is entangled in a noose, placed there on purpose, and so contrived, that a very little action against it shall detach the cord by which the tree is held in the bent position. When that is done, the tree springs up with so much elastic force that it jerks the bear clear of every thing but the noose, and at the same time so tightens that upon him, that he hangs suspended, to be cut down when it suits the convenience of the hunter. In the rugged and mountainous parts of Siberia they contrive in a still more singular, and rather an ingenious manner, to make the bear his own executioner. They fasten a noose to a very heavy block of wood, and place it in the bear's path, near the brink of a precipice. When he finds his neck entangled, and that the rope keeps him fast to the block, he attacks the latter, and with great fury tumbles it over the precipice, as the best means of getting rid of it; but the treacherous cord still unites him to it, and he tumbles headlong after it. Bears are, from the structure of their bodies and the thickness of their covering, little liable to be hurt by falls, unless the height be very considerable; and thus the bear often arrives at the bottom along with the log, without having received any injury. If in such cases there is still a descending precipice, he again moves the log toward that, tumbles it down, and follows it as before; and if there is not, he is at great labour in carrying it up again, and will repeat the operation till he is completely exhausted by the fatigue, unless he shall be stunned by the falls. Indeed, he is so valuable, that no small portion of the ingenuity of the natives is exercised in various modes of snaring and otherwise capturing the bear.

As wild honey, wild fruits, and the other substances upon which the brown bear feeds, are very abundant in the Siberian forests, the animals themselves are there both numerous and well-fed. And there they have little or nothing ferocious in their character, but eat their food peaceably, and when the season of its failure comes, they retire to pass the season of want in their hybernal dens. So far are they from being accounted ferocious or disposed to attack man, that the women and children range about with perfect freedom, and without the least apprehension, in those parts of the forests where the bears are numerous. As they are not much disturbed, except toward the close of the season, when they begin to get fat, they are not timid any more than forward, and it is possible to pass them as closely and as safely as if they were sheep. The sudden appearance of a person in an unwonted dress alarms them and makes them take flight; but it is said that the most certain and efficient of all bugbears is an umbrella, the expanding of which makes them roar and run with all their might; an umbrella is indeed an object of more dread to most wild animals than the most efficient weapon that man can brandish. A fierce bullock is more certainly turned by flashing an umbrella open in his face than by any other means;

and there are recorded instances of the tiger being put to flight in the same way.

This species of bear is found in so many places, and these so wide of each other, that we might expect numerous varieties both in size and in colour. The form of the head is the most permanent characteristic, and serves better than any thing else to prevent the breaking down of the species into several, or the confounding of it with the bears of America, which it often very much resembles both in colour and in size. Even in Europe the "remnants," as we may call them, as they are partial residences of an animal which was once general, differ considerably from each other; but still, the bear of the Pyrenees, the Alps, and the mountains of Lapland, is specifically the same; and it is probable that, with similar interruptions, from tracts of country which are either thickly inhabited or have become deserts, it ranges in Asia, from the Polar Sea to the Himalaya Mountains. The bear of Nepâl is different in appearance from the bear of Kamtschatka; and it is also different from the bears of India and the Oriental Islands; but its characters are so nearly intermediate between the bears of the extreme north and the extreme south, and its locality also so nearly intermediate between them in latitude, that it may be that the whole are, as has been already hinted, climatal varieties. All are climbers, all are vegetable feeders, and all are mild and peaceable in their manners, when they have plenty of food and are not harassed and annoyed.

The proneness of this animal to variety in colour renders it unsafe to infer a difference of species from any thing except difference of form in the skeleton, or differences of habit which cannot be accounted for from differences of climate and food. Hence the distinctions of brown bears, black bears, cinnamon bears, and white bears (as land animals), which have sometimes been described as inhabiting the same or nearly the same parts of the eastern world, instead of being distinct species, are not even distinct varieties, as the colour changes from generation to generation as well as in different individuals.

The abundance of bears in the Swiss Mountains in former times is proved by their having given name to *Berne*, and at that place bear-pits are still kept up in honour of the name. In these pits they are fed entirely on vegetable matter, the chief part of which is bread; but, according to a regulation of the police, all unripe fruit of whatever kind, which appears at the Berne market, is confiscated for the use of the bears. If a similar regulation were made in some other cities, we should probably hear much less about cholera in the later summer and earlier autumnal months. The high condition of the Berne bears, the length of time which the same individuals have lived, and similar circumstances in other places, all tend to confirm the inference from the structure of the teeth, that this bear is essentially and properly a vegetable feeder.

2. The Polar Bear, or Sea Bear (*Ursus maritimus*). The dreary climes to which this species is confined, the perils and privations to which it must often be exposed amid turmoiling waves and reeling mountains of ice, the peculiarity of its form and appearance, its great strength and power of enduring much hunger and the very extreme of cold, the many tales which are told of its ferocity and daring, the strong attachments and kindly feelings which it displays to its kind and in its domestic circle, all conspire to render it not only the most interesting of the bears, but one of the most interesting animals in nature.

The polar bear is well named from its locality, as it is never found without the polar circle, except in longitudes where the extremity of the polar winter extends further to the south; and that takes place in America only. It is a land animal, or more properly an ice and snow animal, rather than an aquatic one; and yet its sole dependence for the greater part of the year, and its principal dependence during the remainder, is upon the sea.

Its office seems to be that of chief scavenger to those regions in which the extremes of season produce the extreme of animal mortality, and though its system of dentition resembles that of the other bears it is, from its locality, as much of an animal feeder as they are of vegetable. Being an animal feeder, it has a more habitual propensity to kill than the land bears. But still, the prey which it pursues and captures in the living state is not land animals, but animals of the sea—not fishes, though occasionally it may not reject them, but the aquatic mammalia; and more especially those smaller kinds which subsist by being fishers. Of these, the seal is perhaps its staple food; and as the seals do not hybernate, but keep breathing holes open in the ice, even in the depth of the polar winter, this species of food is accessible to the bear at all times of the year. In winter too the foxes and wolves of the northern regions seek the ice, because their summer food on the arctic lands has either migrated to milder climates or is buried beyond their reach in the snow; these animals may form part of the winter repast of the bear during the portion of that season when it keeps the ice. Indeed the fact of its hybernating or not is not very well ascertained, though the probability is that the male, at least, is not so long dormant as in the land bears of the north. Neither does it appear that hybernation is general in the species; for captain Lyon mentions having seen one (a male of course) prowling about during the very coldest part of the season. But that the females retire, at least for a time, and that some of the males may do the same, would at least agree with the general habit of the genus. Mobility appears to be the grand preventive of hybernation. Of this we have instances in human beings who have all but perished in the snow; and those who are out in the inclement season, and fatigued under a rigorous atmosphere with the ground clad with snow, know how dangerous it is to lie down in the hope of being recruited by a little rest. The sleep which comes on in these cases is not the common restorative sleep which is so necessary for recruiting the vigour of the body. It is a sleep of the circulating and breathing system, as well as of the powers of sense and observation. It falls in short upon the whole animal, and there is no energy left awake by which a recruiting can in any way be effected. Hence, when it takes place in man, or in the ordinary animals in mild climates, and is continued for even a moderate portion of time at a very low temperature, the system wears out, and life becomes extinct. If the body is covered by a considerable depth of snow, the catastrophe is by no means so speedy; and the lengths of time which both human beings and domestic animals have continued to live under such circumstances have often been referred to as marvels. Those who perish in this manner seem previously to pass into a true hybernating state; and their subsequent death is rather death from starvation than from cold; for when found they are wasted to skeletons, which leads one to suppose that if supplied with a quantity of fat similar to that which hybernating animals accumulate in the autumn, and equally capable of taking up that fat by absorption, those who are wreathed up in the snow might in all probability survive for months.

Thus we see that the necessary adjuncts of hybernation are, protection from the extreme cold of the atmospheric air, and a supply of fat which can be taken up by absorption. The polar bear is in both of these respects, more especially in the former which is the more immediately required means of preservation, exceedingly well provided. His fur is thick, close, of great length, of a bad conducting colour, and it appears to have a property the influence of which in preventing cold in animals has been greatly or wholly overlooked, but which is probably the most efficient of all. The fur of this bear, like the feathers upon diving birds, cannot be wetted in the living state by almost any exposure to water. Of course, hair having this quality cannot be cooled by evaporation of its surface. Now we know from the great danger of catching cold, if the human hair is suffered to continue wet after washing, that evaporation at the surface of the hair cools the body, if not to an equal extent as evaporation from the skin, yet much more than evaporation from the portion of skin upon which long hair grows. Indeed, hair suceptible of being wetted would not be a protection against cold, unless the cold air were perfectly dry; and thus it is natural to suppose that all animals capable of hybernating in the snow have their hair or other covering not susceptible of being wetted. That this is the case with the polar bear is well known, because after swimming, which is a common habit with him, he has little more to do than shake himself in order to be quite dry.

The distinguishing characters of the polar bear are—the great length of the body compared with its height; the length of the neck, the smallness of the external ears, the large size of the soles of the feet, the fineness and length of the hair, the straightness of the line of the forehead and nose, the narrowness of the head, and the breadth or expansion of the muzzle. In the plate, "Bears," (No. I.) Landseer has very faithfully represented this animal with his characteristic accompaniments—the spicular ice, the aurora borealis, the fragment of the walrus, and the crest of the wave as in the very act of congealing. The attitude is that of the bear when he "scents," which he often does at very long distances, and when ranging, if he cannot find his way on the ice, he will swim for many miles, still preserving the scent. His rate of swimming is about three miles in the hour.

The size varies considerably. Some are mentioned as long as thirteen feet; but the accounts of these are in all probability exaggerated. Captain Lyon mentions one eight feet seven and a half inches long, and weighing 1600 pounds, as this is one of the largest specimens on the account of which we can confidently depend, it may not be amiss to quote the particulars as given by captain Lyon from actual measurement.

"*Length.*—From the snout to the insertion of the tail, eight feet seven inches and a half; the head only one foot six inches; from the eye to the ear ten inches; from the nose to the centre of the eye eight inches; of the ear alone four inches and a half; the tail from root to tip five inches; fore claws five inches; hinder claws one inch and a half; canine teeth two inches and a half.

"*Girth.*—Round the body, seven feet eleven inches; neck, three feet four inches and a half; fore-leg, two feet three inches; hind-leg, three feet three inches; round the snout, one foot nine inches and a half; round the forehead, two feet one inch.

"*Breadth.*—Paws, ten inches; between the ears, one foot three inches; canine teeth, three inches."

Bears of so large dimensions as those just quoted are not frequently seen, the usual length being between six and seven feet, and the weight, unless when in very high condition, considerably under 1000 pounds, those killed in the latter part of the season being always heavier in proportion to their lineal dimensions than those killed early. The weight of one only six feet eight inches long, killed by Captain Ross on his first arctic expedition, is described as being upwards of 1100 pounds. When in the highest condition, the girth of the body near the fore-paws, is very nearly equal to the length; but, at other times, they are, of course, more slender. The length of the soles of the paws is about one-sixth of that of the whole animal; and from the measures above quoted, it will be seen that they are very broad. The vessels of the legs are secured from the influence of the cold air, by the very long and thick hair with which their inner surfaces are covered.

These bears are very powerful animals, and there is no species in the whole range of nature better adapted to the situation and circumstances in which it is placed. It seems indeed to be a general law in nature that, in proportion as any species of animal is limited in its distribution, its adaptation to the place to which it is limited is the more perfect. We have instances of this in the apes, the sloths, and various other animals which are confined to particular districts in tropical climates; and we have a remarkable instance of it in the polar bear. The paths of this bear, when he ranges in quest of his food, are in the average of cases over the ice; and he has frequently to stand upon that while, by main force he hauls the food out of the water; and that food is often living animals, which of course make all the resistance in their power. But the vast size of the bear's paws enables him to stand on a broader base than even the elephant, while the great length of his neck gives him the power of reaching to a considerable distance. His claws are neither so long nor so crooked as those of the land bears; and from their form they are digging claws more than climbing, or prehensile ones. These agree with his habits. He is not a climber; and he cannot well be, for there is nothing to climb in the places of his habitation, save rocks and ice-bergs, and animals do not climb these by means of their claws. His want of clavicles enables him to grasp the jutting points of the ice or rock between his fore-legs; and the long hair upon their inner surfaces, prevents them from being lacerated, or benumbed by the cold. The form of the claws enables him to dig his food from under the snow when such an operation is necessary; and the texture and colour of his coat render him proof to all the vicissitudes of seasons and of weather. The Arctic summer with its continual sunshine, and the Arctic winter with its temperature so low as that mercury may be hammered on the anvil, are equally the same to the polar bear. On the ice, or in the water, be the weather fair or foul, nature has furnished him with abundant protection in the natural coat on his back. Thus, he can move about and find his food under circumstances to endure which few other animals are equal; and if food should fail in the severity of the winter, he could, and in all probability does, lie down to hybernate on the bare snow or ice.

The ice upon the polar seas is not so smooth as that which forms upon fresh water in lower latitudes, because, when it is first formed, the water is generally in motion, and there is not unfrequently snow, so that there is a scum of trash, or icy fragments, before the water consolidates into a continued field of ice. This gives it a granulated surface, which is afterwards powdered over with snow, which falls not in flakes, but in small particles, when the cold is very great. This surface, when once it is formed, remains undecayed during the sunless months; but when that luminary begins to exert its influence, the surface alternately thaws and freezes, at which time it becomes so slippery that it is difficult footing. To the polar bear, however, it is a safe path, and that animal never slides or stumbles be the smoothness of the surface what it may.

From its great size and strength, the polar bear is, under all circumstances, a powerful animal; but upon the ice it is peculiarly at home, and the danger of attacking him there is much greater than anywhere else. The following anecdote, recorded in his "Narrative of a Voyage to Greenland," by Scoresby, whose writings have thrown so much valuable light upon the economy of the polar seas, will afford some idea of the conduct of the bear on the ice.

In the summer of 1820, "the ship, a Hull whaler, was moored to a piece of ice, on which, at a considerable distance, a large bear was observed prowling about for prey. One of the ship's company, emboldened by an artificial courage, derived from the free use of rum, which, in his economy, he had stored for special occasions, undertook to pursue and attack the bear that was within view. Armed only with a whale-lance, he, resolutely, and against all persuasion, set out on his adventurous exploit. A fatiguing journey of about half a league, over a yielding surface of snow and rugged hummocks, brought him within a few yards of the enemy, which, to his surprise, undauntedly faced him, and seemed to invite him to the combat. His courage being by this time greatly subdued, partly by evaporation of the stimulus, and partly by the undismayed, and even threatening aspect of the bear, he levelled his lance in an attitude suited either for offensive or defensive action, and stopped. The bear also stood still. In vain the adventurer tried to rally courage to make the attack; his enemy was too formidable, and his attitude too imposing. In vain, also, he shouted, advanced his lance, and made feints of attack; the enemy, either not understanding, or despising such unmanliness, obstinately stood his ground. Already the limbs of the sailor began to quiver; but the fear of ridicule from his messmates had its influence, and he yet scarcely dared to retreat. Bruin, however, possessing less reflection, or being regardless of consequences, began with audacious boldness to advance. His nigh approach, and unshaken step, subdued the last spark of bravery, and that dread of ridicule, which had hitherto upheld our adventurer: he turned and fled. But now was the time of danger. The flight of the sailor encouraged the bear, in turn, to pursue, and, being better practised in snow travelling, he rapidly gained upon the fugitive. The whale-lance, his only weapon of defence, encumbering him in his retreat, he threw it down, and kept on. This fortunately excited the bear's attention. He stopped, pawed it, bit it, and then renewed the chace. Again he was at the heels of the panting seaman, who, conscious of the favourable effects of the lance, dropped one of his mittens. The stratagem succeeded; and while bruin stopped to examine it, the fugitive, improving the interval, again made considerable progress a-head. Still the bear resumed the pursuit with a most provoking perseverance, except when arrested by another mitten; and finally, by a hat, which he tore to shreds between his fore-teeth and paws, and would, no doubt, soon have made the incautious adventurer his victim, who was now rapidly losing strength, but for the prompt and well-timed assistance of his ship-mates, who, observing that the affair had assumed a dangerous aspect, sallied out to his rescue. The little phalanx opened him a passage, and then stood to receive his bold assailant. Though now beyond the reach of his adversary, the dismayed fugitive continued onwards, impelled by his fears, until he fairly reached the shelter of his ship. The bear once more came to a stand, and for a moment seemed to survey his enemies with all the consideration of an experienced general, when, finding them too numerous for a hope of success, he very wisely wheeled about, and succeeded in making a safe and honourable retreat."

Whether the bear would, in this case, have fled from the sailor, if the latter had at once gone boldly in with his weapon, instead of pausing in fear and brandishing it, is not known; and there are no doubt instances in which the bear does attack man, though the grand object of attraction for him is carrion and offal. It is the flesh of the seal, the odour of which becomes very rank, which allures him to the huts of the northern people, just as it is the larder, and not the people, which attracts the black bear of America to the habitations of the back settlers; and the instances in which he attacks the people or their domestic animals are few, and confined to those times at which his proper food fails.

That food is, as has been hinted, the carrion of the sea, or, in the absence of that, the sea mammalia—the seal generally, and the young of the walrus and the whale. The bear of course never attacks the full-grown whale; because the weapons with which he is furnished are not capable of inflicting any vital injury upon it, while the blow of its tail, even on the water, would flatten him like a pancake. He would attack it at a disadvantage too; for, though he can swim for many miles, he is, like all quadruped animals, very powerful only when he has a firm support. He does however often attempt, and sometimes captures the young of the whale, while they are so small that he can drag them on the ice. But this a perilous meal for him; for the whales which he is able to land on the ice are sucking whales, and the mother is generally very watchful of them. The mother can either carry the young one away, far faster than the bear can follow, or she can fight boldly in its defence; so that it becomes food for the bear only by stratagem. The walrus is much more an ice and rock animal than the whale; but still the walrus is never so far from the water as that it cannot easily regain that element; and it has much more command of itself there, and is furnished with tusks so powerful, that though the bear sometimes ventures to measure his strength with it, he seldom gains the mastery. The young of the walrus is, however, often caught by him; but still the seal is his staple food, and it is very abundant. The number of seals in some parts of those northern seas, especially about Jan Mayen and Cherrie Island, is beyond what would readily be supposed; and it is in the vicinity of those islands that the largest bears have been seen.

It is not improbable that the whale fishery in the Arctic Sea may have given an artificial character to the polar bear in the summer, or at all events it has brought him into places where naturally there would be much less to tempt his presence. The smell of the ships, the offal which the crews cast upon the water and the ice, the "kreng" of whales, are all calculated to entice an animal which can smell at so great a distance as this bear. Thus these animals may range further upon the ice than they did before the fishery; and, as there is a new provision of food for them, they may be more abundant than they were once. It is probable too that, about the time of the breaking up of the ice, when there is a general surface current to the south, more of them may drift upon detached boards of ice; and, partly by swimming, partly by walking on the ice, they certainly visit ships in more southerly places than those which they usually inhabit. When they make those visits, they are more bold and daring than when in those places which may be supposed more natural to them; and there are instances when, in these cases, they carry off some of the ships' crews. "A few years ago," says Scoresby, "when one of the Davis's Strait Whalers was closely beset among the ice at the 'south-west,' or on the coast of Labrador, a bear that had been for some time near the ship at length became so bold as to approach along side, probably tempted by the offal of the provision thrown overboard by the cook. At this time the people were all at dinner, no one being required to keep the deck in the then immoveable condition of the ship. A hardy fellow, who first looked out, perceiving the bear so near, imprudently jumped upon the ice, armed only with a handspike, with a view, it is supposed, of gaining all the honour of the exploit by securing so fierce a visiter by himself. But the bear, regardless of such weapons, and sharpened probably by hunger, disarmed his antagonist, and, seizing him by the back with his powerful jaws, carried him off with such celerity that on his dismayed comrades rising from their meal and looking abroad, he was so far beyond their reach as to defy their pursuit."

From the nature of their food the flesh of the polar bears is more rank and fishy, and less agreeable to the taste than that of the land bears, though, with the exception of the liver, which has been found to be poisonous, all the parts of the animal are wholesome. The muscle is whitish, and soft and tender, considering the strength of the animal. The fat resembles tallow, and melts into a transparent oil, which has no offensive smell. The skin is very serviceable as well as handsome for a variety of domestic purposes; and to the northern people it is an article of considerable value. The Greenlanders pull it off entire, and invert it like a sack, into which a person creeps and finds a warm and comfortable bed. The natives about Hudson's Bay dress it to a very pliable consistency. They stretch it on a patch of snow, and stake it down till it is stiffly frozen, then they scrape it till they see the roots of the hair; after which they leave it some time to bleach and dry, and it soon becomes perfectly clean, beautifully white, and very flexible.

The domestic manners of these powerful animals are not much known. The pairing season is understood to be in July and August; and such is the attachment of the pair, that if one is killed, the other remains fondling the dead body, and will suffer itself to be killed rather than leave it. The females retire to their hybernation about Christmas, sooner or later, according to the season. These are often excavated in the snow, and the animals remain dormant in them till about the first of April, when they come abroad with their cubs, usually two in number, which are then about the size of rabbits. She is exceedingly attached to them, and nothing but death itself can put an end to her attentions. When they are mortally wounded, she will fondle them, turn them over, lick them, offer them food, and pay even more tender attention than many human beings; and when she finds that all her efforts are unavailing, she moans most piteously.

The following is one of the many instances of this maternal affection:—

"Early in the morning, the man at the mast head gave notice that three bears were making their way very fast over the ice, and directing their course towards the ship. They had probably been invited by the blubber of a sea-horse, which the men had set on fire, and which was burning on the ice at the time of their approach. They proved to be a she-bear and her two cubs; but the cubs were nearly as large as the dam. They ran eagerly to the fire, and drew out from the flames part of the flesh of the sea-horse, which remained unconsumed, and ate it voraciously. The crew from the ship threw great pieces of the flesh, which they had still left, upon the ice, which the old bear carried away singly, laid every piece before her cubs, and dividing them, gave each a share, reserving but a small portion for herself. As she was carrying away the last piece, they levelled their muskets at the cubs, and shot them both dead; and in her retreat, they wounded the dam, but not mortally.

"It would have drawn tears of pity from any but unfeeling minds, to have marked the affectionate concern manifested by this poor beast, in the last moments of her expiring young. Though she was sorely wounded, and could but just crawl to the place where they lay, she carried the lump of flesh she had fetched away, as she had done the others before, tore it in pieces, and laid it down before them; and when she saw that they refused to eat, she laid her paws first upon one, and then upon the other, and endeavoured to raise them up. All this while it was piteous to hear her moan. When she found she could not stir them, she went off, and when at some distance, looked back and moaned; and that not availing to entice them away, she returned, and smelling around them, began to lick their wounds. She went off a second time as before; and having crawled a few paces, looked again behind her, and for some time stood moaning. But still her cubs not rising to follow her, she returned to them again, and with signs of inexpressible fondness went round first one and then the other, pawing them, and moaning.

Finding at last that they were cold and lifeless, she raised her head towards the ship, and growled her resentment at the murderers; which they returned with a volley of musket balls. She fell between her cubs, and died licking their wounds."

Many other instances might be quoted, illustrative of the character of these singular animals,—animals which are perhaps more characteristic of those dismal regions to which they are confined, than the animals of almost any other region. They dwell, as it were, upon the very verge of the living world, being found as far to the north as the restless foot of human discovery has penetrated; and they are perhaps the only animals not decidedly and habitually inhabitants of the sea, which are found in every longitude, and are in all longitudes exactly the same. We cannot say positively that they range across the pole of the earth's rotation, and pass from Asia to America, and from America to Asia by that route, because there is a zone round the pole of which we have no knowledge. But, as the observations of the recent voyagers for discovery in the Arctic regions, corroborated by some other circumstances, lead us to conclude that the latitude of the magnetic pole (or poles) has the maximum of cold, and that the climate of the pole of rotation is not so severe, we may therefore suppose, without any violent straining of theory, that, in the perpetual day which reigns there for a longer period than in the limits of their habitation southward, the polar bears range over the whole polar zone, till those confines where the sea is too clear of ice for their habits; and that they are thus the only animals which have the command of all the meridians on the globe.

3. The Black Bear (*Ursus Americanus*). The black bear differs from the other species of the genus by having the nose and forehead almost on the same line, though the forehead is rather more prominent. This projection of the front is less apparent at the upper part than in the brown bear of Europe. The palms of the hands and soles of the feet are very short, and the whole body is covered with long, shining, straight, black hair, which is by no means harsh to the touch. The face is marked with fawn colour on both sides, and a circular spot of the same colour is observable in some individuals in front of the eye; others have the muzzle of a shining light yellow, with a white line beginning at the root of the nose and extending to each side of the angle of the mouth. This extends over the cheek to a white space shaded with fawn colour, covering all the throat—it descends upon the breast. The yellow bear of Carolina is also a variety of the black or American bear. Captain Franklin saw adults of this species in the neighbourhood of Cumberland House, which were red, and remarked that the cubs of these red bears were black, while the cubs of the black individuals were as often of a red colour. It is said that the black bear can be also distinguished by its having one more molar tooth than the brown bear. They are found throughout North America, from the shores of the Arctic Sea to its southern extremity. That they must have existed in great numbers throughout this extent of country, before its settlement by Europeans, may be easily believed, from the immense number of skins which can even now be procured of this animal. About thirty-six years ago, one hundred and ninety-two thousand four hundred and ninety-seven bear skins were exported from Quebec; in the year 1822, the Hudson's Bay Company exported three thousand skins of the black bear.

American Black Bear.

On the wooded portions of the rocky mountains, Captains Clark and Lewis saw black bears, and subsequently found them on the great plains of the Columbia, and in the tract of country lying between these plains and the Pacific Ocean. Occasionally they are found throughout the territories of the United States, in the wooded and mountainous regions, and in unsettled districts. Their skins are of great use to the inhabitants as a substitute for manufactured woollens, such as blankets, &c.

Under ordinary circumstances the black bear is not remarkable for its ferocity, nor is it in the habit of attacking man without being provoked. When wounded, he turns on his enemy with prodigious energy and defends himself daringly. During the coupling season, this disposition is more fully shown, as the males are then more excited, and are consequently less lazy and clumsy than they are in the autumn. If this bear is taken when young, it is easily domesticated, and taught many tricks; he is frequently to be seen exhibited by showmen as a "learned" bear; but, poor beast, all grown up children should know enough of natural history to be aware. that these feats are performed by the bear, because he has struggled through a long course of discipline, hard and tortuous, to bring him to this state of supposed improvement. When confined they are remarkable for the persevering manner in which they move backwards and forwards as far as their chain will admit, thus showing their impatience of constraint. This wish for exercise is shown more conspicuously when the animal is confined in a very small cage where he has not room to turn round. Under these circumstances he moves himself in every direction, that his narrow limits will allow by stepping from side to side of his cage, and then, by raising and instantly depressing his body, as if about to leap from the ground, he gives his frame a degree of exercise which tends to the preservation of his health.

In the severe winters at the north, they often have a difficulty in the procuring of their food, they then travel to the southern regions in considerable numbers. In the report of Dr. Sibley, to the secretary of war, relative to the territories bordering on Red River, he states that, from all the information he could gain, immense and almost incredible numbers of these animals descended the mountains and passed southwardly into the timbered country.

In this bear, the sight and hearing seem to be the most acute of the senses as well as in the case of many others of the genus. Although he kills many small animals, he does not follow them by the smell. When walking his gait is heavy and awkward, and when running is not much less so. He, however, in consequence of his strength, moves with great celerity, and sustains himself under the exertion for a long time.

The females bring forth their young in the winter, and exhibit for them a degree of attachment which cannot be surpassed. They generally have two cubs, which they suckle till full grown. The affection existing between the mother and her cubs, appears to be mutual and unchanging. Indeed, this never-varying regard shows the instinctive propensities of the brute creation in a very remarkable degree, as nothing short of absolute destruction can separate the mother from the cub, or the cub from the mother.

A friend of Dr. Godman's, while traversing a wood near Fort Snelling, on the Missouri, saw a she-bear with two cubs (about the size of puppies at a month old) a short distance before him. The cubs immediately ascended a tree, and the dam, raising herself on her hind legs, sat erect at its foot in order to protect them: the rifle, discharged with a fatal aim, laid the parent lifeless on the earth. The hunter then approached and stirred the body with the butt of his gun, on which the little cubs hastily descended the tree and attacked him with great earnestness, attempting to bite his legs and feet, which their youth and want of strength prevented them from injuring. When he retired to a short distance, they returned to the dead body of their dam, and by various caresses and playful movements, endeavoured to rouse her from that sleep "which knows no waking."

Black bears are still numerous in the wooded and thinly settled parts of Pennsylvania, as well as in most of the other states of the Union. Where their favourite food is plenteous they grow to a vast size, and yield a great quantity of oil. Barham says that he was present at the cutting up of one which weighed five or six hundred pounds, and his hide appeared as large as that of an ox of six or seven hundred weight.

The food of this animal is chiefly sweet fruits, bramble and other berries; it is also fond of the acorns of the live oak, on which it grows very fat in Florida and elsewhere. In procuring these acorns they often place themselves in very perilous situations. In climbing the large oak trees, they push themselves along the limbs towards the extreme branches, and with their fore paws bend the twigs within their reach, in doing which they often expose themselves to fatal accidents. They also eat a variety of nuts and esculent roots, and often make long excursions in quest of whortle berries, mulberries, and all finely flavoured and spicy fruits. Birds, small quadrupeds, eggs, and insects, are greedily devoured by them whenever they can be obtained. The frontier settlers do not like them at all, as by their incursions in quest of young corn and potatoes, they often commit great devastation; their claws enabling them to dig up a great number of potatoes in a very short time; and where the bears are numerous the damage they commit is very extensive.

In the north, the flesh of the black bear is considered in high perfection after the middle of July, when the berries begin to ripen, though some berries impart a very disagreeable flavour to their flesh. They continue to be in good condition till January or February; later in the spring they are much wasted, and their flesh is sapless and disagreeable; probably in consequence of their long fasting through the season of their torpidity. Their flesh is also rendered rank and unpalatable by feeding on herring spawn, which they devour with the utmost greediness. At all seasons of the year, the southern Indians kill great numbers of these bears, but no inducement will prevent them from singeing the hair off of all that are in good condition for eating, the flesh of the bear being as much spoiled by skinning it as pork is. The skins, therefore, that these people dispose of to the traders, are those of bears that are too poor for being eaten.

The black bear in the vicinity of Hudson's Bay has been observed, in the month of June, to feed entirely on water insects when the berries are not ripe. These insects, of different species, are found in immense quantities in some of the lakes, where they are driven by gales of wind in the bay, and being pressed together in vast multitudes, they die. The odour which arises from this mass of putrefaction is intolerable. In some places they lie two or three feet deep. The manner in which they catch these insects is by swimming with their mouth open, and thus gather the insects on the surface of the water: when the stomach of the animal is opened at this season, it is found to be filled with them, and emits a very disagreeable odour. They are said to feed on those which die and are washed on shore. The flesh of the animal must be much spoiled by this diet, as individuals killed at a distance from the water are well flavoured at the same time of year.

The black bear is in fact very indiscriminate in his feeding, and though suited by nature for the almost exclusive consumption of vegetable food, yet when pressed by hunger, he refuses scarcely any thing. He is voracious as well as indiscriminate, in satisfying his appetite, and frequently devours so much, that his stomach loathes and rejects it. He seeks, with great assiduity, for the larvæ or grub-worms of various insects, and exerts a surprising degree of strength in turning over large trunks of fallen trees, which, if sufficiently decayed, he tears to pieces in search of worms.

During the season when the logger-head turtles land in vast multitudes from the lagoons at the south, for the purpose of depositing their eggs, the black bears come in great numbers, and dig them out of the sand with so much expedition, that the turtles have scarcely turned their backs when the bears have feasted to excess upon their eggs.

West of the Missouri, the black bears are observed to feed most commonly on grapes, plums, dog-wood berries, and other fruits that lie in their way, and they are frequently to be seen contending with the wolves and the buzzards for pre-eminence in feasting on carcasses that have died by disease, or have been abandoned by the hunters. When the bear seizes a living animal, he does not put it to death, but, regardless of its struggles and its screams, he tears it piecemeal, and, disdaining its torture, eats it while the flesh is quivering with convulsive agony.

It has been asserted that the black bear is not a "flesh-eater." But this is not the fact, as this bear is well known to feed on flesh, even to the rejection of fruits. When pressed by extreme hunger, they will even kill pork for their own use.

The usual retreat of the black bear is in the most remote and secret parts of the forest, where his den is in the hollow of a decayed tree, or in a cavern formed among the rocks. He retires to this place when his hunger is appeased, and in the winter he lies coiled up there during the long period of his torpidity. During the period of gestation, which commences in the month of October, the female of the black bear leads a retired and solitary life for the whole period, which is about one hundred and twelve days. We have no instance on record of a bear in a state of pregnancy being killed, though the mother and very young cubs are frequently destroyed.

In the northern part of the American continent, the subterraneous retreats of the black bear may be easily discovered by the mist which uniformly hangs about the entrance of the den, as the animal's heat and breathing prevent the mouth of the cave from being entirely closed, however deep the snow may be. As the black bear usually retires to his winter quarters before any quantity of snow has fallen, and does not again venture abroad till the end of March or the beginning of April, he therefore spends at least four months in a state of torpidity, and without obtaining food. It is therefore not very surprising, though the bear goes into his winter quarters excessively fat, that he should come forth in the spring a melancholy picture of emaciation.

The black bear is sometimes destroyed by blocking up the mouth of the cave with logs of wood, and then suddenly breaking open the top of it, they kill the animal with a spear or gun; this method is, however, considered both cowardly and wanton, as the bear can neither escape nor offer the slightest injury to his merciless destroyers. The northern Indians display great ingenuity in the manner in which they throw the noose around the neck of this animal, but the barbarous way in which they despatch him with the hatchet or tomahawk, after having drawn him to the top of his hole, has little in it to admire.

Sometimes he is caught in traps, strong steel ones chained to a tree and laid in a path which has been partially stained with blood, by drawing a newly-killed carcass along it. At other times, a noose, suspended from a strong bough, is substituted for the trap, in a path similarly prepared. The bear, whose sense of smell is exceedingly keen, always follows upon the track along which a dead animal has been drawn, even although it has left no trace perceptible by the human senses.

The common mode of hunting this bear is by two or three well-trained dogs. When he finds that he is pursued, he generally pushes forward for eight or ten miles, and sometimes more, in nearly a straight course. But when the dogs come up to him, he turns and strikes at them with his paws, the blows of which are so severe, that one of them taking effect, would instantly fell the strongest dog to the ground. The great art in training the dogs consists in teaching them to avoid these blows, and keep harassing the animal till he is exhausted. When that is the case, he climbs a tree to the height of twenty or thirty feet, at the root of which the dogs remain and "give tongue" till the hunter makes his appearance. When the hunter appears, the bear drops to the ground, not for the purpose of attacking him, but of making a new effort at escape from the now increased number of his pursuers. But, as he is heated by the effort of climbing and by the fall, though bears, from their form and also the nature of their covering, fall with much less injury than any other animals of the same weight, he is much more annoyed by the dogs than before. This makes him take to a tree again for refuge, he then climbs as high as it will bear him, and endeavours to conceal himself among the thick foliage. The hunter now strikes against the trunk of the tree as if he were felling it, which soon puts the bear in motion. He makes his way to the extremity of a long and lofty branch, at which he draws himself partially into the form of a ball, and drops down, often from such a height as that he rebounds up again for several feet, as if he were an elastic substance. He rises again from this fall, still uninjured, and seeks safety by flight as before. His exertions are, however, so much greater than those of his pursuers, that, whatever may be his strength, they in time wear him out, and he is ultimately shot, either when standing up to give battle to the dogs, or when attempting to hide himself behind the trunk of a tree. Such is the mode of bear hunting where there are trees; but in the large open prairies he runs much farther, and the hunt is one of greater ardour, unless when he is shot at an early stage; but, if the marksman is not skilful, shooting is rather a dangerous matter while the bear is unexhausted, as the pain arouses all his strength, and arms him with the most desperate powers of revenge, so that he would be too much both for dogs and hunter.

The Indians consider the black bear as the most valuable of wild animals, and the chace of it as their noblest field sport, its death being always followed by expressions of the greatest exultation. It is, indeed, highly useful to them; and, like the ox and the sheep, there is no part of it which is not applied to some purpose. The flesh is highly esteemed, and the paws are reckoned the richest *bonne bouche* that the wild forests of America afford. The skin furnishes their softest couch, and their most substantial protection against the severities of the winter. Even the claws have their value: they are bored and strung upon the tendons of deer, to be worn as necklaces and other ornaments.

In the early part of the season the bear is not much hunted, because it is then lean, and both more fleet and more ferocious than after it has become fat. The fat of course continues accumulating up to the time when the bear retires to its winter retreat, and the males, which are killed after the disappearance of the greater number of the females, are both in finest fur and "highest grease." The grease or fat collects in great quantities on various parts of the body; and a very limpid oil is obtained from it.

This bear is very tenacious of life, and as he stoutly defends his grease to the very last extremity, it is dangerous to touch him, unless he is shot directly through the heart or the brain. A skilful hunter never advances upon him without taking the precaution to reload his rifle, as the bear often springs up instantly and fiercely from a state of apparent death. Shooting through the brain can be accomplished only when the distance is short, and the bullet hits directly, for the skull is so strong that an oblique shot is sure to graze; and bullets have glanced off flattened from the skulls of bears when discharged from a rifle at the distance of ninety yards, without apparently having injured the bone. At close quarters the blows of a blunt instrument have little effect upon the body, or even the head of the bear, unless he is hit on the snout, upon which a moderate blow will stun and stupify him. This is easily accounted for, from the exceedingly acute sense of smelling in the animal, and the necessary abundance of nerves in and about the nostrils. It is worthy of being borne in mind, as one means of defence against wild animals generally, that if the animal is remarkable for the superiority of any one sense, the organ of that sense is always the most vulnerable part.

A sharp instrument, which is used with a short grasp, requires very skilful management at close quarters with the bear; and those who rashly attempt to assail him with such a weapon often pay dear for their temerity. If, however, a man has sufficient presence of mind, and can keep his arm disentangled, he can master the bear even at its own favourite practice of hugging, as he has only to grasp the animal's windpipe as tightly as he can close by the root of the tongue, and hold it determinedly, in order to make the bear almost instantly relax his clutch, and speedily part with that life which he maintained so desperately against wounding. Thus, in the case of this animal, as in most other cases, a very little skill, used with coolness and self-possession, succeeds far better and more speedily than the most powerful exertion of mere strength.

4. The Grisly Bear (*Ursus horribilis*). A very characteristic delineation of this bear is given by Landseer, in the plate "Bears," (No. II.) It is described as the largest and most formidable of American bears, and indeed of all land bears; and the character of its habitation points out the purpose which bears answer in the grand system of nature. The whole genus, as already noticed, have a polar rather than an equatorial character, and may thus be considered as geographically the reverse of the more formidable among the strictly carnivorous animals—the lion and tiger in the eastern world, and the jaguar in the western. These are all tropical in their home, habitually ardent in their temperaments, and, though they can endure hunger for considerable periods, they feed all the year round, and thus have no season of repose. The bears again are seasonal animals, retiring during the winter, and coming abroad in the spring. But it is not from the storm that the bears retire, it is from the cold serenity—the almost total cessation of atmospheric as well as living action which reigns during the polar winter: the storm is both seed time and harvest to the bears. During the utmost of its fury they range the wilds and forests, accompanied by those more powerful owls and hawks, which, like the bears, are equally remarkable for their strength and their impenetrable covering. At those times many of the smaller animals are dashed lifeless to the earth by the storm, or shrouded in the snow, and upon these the bears make an abundant supper—a supper of days, and even of weeks, before they retire to their long rest. So also, when the storm begins to break, they find a plentiful collection of the carcasses of such animals as have perished in the snow, and been concealed from sight, and preserved from putrefaction under it.

The devastation is of course much greater, because the storms are more severe among the mountains in North America, than on the plains or in the forests of the valleys. Those mountains are not very lofty, but they are exceedingly wild and rugged, presenting rocks and precipices of more harsh and ragged character than are to be found to the same extent in any other part of the world. It is for this reason that they have gotten the name of the "Stony Mountains," and that name is peculiarly appropriate.

These stony mountains are the habitation of the grisly bear, which was an animal unknown to natural history until inquiry and observation had been extended to that side of the great central valley of which they formed the boundary; and that this bear, which is their proper inhabitant, should be the most powerful and the most ferocious of land bears, shows that the energy of these animals is ever in proportion to the waste of nature which may be supposed to take place in the region which they inhabit. The most formidable of the equatorial preyers inhabit lower down—the lion in the thicket, and the tiger in the jungle; but, as is proved by this species, the bear of the mountains is much more formidable than the bear of the plains; and we have a collateral proof in the land bear of Europe and the north of Asia, which invariably becomes more of a mountaineer the farther that it extends into southern latitudes.

Dr. Godman, to whose valuable work on the Natural History of America we are indebted for a good practical account of the bears of that part of the world, thus characterises this formidable animal: "This bear, justly considered as the most dreadful and dangerous of North American quadrupeds, is the despotic and sanguinary monarch of the wilds over which he ranges. Gigantic in size, and terrific in aspect, he unites to a ferocious blood-thirsty disposition a surpassing strength of limb, which gives him undisputed supremacy over every other quadruped tenant of the wilderness, and causes man himself to tremble at his approach, though possessed of offensive weapons unknown to any but the human race. To the Indians the very name of the grisly bear is dreadful, and the killing of one is esteemed equal to a great victory; the white hunters are always willing to avoid an encounter with so powerful an adversary, and seldom or never wantonly provoke his anger." We are informed by the same authority that this bear, when excited by hunger or passion, pursues, attacks, and slaughters indiscriminately all animals which are unable to escape from him by speed or by artifice; and that even the American bison, which is an animal of great strength and power, is vanquished by this bear, and its heavy carcass dragged along with the greatest ease to a place where it can be consumed at leisure.

Independently of its size, its colour, and the ferocity of its disposition when roused, this bear may be readily distinguished from every other species, by several well-marked characters. The line of its forehead and muzzle is straighter than in any other species, and its claws, especially those of the fore feet, are much more produced, and far more crooked, though its general habit is not that of a climber. The snout is black, and moveable; the central furrow being distinct; the lips are partially extensile; the eyes very small, having no third eyelid, and the irides being of a light reddish-brown. The ears are short and rounded, and the line of the forehead thence to the eyes is a little convex, but it continues straight to the point of the snout. The hair on the face is very short; but on the body generally it is long and very thickly set. When young, its general colour is not unlike that of some varieties of the brown bear of Europe. Like that too it is subject to considerable variations of shade, not only from age and season, but also in different individuals. But when full grown, the prevailing colour of the body is a mixture of white, brown, and black, from which they have received the epithet of grisly; but the legs, the feet, the shoulders, the throat, the belly, and hinder parts of the thighs, are darker and more inclining to black than the rest of the body, while the snout, so far as it is covered with hair, is paler. The tail is very short, and in the living animal, completely hidden by the hair.

On the fore-paws, the claws are rather slender, but long, as well as crooked, and sharp at the tips, though the sharpness is rather that of a chisel, by being narrowed at the sides, than a point. This structure gives the tips of them great additional strength, and accounts for the severe gashing wounds which are inflicted by their stroke. The toes of these paws are furnished each with a sub-oval naked tubercle, and the anterior half of the palm is also naked, and of an oval shape, placed lengthwise across the palm; while the anterior part has a rounded naked tubercle. The interstices of these tubercles, and also between them and the claws, are covered with thick and strong hair. The soles of the hind feet are also in great part naked; and the claws on them are considerably smaller than those on the paws, though much more crooked; and their trenchant points form very terrible lacerating instruments when the animal closes with its enemy in hugging. They are sufficient to tear the abdomen of even a large animal to shreds, while the fore-paws are at the same time compressing its thorax to suffocation.

The size of this species varies considerably. The statement made by the Indians, that some specimens are fourteen feet long, must be regarded as an exaggeration to probably double the actual size; though one specimen killed by Lewis and Clark and their party on the banks of the Missouri, measured eight feet seven inches and a half from the nose to the extremity of the hind legs when extended. The length from the nose to the tail, which is the usual measurement of an animal, is not mentioned in this specimen; but it cannot have been more than between five and six feet; and five feet two inches is the length of those in the museum of Philadelphia. The girth round the breast of that mentioned by Lewis and Clark was five feet ten inches and a half; and that round the middle of the fore-leg three feet eleven, a size far exceeding that of the paw of the lion, and giving sufficient reason to believe that the paw of this bear is probably the most formidable striking instrument possessed by any kind of animal, and in all the departments of nature surpassed only by the tail of the whale. The want of clavicles, and the consequent freedom of motion in the shoulder, which enables the animal to add the blade-bone to the lever power of its paw, greatly increases the effect of its murderous stroke. The claws on the specimen alluded to were four inches and three-quarters in length. Its weight, though inferior to that of the larger specimens of the white bear, was between five hundred and six hundred pounds, so that altogether he was an animal of giant strength.

It does not, however, appear that he seemed inclined to use that strength like a giant, at least against the party; for when they fired at and wounded him, he showed no disposition to attack them, as is generally the case with the less formidable black bear, but made off with a tremendous roar; and such was the power of life in him, that, though five balls had passed through his lungs, and an equal number of gun-shot wounds had been inflicted on other parts of his body, he swam more than half way across the river to a sand-bank, and lived for more than twenty minutes.

The shooting of this animal by a single hunter is both a dangerous and a difficult matter. One shot will not kill, or even for a long time disable him, unless it directly penetrates either the heart or the brain. The former of these is much protected by the thick hair, the strong muscles, and the stiff ribs; and the latter by the equally strong muscles on the side of the head, and the firmness of the skull, which is impenetrable to a rifle-bullet at any moderate distance, unless that bullet takes effect perpendicularly to the surface.

But notwithstanding the formidable weapons and vast strength of this animal, it does not appear to be in accordance with his general habit to use them for murderous purposes; and the character of ferocity which has been so liberally bestowed upon him by hunters and travellers, appears to be, like the savage character given by showmen and bear-wardens to the brown bear of Europe, the result of their own cruel treatment, rather than of any instinctive propensity in the animal. Thus the trivial name "*horribilis*," which has been given to it by the Americans, though, as the original specific appellation, it must be allowed to stand, is yet an exaggerated name, and savours not a little of that love of amplification which never suffers a man to fall accidentally from a height of less than a hundred feet, or jump a chasm, the jaws of which are not half that distance asunder.

In the formation of its teeth, the grisly bear has no more carnivorous character than the mildest of the other land bears; and if we are to suppose that the number of false molars, which are small in size and speedily fall out, any indication of an uncarnivorous character, this species should have that character in greater perfection than any of the others, inasmuch as it is furnished with a greater number of those teeth.

That the grisly bear is a vegetable feeder as long as vegetable food can be found is unquestionable; and if its economy in its wild state could be observed calmly and without hostility, there is as little doubt that it would be found, even when vegetable food fails, not to attack any living animal, as long as it can find out, by its keen sense of smelling, the carcass of a dead one. The constitutional character of the genus, as has been already mentioned, is, in so far as it is carnivorous, to destroy the remains of life rather than life itself. In physical nature, the whole race are in their locality, and consequently in their habits (for locality and habit are always in keeping with each other) allied to the destroying powers, and not to the productive ones; and therefore it accords with the analogy of nature that we should find them removing the effects of the havoc which destruction has made, in preference to being in themselves constitutional and primary destroyers.

As has been mentioned of the brown bear of Europe, and as seems to be true of all the genus, with the exception perhaps of the white bear, whose habits are more aquatic than terrestrial, and therefore not suited to domestication by man, the young of the grisly bear might be tutored without much difficulty.

No inference to the contrary of this can be drawn from the accounts of the two which were in the museum at Philadelphia, and had to be killed because of their ferocious disposition. Every one who has observed the difference of character between the same watch dog in the chain and in a state of freedom, must feel convinced that confinement is not the specific for softening the disposition of any animal; and the two bears in question were caged. Whether they were "stirred up with the pole," as is usual in the ease of show bears, is not mentioned, neither is it denied.

These bears were taken in rather a southern latitude among the Stony Mountains; and they are said to have been littered about the 1st of March, 1807 (which, by the way, shows that this species produces later in the year than the brown bear). They were so young that they could take only milk; and in that state they were carried a long distance. Pike's account of their conduct on the march, shows both how they might have been tamed, and how they were not:—"I had a cage," says he, "prepared for both, which was carried on a mule, lashed between two packs; but I always ordered them to be let out the moment we halted, and not shut up again till we were prepared to march. By this treatment they became exceedingly docile *when at liberty*, following my men like dogs through our camps, and the small villages and forts where we halted. When well supplied with sustenance, they would play like young puppies with each other and the soldiers; but the instant they were shut up and placed on the mule, the beeame cross, as the jolting of the animal knocked them against each other, and they were sometimes left exposed to the scorching heat of a vertical sun for a day without food or a drop of water, in which case they would worry and tear each other, till nature was exhausted, and they could neither fight nor bawl any longer."

The following is the account of their conduct in the museum:—"When first received they were quite small, but speedily gave indications of that ferocity for which this species is so remarkable. As they increased in size they beeame exceedingly dangerous, seizing and tearing to pieces every animal they could lay hold of, and expressing extreme eagerness to get at those accidentally brought within sight of their cage, by grasping the iron bars with their paws and shaking them violently, to the great terror of spectators, who felt insecure while witnessing such displays of their strength. In one instance, an unfortunate monkey was walking over the top of their cage, when the end of the chain which hung from his waist dropped through within reach of the bears; they immediately seized it, dragged the screaming animal through the narrow aperture, tore him limb from limb, and devoured his mangled carcass almost instantaneously. At another time a small monkey thrust his arm through an opening in the bear cage to reach after some object; one of them immediately seized him, and, with a sudden jerk, tore the whole arm and shoulder blade from the body, and devoured it before any one could interfere. They were still cubs, and very little more than half grown, when their ferocity became so alarming as to excite continual apprehension lest they should escape, and they were killed in order to prevent such an event."

Upon comparing the account of the soldier, who had no "story" to tell but simply the truth, with that of the Museum describer, in regard to these the same animals, it cannot fail to strike the reader that there is a wonderful coincidence between these and the accounts of similar parties respecting the common hyæna. Every one who knows anything about domestic economy in the Dukhun, must be aware that the domestication of the hyæna as a substitute for the dog is a very common occurrence there; and the memory which the hyæna at the Zoological Gardens retained of the kindness of colonel Sykes, after the lapse of two years, and the apparent joy with which it welcomed him though he gave it nothing, are interesting traits in the animal economy. Yet this same hyæna has, "time out of mind," been the "ferocious and untameable"—the very ultimate example of unrelenting cruelty.

Some of the habits of the bears and the hyæna are similar: for instance, they both consume dead carcasses; but otherwise, the hyæna is by much the more carnivorous animal of the two, especially in the structure of its teeth; and therefore the accounts of the untameable disposition of the one animal are no more deserving of rational credence than those of the other.

We have no intention of pleading specially for the grisly bear, or for any animal whatever; but, though it is nearly exploded among all who *study* natural history, there is a great deal of the ridiculous exaggeration introduced by the showmen, still current in the country and in so far perpetuated by compilers; and this remaining delusion it becomes our duty, writing as we do for the public, by every means in our power to dispel. It is also our duty to mention, for the sake of those who have not the opportunity of seeing animals in a state of nature, or in that semi-freedom which they enjoy in zoological gardens, that, in the pigeon holes of a travelling caravan they see only the dwarfed or the emaciated forms of the animals, and nothing whatever of their natural dispositions. Indeed, if the gentlest mouthpiece of the menagerie that ever told the terrors of a tiger to the wondering rustics at a fair, were to get only twelve months of the tenement and treatment of his beast, he would be the more ferocious animal, and therefore the better spectacle of the two.

But while we must not judge of the character of the powerful bear under notice from the museum account, as little can we do it from the aecounts of the hunters; for if the one shows us an animal soured and irritated by captivity, the other displays it with all its formidable energies aroused in defence of its life. Of these accounts by the hunters we shall, however, give the substance of one instance from the expedition of Lewis and Clark on the Missouri. One evening, the men in one of the hindmost of the canoes perceived a grisly bear lying on the open ground about three hundred paces from the river; and six of them, good hunters, went to attack it. They got within forty paces unperceived, when four fired, all hitting, and two balls passing directly through the lungs. The bear sprang up and ran furiously at them with open mouth, upon which the two hunters who had reserved their fire, gave it, both hitting, and one breaking his shoulder blade, which somewhat retarded his motions. But before they could reload, he came so close upon them that they were obliged to make directly for the river, and before they reached it the bear was almost within paw's length. Two jumped into the canoe, and the other four, concealing themselves among the willows, fired as fast as they could load. They struck him several times; but that only made him proceed more furiously in the direction whence the wound came.

At last they were obliged to throw down their guns and pouches, and jump from a bank twenty feet high into the river. But bruin is more expert both at jumping and swimming than even a back-woods' rifleman, so he plunged in after them, and was almost in the act of seizing the hindmost man, when one of those on shore shot him through the head and he expired. When they dragged him on shore, they found that eight balls had passed through his body in different directions.

There are many similar occurrences mentioned, but notwithstanding them all, the real character of this animal does not appear to be made out in a manner altogether satisfactory; and thus, like most objects while seen through a fog, this monster of the American wilderness may appear much less formidable when we come to closer inspection.

Though the black bear and the grisly bear are the only two species of North American bears that have been definitely ascertained, the former as an inhabitant of the low ground forests, and of these only or chiefly, and the other as an inhabitant of the mountains, or at least more upland as well as more southerly than the other; yet it is not improbable that there is a third species, more resembling the common bear of the eastern continent than either of the others. This species prowls about in the open wastes; and therefore it has been styled

5. The Barren Ground Bear (*Ursus arctos Americanus*). Whether there is any structural distinction between this and the other American bears, has not been very clearly ascertained. Indeed the structural distinctions of bears differ much less than those of almost any genus; the chief ones, colour and size apart, being the facial line (which is not indented at the eyes in the American species), and the greater or less production of the hair and claws, the former of which may be the effect of climate, though it is not easy to see how climate could produce the latter. The bears which are found on the barren plains (that is, the woodless districts) of North America, are lighter in the colour than the climbing bears of the woods; and the Indians, who are their principal historians, represent them as being much more ferocious and dangerous. In this respect there is no reason to doubt the testimony of the Indians; but the ferocity may in part arise from the greater excitement to which the animals are exposed in those open places.

That bears become torpid when the temperature sinks to a certain point, shows that they are, notwithstanding the thickness of their covering, very sensitive to the action of the weather; and the bears in question are much more exposed both to common atmospheric action and to light, than those which inhabit the woods. It is therefore natural to suppose that, during the summer at least, their system is in a state of higher and more constant excitement; and if this be true, and it certainly is true, of the whole system, it must be true also of the appetite for food; and as those bears have to range more in quest of their food than the woodland bears, that again must increase their activity, and consequently their voracity. They thus, in some measure, approximate in character to the polar bear; and partially also to the grisly bear of the mountains, which is more a ground hunter than a climber.

Bears of this description prowl much on the shores of the northern sea, and divide the spoil with the white bears. One mentioned by Dr. Richardson, had in its stomach portions of a seal and a marmot, and also some grass and berries, showing that, in this instance, bruin had dined in style—having two courses with vegetables and a desert; and though the seal cannot strictly be considered as fish, yet being a marine animal, it may pass muster as a substitute. This compound shows, at all events, that these bears are pretty ravenous as well as miscellaneous in their feeding. Still it is not very probable that they will attack human beings unless very much pressed with hunger, unless indeed those by whom they are seen endeavour to escape by flight.

It is this last circumstance which renders the bear so dangerous an animal to those who are not well-armed with weapons, and especially with presence of mind. It has been stated in the case of some other animals, and it is confirmed in this, that flight in the prey is one of the main causes of pursuit in the preyer; and though it is doubtful whether any of these bears ever unprovokedly attacked a human being when advancing upon it, there is little doubt that they will follow, and endeavour to capture either man or animal when they seek safety by flight. When Mr. Drummond was botanising among the wild rocks in the northern parts of America, he sometimes, at the turning of a rock, found himself almost close upon a grisly bear; but Drummond is as remarkable for presence of mind and philosophical courage as for love of science, and therefore he outfaced bruin without irritating him; and when the bear found that Mr. Drummond would neither fight nor fly, he took to his heels, and left the naturalist master of the field. If he happened to see them at greater distance, he got rid of them more readily, by simply drumming on the tin box in which he carried his specimens. This, though we believe it happened chiefly with the grisly bear, may be considered as the general character of all the species, and of course of the barren-ground bear among the rest.

It is worthy of remark, and not of remark merely, but of careful investigation and study, that there appears to be in the north-east of Europe, and more especially in the north of Asia, a species, or variety, or modification of the land bear, very similar to the American one now under consideration. Like that, it is found chiefly to the northward of the woods, near the margin of the sea, bordering closely with the white bear, and approximating somewhat to that bear in colour, and, as it is said, in disposition. The data are not sufficient for determining whether this intermediate bear is or is not entitled to systematic distinction as a species: but whether it be species or not, its existence is established by the testimony of those who range the plains which it inhabits, and its character, and the characters of those places, appear very much to resemble each other in the two continents, if they are not perfectly identical, at least in so far as the animals are concerned.

This is a point of some importance in natural history, inasmuch as it shows that there is perfect identity, or acknowledged sameness of species, in those bears which inhabit nearest the pole; and that as we proceed southward the resemblance between those of the two continents becomes less and less. At the same time there is a departure from the appearance of the polar bear, though the species of corresponding climates have still some resemblance to each other. The colour is first pale brown; then it passes to soot black; the latter continues as the prevailing colour in the bears of warm countries, but they have the hair shorter and more glossy, and some markings of brighter colour, especially about the head. It will, however, require much observation before the gradations of the species can be distinctly traced, and the causes by which they are produced clearly seen. It is certain, however, that one species of bear inhabits round the whole globe in the arctic regions, and is the northernmost of the genus; and that as the latitude lessens, the bears of both continents vary in their characters from those common to the two, and each series also assumes distinctive characters of its own.

6. The Spectacled Bear (*Ursus ornatus*). This is the tropical bear of the American continent; and it has received the specific appellation of *ornatus*, or ornamented, from the markings on its head, especially those round the eyes. These are circles of bright brownish yellow, which encompass the eyes and are generally united by a small arch on the lower part of the forehead, which gives them very much the shape of a pair of spectacles. It does not appear, however, that these markings are constant; for, of two specimens at the gardens of the Zoological Society, one has the spectacles quite perfect round both eyes, but in the other one eye only has the mark round it. This shows, by the way, that the peculiar markings of colour which may be said to distinguish the bears of warm countries from those of cold and temperate ones, are not invariable in the species, and cannot, on that account, be received as specific characters.

This species is found in the Andes; and though it has not been traced all the way, and is not indeed abundant or very frequently seen, it appears to take up the mountain range where the locality of the grisly bear ends. Its history is very imperfect; but it appears to be much more exclusively vegetable in its feeding than the bears of the north; indeed, in all longitudes bears seem to get milder in character as they inhabit nearer the tropics; and while the polar bear, and those bears which inhabit the plains on the shores of the polar seas, are to a great extent carnivorous, or at least feeders upon animal matter, as we proceed southward we find them more mild in their characters, and less given to consume animal food. They are also smaller in size, feebler in their structure, and their covering is less shaggy. Even they, the most tropical of them, are not handsome animals; but they are certainly not so ragged and formless as the bears of the north. All this tends to prove what we have already assumed,—namely, that the whole genus are naturally and properly polar animals; and that the influence of improved climate produces an effect on their peculiar characters. The reverse is the case with the carnivorous animals, properly so called; so that there seems to be a little inconsistency in classing them together in the same order. The proper function of the carnivorous animal is to restrain the exuberance of living creatures; and it is with great difficulty that they can subsist upon vegetable matter. The bears upon the other hand, seldom kill; and those of tropical countries subsist chiefly upon vegetables. This in a great measure accounts for their greater mildness of character there than in those parts of the world where necessity compels them to be more predatory.

The annexed figure will give a general idea of the form of this bear, which perhaps approximates more nearly to some of the varieties of the black bear than to any other of the American species. The chief difference is in the peculiar marking on the face of this one; and it has been mentioned that many of the black bears have the rudiments of this marking, in the brownish-yellow spots over the eyes, and in this species the circles, as has been said, are sometimes wanting. This one is, however, only a recent addition to natural history, and its manners, and the extent to which it inhabits the Andes, are but imperfectly known. No mention is made of it as found in the mountains of Patagonia, or even in Chili; neither has it been met with on the mountains of Brazil, or in any other of the detached ridges which are inferior to the Andes in height. As is the case with the bears of all tropical countries, its fur is short, and, consequently, its skin is not so much furzed as that of the northern bears. There is also reason to suppose that it does not accumulate fat to nearly the same extent; and that, taking it altogether, it is a much less important animal, both in the natural history of its locality and in the domestic economy of the people.

Spectacled Bear.

Either there are different species of bears in the Andes, or the one species is subject to considerable variations, at least in colour and in size. Sir R. K. Porter, in a letter to the secretary of the Zoological Society, dated Caracas, Aug. 14th, 1833, mentions one then living in that city, which differs in the markings on the face from any of the individuals which had been previously examined or described by Europeans. The yellowish-white of its face begins on the bridge of the nose, between the eyes, and describes under each eye a semicircle, whence it extends over the whole muzzle, taking rather a greyish hue until it ends in pure white, covering the whole throat and chest, and forming a point between the fore legs. The rest of the animal is jet-black, the hair being silky and shining. It is smaller by far in size than the bears of the northern countries of Europe, and is more compact in form.

The account of this specimen, with the variations that have been seen in others of the few which have been examined, show that it is necessary to observe much caution before any positive conclusions are come to with regard to the specific arrangement of the bears of warm climates. Even in the temperate and the cold latitudes, bears are very sensitive to variations of situation and climate, even when these are not so considerable as to affect almost any other species of animal; and therefore we may naturally conclude, that in a situation like the Andes, where there are all descriptions of climate within a very short distance of each other, the variations of these sensitive animals must be correspondingly great; so that before we can decide what is a different species, and what a mere climatal variety, we must know much more of the history of the animals, in different localities, and in the successive periods of their age. Even the teeth of bears form a much less certain character, at least in so far as species are concerned, than those of most of the mammalia; for not only are the false molars liable to drop out at different ages, but it is doubtful whether there be not also differences in the number of incisive teeth, in species which are in other respects exactly the same.

This caution is necessary, not with regard to the bear, or bears, of the Andes only, but also with regard to those of the south-east of Asia. Of these there are usually reckoned four species,—the Nepâl bear, the common bear of India, the jungle bear, and the Malay bear, and as these seem to vary just as much as those of central America, there is little doubt that, by procuring them of different ages, and from places differently situated, each of these might be multiplied into two or three species more; whereas, if they were reared alike for two or three successive generations, and then compared at the same age and in the same condition, it is highly probable that they might turn out to be all of the same species. These circumstances, together with the very little which is known of the habits of some of them, further than is inferred from the fact of their being bears, render it necessary to be very brief in a popular notice of them.

All these bears have the prevailing colour black, the hair being shorter and smoother, and the markings on the head and throat more conspicuous, in proportion as they inhabit lower down or farther to the south.

7. The *Nepâl bear*, or Thibet bear (*Ursus Thibetanus*). This is a mountaineer, inhabiting the forests and brushes on the slopes of the Himalaya, and pretty generally distributed over that vast mountainous range, though not, as it would seem, from the scanty information which we have of its habits, very numerous in any one place. It is, indeed, doubtful whether there are not more than one species of bear in those mountains, or if there is only one, then that one varies considerably in appearance. That usually described under the specific name which we have given, is rather of small size, and with the feet and claws considerably smaller than those of the northern bears. It is all over of a black colour, with the exception of a large and conspicuous mark on the breast and throat in the form of the letter Y. The profile of this species is much straighter than that of the northern bears; and in this respect it has some resemblance to the bears of America. It is understood to feed chiefly upon vegetable substances, insects, and the bodies of animals which perish in the mountain storms. As the winter is very severe in the upper districts of the Himalaya, it is probable that this species, or at least the females of them, hybernate for a short time. Mention has been made of a bear being seen in the same mountains, more resembling the northern bears in its profile and the texture of its fur, than the species above alluded to, but the account of it is very vague.

8. The Jungle Bear (*Ursus labiatus*). This species gets the name of *labiatus* or "lipped," from the great elongation of the cartilaginous part of its nose, and a similar elongation of cartilage on the extremity of its under jaw. These elongations are moveable, and their consistency is such, that the animal can use them as prehensile instruments, and even manage to divide soft substances with them. Its general colour is black, with the muzzle and the extremities of the feet of a yellowish or greyish-white, and a Y-shaped mark of a similar colour on the throat, with its points forming a demi-collar on the neck.

Jungle Bear.

This species is very subject to lose its incisive teeth through age, and that indeed long before it shows any other symptom of decay; and on this account, as well as from the produced and peculiar form of the muzzle, it has sometimes been described as a sloth, and not as a bear. In all its characters it is, however, a true bear. A disposition to lose the teeth is not confined to this species, but is pretty common among all the bears which inhabit warm countries, or live much upon sweets; and from the injury that we know to be done to the human teeth by an excess of that description of food, we can, in part at least, see the reason of this loss in the bears. The species under consideration lives, as its name imports, in low situations, which are rich and tangled with an exuberant vegetation. It is an expert climber, and not only consumes great quantities of the common succulent fruits which grow so abundantly in India, but readily climbs the cocoa-nut trees, contrives to tear the rind and break the shell of these, and extract the milky juice. In this, and in many other of its modes in feeding, it has little use for incisive teeth, as the cartilaginous lips are sufficient for so breaking or squeezing soft fruits as that the juice of them can be extracted; and the shells of the cocoa-nuts are, of course, broken by the canine teeth.

9. *The common Bear of India*, if a different species from the above, and also from the bears of the mountains, is described as inhabiting places which are rather more dry and open than those inhabited by the jungle bear, though still in the low grounds, rather than in the mountains. It is said to be black and glossy, with the muzzle and throat of a pale-reddish brown colour. It is not of large size, nor in any way ferocious, but feeds much upon those social insects of which the species and the swarms are so abundant in all the fertile parts of India, especially the white ants. It is not understood to be in the least dangerous to man, and indeed none of the bears of warm latitudes

or warm localities can be considered as formidable animals.

10. *The Malay Bear* (*Ursus Malayanus*).—This species is found in the Oriental Archipelago and the Malay Peninsula, and it probably exists in many parts of India. It is but a small animal, the body seldom measuring as much as four feet, so that it is not one-eighth of the weight of the largest specimens of the polar bear. Its feet are smaller, and its legs taper more than those of most bears; but though rather low on the legs, it is a stout animal. The prevailing colour is black; the hair short and stiff, but smooth and shining, except on the ridge of the neck and back, where it is frizzled; the nose, and more or less of the face, is rust coloured, and sometimes inclining to grey; and there is often a spot of a similar colour, more or less conspicuous, over each eye, and another near the corner of the mouth. There is also a crescent-shaped spot of white on the breast or under the neck. The snout is produced something in the same manner as in the jungle bear, only the sides of the production have more the appearance of appendages to the nostrils.

Malay Bear.

The habits of this bear are also very similar to those of the jungle bear. It is a climber, and in a state of nature subsists chiefly upon fruits, and nearly the same sort of fruits as the other. Like that it is an animal of rather gentle manners; but still it is one of great strength, and might, as is the case with all bears, do mischief if irritated. It is, however, very easily tamed, and remarkably docile if duly fed and properly attended to. Sir Stamford Raffles, when in its native country, had a very tame one, which was very fond of eating mangoes and drinking champagne, though it despised wines of less celebrated growth. It played indiscriminately with the children and the dogs, and was withal very gentle and good-natured in its play; but as it grew up it treated the vegetable tribes with less mercy, for when it got into the place where they were cultivated, it used to seize the stems of large plantains with its paws, and wrench them up by the roots.

Such is a very slight outline of at least the prominent species of this very interesting and, in many respects, useful genus of animals. Some of the species that have been mentioned are probably only varieties; and there may be some omitted which future observation may show to be really distinct species. In the present state of our knowledge, however, mistakes both ways are unavoidable, more especially in the case of animals upon which temperature appears to have so much influence as it has upon bears. In those cases mistakes being almost unavoidable, ought not to subject to very heavy censure those who fall into them; but the danger of so falling ought to teach the utmost circumspection in managing the information which we have, and stimulate to the utmost vigilance in acquiring more.

We have treated of those animals at something more than the customary length for several reasons. In the first place, they may be said to extend in latitude over the entire quadrant; and therefore we have the means of observing the effects of all latitudes and all climates upon them. Secondly, they are every where not only animals of wild nature, but of wild nature in a particular state, as regards the soil, the climate, and its productions; therefore their history becomes an index to a considerable portion of the progressive history of the globe. Thirdly, they are animals of wild nature only; and, according to our present notions at least, they cannot be brought usefully within the pale of domestication; that is to say, we cannot apply their strength, great as it is, to any mechanical purpose; and as they seem to be impatient of restraint, they could not be kept for the sake of their flesh so advantageously as the animals which we at present rear for that purpose, even though a mode of feeding them should be discovered by which their flesh could be rendered as palatable. Fourthly, bears are animals which are equally peculiar in their structure and their habits; and therefore by carefully studying them we put ourselves in possession of many of those general elements which are so serviceable in working out those supplemental parts of natural history upon which direct observation furnishes us with hints, but not with proofs. Their teeth are carnivorous, but only partially so; and their carnivorous structure is more in the canines than in any of the others, so that they are better fitted for wounding and lacerating than for gnawing flesh. The absence of clavicles gives them a wonderful strength in compressing objects between their fore-legs, whether in clasping that on which they climb, or in hugging their enemies. The absence of the same bones admits of much more play in the scapula than in animals which have clavicles; and thus a bear can reach further, and also strike a severer blow than any other animal having equal length and weight of paw. The great size of their plantigrade feet is of great service to them on rough or unstable surfaces. The northern ones walk the surface of the snow with the same ease as people walk when they have snow shoes on. The same form enables them to support their heavy weight upon twigs, or leaves, or grass; so that when they have to range among the bushes or the small trees for berries, and the nests of wild bees and birds, they walk much more lightly and with far less fatigue than one would from the study of their apparently clumsy form be apt to suppose. The same form of the feet, and the fact that the whole length of the tarsi of the hind ones is on the ground, and the first joint above the ground, one with a forward flexure, as in the human knee, gives them not a little of the same stability on the hind feet which man himself possesses;

because, by different bendings of the knee-joint, they can always contrive to make their weight press equally upon the whole sole of the foot from heel to toe. Even the shortness of the tail, or the almost total absence of that organ in some of the species, is convertible into a means of stability, inasmuch as they can bring their buttocks to the ground, and add the support of these to that of the feet, still retaining the uniformity of pressure on the whole soles of the latter. Thus though a bear cannot support the horizontal spine on the hind feet alone, it can stand erect so firmly upon them as to have the most perfect command of its paws, and, with the exception of man, the bears are the only genus of mammalia that can do this, at least to any degree of perfection. There are many other interesting points in their structure, but the above are the leading ones.

BEARDED REED-BIRD (*Calamophilus biarmicus*—Leach); provincial, Reed Pheasant,—Bearded Titmouse. This most elegant and truly beautiful of our indigenous small birds, is an inhabitant of large reedy tracts in various situations both of Europe and Asia, being found in Sweden and other northern countries, and plentifully along the reedy borders of the Caspian Sea; though nowhere in such abundance as in Holland. In this country it inhabits the fenny districts of Norfolk and Cambridgeshire, where it is not uncommon; and is found also in the Essex marshes, and in those of Sussex, bordering on the sea; also in Gloucestershire, Lancashire, and Cornwall. It has likewise been seen near Paisley, in Scotland.

It is a small species; but from the very great length and thickness of its plumage, and the length of its tail and legs, it appears when alive almost as large as a robin. The bill is small and delicate, somewhat of the form of the titmice (*Parus*), but much weaker, and more arcuated, and the upper mandible is slightly curved, and pointed; of a rich yellow colour inclining to orange, but fading almost immediately after death. Irides, fine yellow; in the young of the year, white, with a yellowish tinge. Between the bill and eyes is a tuft of pendent pointed feathers on each side, forming a kind of moustaches; glossy jet black in the male, and of the same colour with the surrounding plumage in the other sex. The head, neck, and breast of the male, of a beautiful pure bluish grey; the latter softly tinted with purplish black; chin and throat very pale ash-grey, almost white; flanks yellowish-brown; the back and tail a very rich yellowish brown, inclining to orange, forming a fine contrast with the grey neck; scapulars wood-brown; greater quills blackish-grey, having their outer webs edged with white; secondaries edged with orange-brown; tail long, and very wedge-shaped, the exterior feathers having their outer webs and tips pale reddish white, under tail-coverts jet black, legs and toes black; in the female, the chin, breast, and sides of the neck, are whitish, with a slight tinge of pink; crown of the head, wood-brown; the occiput sometimes spotted with black; back yellowish brown, in some having a list of blackish spots down the middle; vent, and under tail-coverts, pale yellowish, inclining to wood-brown. The young of the year resemble the adult female, excepting in the colour of the iris, and in having a very broad black line along the back.

This species has been arranged by Linnæus, and by the majority of subsequent writers, with the titmice in the genus *Parus;* and some have even classed it among the shrikes; but the reed-bird differs essentially from both these in several important particulars, though on the whole, perhaps, it more approximates to the former. We have, however, minutely studied it in confinement, and with great attention, when in company with all the English species of Parus, and cannot perceive in it a single character in accordance with the titmice, of sufficient importance to entitle it to range in that genus. It forms one of the numerous connecting links between the small granivorous and insectivorous birds, in many particulars nearly approximating to some of the smaller exotic finches; but we know of no congruous species with which it can be placed, and are inclined to Dr. Leach's opinion, who forms of it a distinct genus, *Calamophilus.*

It differs widely from the titmice in the structure of the digestive organs, the stomach or gizzard being much more muscular than in those birds, and the œsophagus or gullet, containing a considerable enlargement, or crop, as in the finches.

Its manners and habits, also, its whole form, and the nature and disposition of its plumage and colours, all are quite at variance with the titmice: but here it would occupy too much space to enter largely into these particulars. Its mode of progression, when on the ground, is by a peculiar shuffling walk; that of the titmice is by successive hops. It builds itself a regular nest in clumps of reeds or rushes; the genuine *pari* all nidificate in holes. In all the latter the two sexes are much alike; in the reed-bird they are very dissimilar. Their food also, and their haunts, are altogether different.

The reed-bird frequently places one foot upon its food, while it picks it to pieces with its bill, in this somewhat resembling the genuine titmice. But this habit may be observed in various genera, and is even different in the reed-bird from what it is in the *pari;* the latter usually grasp their food (a hemp-seed, for example) with both feet in a peculiar way, and after breaking the husk with quickly-repeated hard knocks of the bill, draw forth and eat the kernel; but the species now under consideration has not the least notion of thus hammering at a seed; nor could it succeed in this, were it even to attempt it, its bill not being formed for such labour; but, in confinement, we have frequently seen it sit by the side of a titmouse that was so employed, and, as soon as the seed was broken, endeavour to make off with the prize. This trick was so often successfully practised by an individual we possessed, that the different titmice which were confined with him became at last extremely shy of attempting to crack a seed when he happened to be near them.

Bearded reed-birds have a remarkable habit of scratching each other's polls in the manner of parrots; and when in the aviary, without a companion of their own species, will frequently go up to other birds, and, presenting the poll to them, seem to implore them to perform the kind office. We have witnessed this repeatedly, and have even seen its desire gratified by birds of very different natures, as the aberdavine (*Carduelis spinus*) and the mountain linnet (*Linaria montana*). Among themselves they are doing this continually.

We have noticed another curious habit in the individuals which have been kept by us in confinement. Among the various seeds which were daily placed in the aviary for the sustenance of their granivorous companions, chanced occasionally to be a small extraneous seed, of which the reed-birds were particularly fond; but as there were never but a very few of these seeds at a time, they had of course some difficulty in finding them from among the rest. The method, therefore, taken to scatter the seed about the cage, to get at the bottom of the pan, was curious, not with the bill, as a finch, or as most other small birds would have done, but by jumping into the pan, and kicking them about in all directions.

The usual call-note of this species is loud and monotonous, and not very unlike the querulous piping of a young chick, that has strayed from the hen; or it may be written thus, *ptear, ptear*, pronounced with some emphasis. When particularly pleased, it utters a low note resembling *pitt, pitt;* and it emits almost continually a low kind of chirp, which also bears some similitude to the faint cry of a newly hatched chick. Besides these, the male sometimes chants forth a variety of hoarse croaking chirps, which may be considered his song; but we have never yet heard the musical note it is alleged to utter among the reeds, resembling *ping, ping-ping-ping-ping*.

Some interesting accounts of the reed-bird in a state of nature, have been published in the magazine of Natural History by Mr. Hoy. "The borders," says he, "of the large pieces of fresh water in Norfolk, called Broads, particularly Hickling and Horsey Broads, are the favourite places of resort of this bird; indeed, it is to be met with in that neighbourhood, whereon there are reeds in any quantity with fenny land adjoining. During the autumn and winter they are found dispersed, generally in small parties, throughout the whole length of the Suffolk coast, wherever there are large tracts of reeds." * * * * "It begins building in the end of April. The nest is composed on the outside with the dead leaves of the reed and sedge, intermixed with a few pieces of grass, and invariably lined with the top of the reed, somewhat in the manner of the nest of the reed-wren" (or reed verderolle, *Salicaria arundinacea*), "but not so compact in the interior. It is generally placed in a tuft of coarse grass or rushes near the ground, or the margin of the dikes, in the fen; also sometimes fixed among the reeds that are broken down, but never suspended between the stems. The eggs vary in number from four to six, rarely seven; pure" (or rather pinkish) "white, sprinkled all over with small purplish red spots, intermixed with a few small faint lines and markings of the same colour; size about the same as those of the ox-eye" (great titmouse), "but much more rounded at the smaller end. Their food during the winter is principally the seed of the reed, and so intent are they in searching for it, that I have taken them with a bird-lime twig attached to the end of a fishing-rod. When alarmed by any sudden noise, or the passing of a hawk, they utter their shrill musical notes, and conceal themselves among the thick bottom of the reeds, but soon resume their station, climbing" (walking up) "the upright stems with the greatest facility. Their manners in feeding approach near to the bottle-tit, often hanging with the head downwards, and turning themselves into the most beautiful attitudes. Their food is not entirely the reed-seeds, but insects and their larvæ, and the very young shell snails, which are numerous at the bottom of the reedlings." One we lately examined, which had evidently escaped from confinement, and which was knocked down with a stone, contained in its stomach the remains of flies. We have seen them eat small shell snails, in confinement. Mr. Hoy continues, "I have been enabled to watch their motions when in search of insects, having when there has been a little wind stirring, been often within a few feet of them quite unnoticed among the reeds. Were it not for their note betraying them, they would be but seldom seen." * * * * "The males and females I have always observed in company; they appear to keep in families until the pairing time, in the manner of the bottle-tit; differing in this respect, that you will occasionally find them congregated in large flocks more particularly during the month of October, when they are migrating from their breeding place."

Another correspondent of the Magazine of Natural History observes:—"The bearded titmouse" (reed-bird) "inhabits the marshes bordering on the Thames, both in Kent and Essex. I was told in December last that some had been seen in a large piece of reeds below Barking Creek; and being desirous of observing them in their haunts, I went out, accompanied by one person and a dog, to the above-named place, on a cold windy morning; the reed-cutters having commenced their operations, I was fearful of deferring my visit, lest my game might be driven away. Arrived on our ground, we traversed it some time without success, and were about to leave it, when our attention was aroused by the alarm-cry of this bird. Looking up, we saw eight or ten of these beautiful creatures on the wing, just topping the reeds over our heads, uttering in full chorus their forcibly musical note, which resembles the monosyllable *ping, ping*, pronounced at first slow and single, then two or three times in a more hurried manner, uttered in a clear and ringing, though soft tone, which well corresponds with the beauty and delicacy of this bird. Their flights were short and low, only sufficient to clear the reeds, on the seedy tops of which they alight to feed, hanging, like most of their tribe," (that is, like the various titmice) "with the head or back downwards. If disturbed, they descend by running, or rather by dropping. The movement is rapid along the stalk to the bottom, where they creep and flit, perfectly concealed by the closeness of the covert, which resembles the tint of their plumage. After some time we were fortunate enough to shoot one, a male in fine plumage. I held it in my hand when scarcely dead. Nothing could exceed the beauty of the eye; the bright orange of the iris, surrounded by the deep glossy black of the moustaches and streak above, receives additional brilliancy from the contrast, and struck me as a masterpiece of colour and neatness."

Fine specimens of this beautiful bird may often be procured in the London markets during the winter months; these are brought from the Essex marshes. In summer they are less valuable as specimens, as the tail feathers and other parts of the plumage are often injured, and sometimes soiled with dirt. Great numbers of them, also, are annually brought to London alive, about the fall of the year, from Holland, and may be purchased of the dealers for a trifle. They are tolerably hardy, but exceedingly subject to fits of apoplexy, if fed upon too nutritious food: we have seen them fall from their perch three or four times in the course of the day, and such as do so rarely survive many weeks. They are usually, however, stout and healthy birds, if not suffered to get too fat; and very ornamental in the aviary, though it would not be advisable to procure more than a single pair, on account of their being so garrulous and noisy.

Male Bearded Tit, or Reed Bird.

We hardly remember having noticed any bird so remarkably fond of society as this species. A fine male, which we long kept in confinement, in a large cage, together with a variety of other small birds, generally passed his time on the higher perches, where, if left alone by the others even for a moment, he raised a most pitiful outcry, endeavouring by every means in his power to call them up; and then sometimes, when all his efforts were unavailing, and he could brook solitude no longer, he would descend, and strut among his companions, chuckling with pleasure at being again in their society. He was most unceasingly active, insomuch that it was often difficult to obtain even a momentary view of his lovely plumage; and his movements were at all times remarkably light and graceful, bearing a curious resemblance to those of the monkeys in the large cage in the Zoological Gardens; a resemblance not altogether fanciful, for it was remarked by several persons. Like the monkeys, he often hung by one leg from the top of the cage, and looked around him: but perhaps some of these traits were chiefly owing to the large size and convenient form of the cage which he inhabited; for in describing the habits of birds in confinement it is always necessary to have an eye to such circumstances, their habits being often affected by the peculiar size or form of the cage in which they may chance to be confined, as we might illustrate by numerous examples.

The bearded reed-bird is of a very timorous nature, and is often a very long time before it becomes sufficiently familiar to feed when a person is looking at it. Some pains were taken to tame the individual above-mentioned, and he would take bread and milk from the hand, but not without the greatest circumspection, and the most extreme readiness to retreat at the least move of the person who offered it. He was immoderately fond of this food, but it did not agree with him, as he was always ill after eating it in any quantity. His extreme timidity was also shown when disturbed from his roost at night, being alarmed at the slightest noise, and flying about with his long pheasant-like tail expanded wide, which made him look even handsomer than usual.

The legs and feet of this species are large and strong, and would appear disproportionate, were it not for the plumage being so exceedingly thick and puffy; the claws are long and pointed, very unlike those of the different titmice, but resembling those of the American rice-bird (*Dolychonix orizivora*), and other species which pass their time on the perpendicular stems of reeds and rice plants.

BEAVER (*Castor fiber*). A genus of mammalia belonging to the order *Rodentia* or gnawers. It consists of only one species, and that species is peculiar in its locality, being found only in the colder parts of the temperate latitudes in the northern hemisphere, and there only in wild places, by the banks of pools, lakes, and streams, which lie in the fastnesses of the forests, or otherwise secluded in their character, and distant from the abodes of civilised man.

But though there is, in this genus, no variety of species, and not very much diversity of haunt to be described, it is still an exceedingly interesting animal, and one of which perhaps more marvellous stories have been told and printed than of any other. It would be foreign to our purpose to repeat those stories even for the sake of refuting them; and we shall therefore take the shorter method of pointing out what the animal is like, where it inhabits, what it is capable of doing, how it is captured, and to what uses it is applied, adding, as the occasion may suggest, a few words on its general relations to the rest of nature.

The beaver is so decidedly a gnawing animal in the structure of its teeth, that it may without impropriety be considered as the most perfectly typical one in the order to which it belongs. Its cutting teeth are two in each jaw; very large and strong; and standing so far clear of the lips, that the animal can easily gnaw or cut a hard substance without the least danger of injury to these. The structure of these teeth, though common to most of the order, is peculiar and well worthy of notice. On their front sides these teeth are broad and flat, not white like the teeth of most animals, but of a brownish yellow, or a chestnut colour. They have along the front surfaces, a plate of very hard enamel, which covers the bone or principal substance of the tooth, just as a piece of steel may be seen covering the iron on the cutting edge of a chisel, which is both sharp and not liable to be broken. The body of the tooth is compact, but not very hard bone; and it is strengthened by a projecting ridge on the posterior surface, in the same manner as hoes and various other tools are fortified, by a ridge extending from the socket which receives the handle. The tooth is thus formed upon the most skilful mechanical principles, both in the distribution of the materials and in the form. Bone, though not so hard a substance as enamel, is tougher, just as iron is tougher than hardened steel. The softness makes it wear faster than the enamel, and the toughness makes the tooth less easily broken. If the whole tooth had been enamel, it would have in time got blunted, by the cutting edge wearing down faster than the rest; but the bone wears with less action than the enamel; and thus the enamel always stands highest, and forms a cutting edge, while the bone supports it behind like the basil or sloping edge of a tool. Thus the cutting tooth of the beaver is a chisel, and whether the carpenter's chisel has been made in imitation of it or not, the same arrange- of iron and steel as there is of bone and enamel in the tooth, is the best possible for a chisel of all work. There is one property in the chisel of the beaver, however, which no art of man can give to the chisel of the carpenter; the incisive or chisel teeth in the beaver have not roots consisting wholly of bone, as in the teeth of most animals, and as in the grinders of the beaver itself. They are inserted deeply in the jaws; but they are inserted in a peculiar kind of socket—a socket which exists only during dentition in other teeth. These sockets continue gradually to produce the tooth in such a manner as that both bone and enamel grow at the root as fast as they are worn down at the point; and consequently those chisel teeth remain in good condition during the whole life of the animal. Their chisel edges are directly opposed to each other, so that when the animal bites, it bites clean, just in the same manner as a workman cuts a wire or other small piece of metal, with his cutting pincers. If by any means a beaver loses one of those teeth, the opposite one in the other jaw, having nothing to act against, is not worn down, but continues growing till the point of it projects beyond the mouth, and the animal bites less effectively than if that one had been removed as well as its opponent.

As is the case in all the rodentia, beavers have no canine teeth. Such teeth would not only, from the nature of their food, be perfectly useless to them, but would be in the way of the cutting teeth, and prevent them from acting properly. The grinders are four in each side of both jaws, flat on the crowns, and adapted for masticating vegetable substances. They are, indeed, better adapted for this purpose than the grinders of most of even this order, being marked with projecting ridges of enamel, which can divide substances of almost ligneous texture. Of these ridges or folds, there are four on the crown of each tooth; but they are differently arranged in the two jaws. Those of the upper jaw have three folds on their outer surfaces and one on their inner, and those in the lower jaw have one on the outer, and three on the inner; by this means the bark and other dry and rigid vegetable substances which the animal masticates preparatory for the stomach, are broken at the middle of the tooth, and reduced to smaller portions at each edge. The jaws have no lateral motion upon each other; so that the action of the cheek teeth upon the food, more resembles that of a bark-mill than the ordinary grinding motion in ruminant animals. These cheek or grinding teeth have proper roots, and not the same kind of socket as the front teeth, so that they do not increase by growth at the roots, as they wear down by using at the crowns.

In the different modes of structure and growth of the two sets of teeth in these animals, we have a striking instance of the economy which is displayed in the structural adaptations of nature. The cutting teeth have not only the severest labour to perform in the finding of the food; they have various other functions: they cut the wood, the bark of which is to be the winter store, and also that which is to be used in the construction of the dam or the hut; and, in the performance of these operations, they have a harder task than the teeth of most animals. The cheek teeth though they have to grind harder food than those of most of the mammalia, have slight labour as compared with the cutting teeth; and thus, while the latter are in constant growth, the former attain their full size in the usual manner, and afterwards grow no more. Thus, in the beaver, where the extraordinary work has to be performed, we have the extraordinary instrument for the performance of it, and in that part where there is no extraordinary work, the instrument follows the ordinary law; only the structure of the coronal surfaces of the grinding teeth, is, as has been said, adapted for dividing substances approaching to the nature of wood, rather than succulent or soft vegetable matters.

And this is a general law in nature, and one which most clearly establishes not only a purpose, and by consequence a Maker, in all that nature displays; but it shows that, anterior to creation itself, that Maker must have known intimately, in itself and in its connexion, every property of every substance, every law of every combination, and every principle of every science, mechanical, chemical, or whatever else. Nay more, that the properties, the laws and the principles must have emanated from that Maker, and from Him alone; and that all which the most learned and the most studious of the human race can know of any of those subjects, or of any part of them, is not originally of human invention or human skill; but the humble and simple discovery of that which God has ordained, and bearing probably no more proportion to the knowable part of the whole than a single dew drop of the grass bears to the congregated waters of the Ocean. Then, though we could carry our knowledge to the full measure of this science—the science which being perceived by material organs of sense, must be in itself material, there remains behind a portion of the system far mightier in its extent, and more wonderful in its operation—the law of life—that mighty mandate which is one and continuous, yet varied as the races of being, and the ages at which they live—nay, as the individuals of those races, and as those small moments of their existence, which no sense or instrument can measure.

To this portion of the subject, into which it is not given to mortal eyes to look, the mind can contemplate only an infinitude in every part, or so to express that to which no tongue of man is equal, an infinitude of infinitudes in the whole; a reflected but express image of the Omniscient and Almighty Maker and Governor.

Nor, when we come even to the details, do we fail to find proofs of this. Every power of life, considered in itself, and without reference to the quantity of material substance on which it acts, is, to our comprehension, infinite in its power; and, as we have had occasion to state again and again in the course of this work, there is not a living energy recorded within the whole volume of nature's book but which, if it had full scope for its working, would in brief space replenish the earth with its own species; and it would be easy to demonstrate, upon principles the best known and the least liable to mistake or fallacy, that in some species (as, for instance, in the common cod-fish) this energy, originating in a single pair, could turn, in half the average period of human life, as much matter as there is in the sun and all the planets into that species of fish.

Thus on this part of the subject there is no need for economy, or saving in any sense of the term. That which the line cannot measure, and the balance cannot weigh, cannot be meted off by the line or weighed off by the balance, so as to diminish its quantity by any nameable fraction of a hairbreadth or a grain. When it works it is never weary; when it gives even to the excess of its bounty, it is never one tittle the less. It stands invisible to every material sense, unless when displayed in material substance; but it stands to our mental view as immeasurable and immortal; and though obscured as our mental contemplation is by the material body, we cannot *now* know and behold it in its essence, yet we dare not say, even if we take the remotest points in time or in space which arithmetic can express or imagination picture, "here it begins, or here it ends."

But wherever matter is the element, be the application of that element what it may, we find the most perfect economy exhibited throughout the whole system; and that whether in what we call mechanical structure, or chemical combination, or the action of either or both. In machines which are made by mechanics, those are reckoned the most perfect which are the least loaded with unnecessary parts, or unnecessary weight. From the limited extent of our knowledge, we make but very loose approximations in this way; and as one part moves fast and another slow, one is exposed to variable and one to uniform temperature, and so forth; we are unable to adapt the form and the quantity of our materials to these, and therefore the works of our most skilful artists wear out much more in consequence of not being made on true principles, than of what may be termed fair wear.

In nature it is not so; for taking the average of nature's productions and of the functions which the parts of them are called upon to perform, there is not a single grain either redundant, defective, or one hairbreadth out of its place. It is this which makes the study of animal mechanics so instructive and so useful in every art, and therefore to every man; though (as has been too often the case in our views of nature) we have done as the ignorant man did with the spy-glass, looked in at the wrong end, and thereby driven away and diminished that which the skilful use of the instrument would have brought nearer and magnified. We have carried the principles and even the applications of human mechanics, as the models in our judgments of nature; and as these are all imperfect and really imitations (though frequently unknown imitations) of nature, we have gone about as though we had been to teach nature instead of learning of her.

The structure of the beavers' teeth gives us, as we have already seen, the models of some of our mechanical instruments in their best forms, though with us they are made of different materials; and as the beaver is, even discounting all the exaggerations which have been related of him, the most mechanical of all the mammalia, we have thought that it would be at once more useful, and savour less of the mere parade of science, to introduce these general observations in our account of the beaver, than in any article more expressly on the subject of animal mechanics, and of the limit beyond which we must not carry our mechanical theory when treating of the structure and economy of animals as they appear to us in wild nature. Having done so, we return to our structural account of the beaver.

We have already described the teeth; but we must mention several of the other parts before we be in a condition for understanding the habits of the animal; for, as there is but one species of beaver, and as that species is the same, and inhabits the same kind of localities in all countries in which it is found, it is one of the very best species from the study of which to see clearly the natural connection which subsists between structure and locality. The relation between these, once clearly seen, and well understood in one instance, can with much safety be carried to other instances, and forms at once one of the securest and the most instructive of analogies.

The beaver is low and squat in its body; the line of its profile from the occiput to the muzzle is unbroken; the muzzle is oblique and blunt; and the upper lip cleft, as in the hare. The eyes are small, oblique, and wide apart from each other; and the ears also are small. The fur is remarkably close and soft; but interspersed with longer bristly hairs, which get more abundant as the animal grows older; both the hind and the fore legs seem short in proportion to the size of the animal when it walks on the ground; but, as is the case with all animals of the order, the habit of which is generally to leap, to stand up, or to support themselves on their hind legs, these are much longer than the fore ones. They are, however, differently articulated, especially at the knee joints, which turn inwards, as in a man who is what is called "knock-kneed," and thus the hind feet are shambling and wide apart from each other in walking, though in their other function of swimming they answer better in consequence of this mode of articulation. Swimming feet, and especially the hind feet of swimming mammalia, are always constructed in this manner, except in those species in which (as in the seal, for instance) they are formed into a swimming sail, and in consequence of this they act more horizontally, and consequently impel the animal forward in the water with more velocity by less exertion. Animals which are constructed principally for walking on the land, make the chief exertion with the fore feet when they swim; and therefore they are sooner fatigued than when they move even faster upon land; but quadruped animals having a regular swimming habit, impel themselves chiefly by means of the hind feet, and on this account they are no more fatigued in the water than they are on land. The reason of this will be readily understood by those who are aware how much more easily a boat is pulled by oars nearly on a level with the water, and near the quarters, than by oars which have to dip much downwards and are used near the bows.

The beaver has this swimming property of the hind feet in greater perfection than almost any other quadruped; because when making way by means of these, it often has occasion to use the fore feet for purposes not connected with swimming, such as in assisting in moving along billets of wood, stones, or such other matters as the animal requires for its food or its buildings. These feet in the beaver are in consequence rather more awkward upon land than any other feet of the same length and muscular power; but, generally speaking, it is in the water that the beaver performs the more arduous portion of its labours, and the instruments of motion in that element are best adapted for it. There are five toes on each of those hind feet, which are free in the joints of all the phalanges of the bones; so that they can come close together when the animal walks on land, and spread wide of each other when it swims in water. They are all united up to the claws by strong but soft and flexible membrane, so that the feet form very effective paddles, and they can be spread to their full extent for the stroke, and closed while they are recovering, which answers the same purpose as "feathering" an oar, only it answers that purpose much better. The nails upon the toes of these feet are thick and strong; and the second one is a sort of double, by having a supplemental part in the form of a sharp ridge on the under side, the use of which is not very well known; though it may answer some purpose in scraping or otherwise dividing substances.

The fore feet are not so strong as the hind ones; the joints of them are articulated more in the common manner of those of walking animals. The toes on them are completely divided, and admit of so much motion in their phalanges that they act something like thumbless hands, in which the point of resistance to all the five toes is the wrist; but hands or paws of this description are best adapted for acting against each other, or in concert with the mouth, as is very much the habit with the beaver either when moving substances on land when it is not walking, or for moving substances through the water.

In the use of its feet in walking the beaver combines two distinct habits. On the fore feet it is *digitigrade*, or walks on the toes only; and on the hind feet it is *plantigrade*, or walks on the entire length of the sole. This, again, gives the fore feet more apparent stability than the hind ones in walking, but it gives the whole animal a wriggling gait, and it is in consequence rather a slow animal upon land.

The tail of the beaver is the most peculiar part of its structure. It is very large, nearly half as long as the body of the animal, oval in shape, and flattened on the upper and under sides. It is also, with the exception of a small portion at its base (which is very thick and strong), covered not with fur, like the rest of the animal, but with a sort of horny scales, which are produced by a thick and dark coloured skin. The singular structure of this organ, and the remarkable difference between its covering and that of the rest of the body, has furnished a theme of much exaggeration with those who have *imagined* the habits of the beaver from the structure of the dead animal, and that apparently with marvellously little either of anatomical or of mechanical knowledge to guide them to any thing like rational, or even possible conclusions. It has been described as a mattock for digging pits, a ram for driving stakes, a trowel for smoothing plaster, and many other unbeaver-like operations; and as the arrangement of the scales is not very unlike the toothing of a file, it is somewhat astonishing that they did not add the function of that instrument also in smoothing and polishing the ornamental wood-work of its dwelling! But the plain fact is, that there is not one word of truth in any of these statements; and no one who had ever seen a living beaver, or examined a dead one, with even a very moderate degree of the requisite knowledge, would have been guilty of any thing so totally inconsistent both with the habits of the animal and the structure of the organ. The tail of the beaver is not even very efficiently a swimming tail, but rather a rudder for the directing of the animal's aquatic course. It has very little vertical motion, being capable of just rising above the straight line, having remarkably little flexure in that way in its length, and generally being partially in contact with the ground when the animal walks. Its lateral motion is also by no means great; and from that, as well as from its shape, it cannot be very effective in impelling the animal through the water, though the resistance of the scales may prevent a recoil from the stroke of the swimming feet; and the steadiness of the tail—its very inaptitude for the purposes to which authors have applied it, fits it the better for answering this purpose. There is also another use of the tail, and this, too, depends in no small degree upon its stiffness: it is sometimes used as a means of support. The loose articulation of the knee joints, and the tendency which these give the feet to separate, render them alone a very unstable base when the animal stands up, as it often has occasion to do in the procuring of its food and materials, and also in the constructing of its dams and dwellings. In these operations it very often requires to have both mouth and fore paws at perfect command, without much reference to the balancing of its body; and as the stiff tail converts it for the time into a sort of tripod, it is in that way very serviceable. We may therefore thus briefly sum up the functions of the working organs in the beaver: the fore teeth are cutting pincers, or double chisels, so that they act against each other, and their action is so powerful, that they will cut a moderately thick twig as clean across as if it were done with a knife. The grinders are adapted for bruising bark; the fore paws are the most efficient working instruments, and also in some degree hands; the hind feet are most effective as swimming paddles; and the tail is a rudder in the water, and occasionally a supporting prop, when the position of the animal requires one. From this general description of the structure, the functions of the parts may in a great measure be inferred.

Beavers are found in most of the northern latitudes of both continents, in places which are adapted to their habits, that is, in places which are remote from the dwellings of man, and abound in wood and water. They were not unknown in the British islands; for though we cannot implicitly credit all the accounts of them in the living state, and certainly not those which mention their existence as recently as the fifteenth century, yet we cannot disbelieve all the older accounts, supported as these are by the unequivocal proof of the bones of the animals found embedded in the soil. Such remains are not very numerous, or generally distributed; but they have been found in Berkshire in marl under peat.

This carries us back to a very remote period, and one in which the state of the country must have been very different from what it is at present. We are not aware of any situation in which a deposit of marl can form other than in stagnant water, and then either by calcareous oozings out of the earth, or by the deposit of the shells of fresh water mollusca, carried on through a long period of time; for when peat forms upon a bottom which is not covered with water, the substratum under it is not marl, but sand, gravel, or clay. If we look at the description of places which beavers now inhabit, we shall be enabled to form some idea of what must have been the state of our own country during the era of the beaver—forests of deciduous trees, for the beaver is not so fond of the bark of pines, with numerous streams, pools, and lakes; long winters, with heavy falls of snow, and probably continued drought in the summer, because there is much less atmospheric action between the sea and the land in a wood-clad and humid country than in one which is cleared of its forests and drained.

At present, though there are some beavers in the west of Europe, as far to the south as Germany, they may be said to be few and scattered in that part of the world, and not very numerous in the north of Asia. Their head-quarters are in North America, though even there they are fading fast before the invading foot of human settlement, and the unceasing labours of the hunters. There are still, however, immense tracts of that country remarkably well adapted to their habits, and there they are proportionally abundant.

Some slight differences have been found (or fancied) between the skulls of the few beavers of the two continents which have been examined, but certainly not greater than those which may be observed between the skulls of human beings of the same nation, or even of the same family. It has also been said that their habits in the two continents differ from each other; but the difference is not greater than between the beavers in different parts of the same continent. Thus there is no reason to conclude that there are even two varieties of beavers, far less that there are two species.

From what has been said of the structure of these animals, it will be seen that they have a double element, being adapted both for the land and the water, and perhaps for both in nearly an equal degree; for though the hind feet are aquatic rather than terrestrial in their structure, the structure of the fore ones is wholly terrestrial, and the animal is in no respect a water-feeder. It spends, indeed, a considerable portion of its time on the margin of the waters, and some part of it in that fluid, but the water directly produces nothing which can be considered as beaver's food. The beaver eats no animal substance; and plants which are strictly aquatic, and grow in the water without being rooted in the soil, have no matter in them adapted for its support. Sometimes, indeed, beavers eat the roots of water lilies, and other plants which form bulbs or other roots, containing, during the season of their repose, a considerable quantity of albuminous matter; but these are not, strictly speaking, water plants; they are marsh plants, and though water is necessary to their growth, soil is equally so, as we never find them on the washed sands or clean gravel of running streams.

But as the beaver has thus a double element, it has a double habit, answering to different seasons of the year; and though it never inhabits so far landward as that the water is out of its reach as a means of escape from land enemies, and might be said never absolutely to inhabit the water at all, it is almost exclusively a land animal (except for safety) in the summer, and much more towards the water in the winter. This double habit is carried on with some difference, at least in the winter portion of it, according to the locality; but still it shows us the use of the beaver in wild nature, and that brings us back again to the peculiar state of countries in which beavers inhabit them. Deciduous shrubs and trees, which of course grow most abundantly and luxuriantly in humid, but not, generally speaking, in marshy places, are the characteristic vegetation there, and would in time overcome and destroy all else, and finish the scene with self-destruction, if their exuberance were not by some means or other restrained.

To restrain this exuberance is the peculiar province of the beaver, in like manner as it appears to be one of the natural uses of the hare to restrain the over-abundance of forest trees on dry grounds, by barking the seedlings in the winter, so that they perish. Accordingly, while those trees and bushes which the beaver has more immediately in charge are in a state of growth, the beaver ranges about among them, eating the young shoots, the young seedlings, and also the berries, in their season. But when the trees become leafless the animal instinctively lops the twigs, even those of considerable size; then cuts them in lengths, so that it can remove them; and carries them to the water, where they remain in little floats, secured in proper places against being swept away by the floods, and removed thence to the winter dwelling of the animal, as occasion requires. Sometimes, also, it stores up twigs in the winter habitation; and it does so the more decidedly the deeper that the water on the margin of which that habitation is situated is liable to be frozen.

In summer, beavers, as is the case with many animals which are social in winter, disperse themselves through the groves and brakes on the banks, and lead solitary lives, reposing for the night or the day, as it happens (for they are equally fitted for work during the one as the other), in the shelter of whatever bush or hole close by the water may be most convenient to them. During the time which they so inhabit they are not very much molested by the hunters, at least by those hunters who kill them solely or chiefly for the sake of their skins; because then, as is the case with all animals of countries having hot summers and severe winters, their fur is neither so abundant nor so valuable as during the cold season. In the early part of the summer the old fur is dead and loose, and the new is only partially grown; whereas against the time that the coldest winter weather comes round, all the fur which is on the animal is alive, and in the greatest abundance and ripeness. There are other reasons in favour of the winter capture: in summer there is an effort for each solitary individual, whereas in winter those which associate may be taken *en masse* by means of nets and other devices. In summer, too, the flesh of these animals is not quite so good as in winter, or at least as at the commencement of the latter season: and hence the winter is the grand time for the capture of them for food as well as for clothing, or for materials of which articles of clothing may be manufactured.

During the summer season the habits of all beavers are as nearly the same as the nature of the places in which they reside will admit; and the chief differences are more or less labour in the finding of their food, in proportion as that food is less or more scattered over the surface. With equal temperature, those places which are the most humid, and on which the water remains the longest, without stagnating, so as to prevent the growth of shrubs and trees, are the best adapted for the support of beavers during the summer. The decline of the surface of much of Europe and Asia, in this respect, is one of the causes of the diminished and diminishing number of beavers there; and the same may be said of those parts of America in which they are few and scattered, and have the same habits as in Europe.

The winter habit varies more than the summer one. It is not ascertained, and indeed not very probable, that beavers hybernate under any circumstances of climate or season; but as they are much more active during summer than during winter, it is probable that they eat much less during the latter period. Indeed it has been found that beavers which have been kept in a state of solitary confinement from early youth, and have not required to exert themselves either in the finding of food, or in the constructing of winter habitations, have spent a very considerable portion of time in a dormant, or, at all events, in an indolent state. Others, taken later in life, have shown more activity, and have displayed more of a peculiar instinct in their nature, as will appear from a notice of one which we shall quote in the sequel.

But whatever may be their habits in a state of confinement—and their habits there, or at all events their propensities, are not solitary, inasmuch as they evince an attachment to those who are kind to them—they all, in a state of nature, make some preparations for the approach of winter, and the nature of those preparations seems in a great measure to depend on the numbers which are in the vicinity of each other during the summer. If scattered far apart they must be as solitary during one season as another; but when they are near each other they can associate. In the former circumstances they burrow for their winter habitations; and in the latter they partly excavate the ground, and partly build. Their fore-paws are well constructed for the first of these operations, and they are by no means unserviceable in the latter.

The burrow of the beaver, even when formed for a single pair or a solitary animal, has usually two openings—one under the surface of the water, by which the animal can escape into that fluid for protection, or fetch provisions from it, as occasion may require; and a smaller one towards the land, through which atmospheric air may come for the supply of the animal in breathing. Other than these two apertures, and some other animals have more than two, there is no indication of superior ingenuity about the burrow of the beaver. It is, indeed, much inferior to that of the common mole, and those of many other animals.

Though the beaver thus constructs its burrow on the bank, with an opening under water, water is not absolutely necessary to its existence, or even to its health. It is altogether a land animal in its breathing and circulation; and while it is active these go on with moderate rapidity, though not so quick as in many of the mammalia. Such being the nature of its vital system, it is unable to remain under water for any great length of time. Both the nostrils and the ears are so constructed as to close and exclude the water when the head of the animal is immersed; but as the beaver only occasionally works with the head under water, and does not require to feed with it in that state, it cannot remain nearly so long without coming up to breathe as the seal, which is a fisher, and as such dependent on the water for its food. The eyes of the beaver, of course, require no protection from the water when it has occasion to use them under the surface, because the eye of no animal is injured by simple contact with water. Persons who accustom themselves so far to it as to be able to get the better of the shock, which takes place upon immersion, can see quite well in the water when they dive.

From what appears to be the principal use of water to the beavers, we can form some estimate of the contrivances to which they resort for keeping it at the same level in places where they live in societies. The nature of the places is such that the animals cannot range for their food in winter as they do in summer. The trees are leafless, the ground is covered with snow, and those twigs which they can reach with ease in summer are buried under it. They must therefore collect a store: that store must be proportional to the numbers; and if these are considerable, it must be fetched from some distance, and the greater, the longer they have resided in the same neighbourhood. The reason of this last fact will become apparent when it is considered that the winter food of the beaver must be the bark of twigs of more than one year's growth. They are not climbers, and then they cannot reach any higher than when they stand on the hind legs supported by the tail, in the tripod fashion which has been mentioned. A number of them would soon clear the bushes and trees to their height over a considerable space, though each season might throw out shoots, sufficient for their food in summer when they live dispersedly. Besides, those deciduous trees, or bushes with branches within the beaver's reach, do not grow over the breadth of the forest in any latitude, and especially not in those latitudes which beavers inhabit. On the dry "barrens," and also on the swamps, there are pines and other evergreen coniferæ; and where these are tall and close, as they always are in comparatively rich places of the kinds which suit them, there are no deciduous shrubs under them. Mosses, lichens, and fungi, are then the under growth, and they are not beaver's food, neither are they accessible after the snow has fallen. The stores for the food, and especially for the winter food of the beavers, is thus found in lines along the margins of the waters; and they must range these for a considerable length before they can find food for a colony.

Beavers are but lame walkers for long distances, and they are of course still more incapable of carrying burdens very far. One of the stories, indeed, is that they use the tail as a sledge; but that, if one of them can be more absurd than another, is the most absurd of the whole. None of the land mammalia can bear much strain on the tail, and the tail of the beaver appears to be quite burden enough to the parts which support it when the animal walks on land. Of course the possibility of its carrying a load upon that organ is entirely out of the question.

Its ordinary means of carrying, when the object is not too large for being so carried, is by the mouth. The billet which can be carried in this way for any distance must be short and light, otherwise it would constantly be getting entangled in the bushes, and the animal could not fetch it along. Even when the billet is larger, the mouth must still be the holding instrument, and one of the points of support in the carrying; because the animal could not walk at all if it held with its paws. The shoulder is the part brought in to assist in these cases; but as the billet is inflexible, and cannot be carried as a fox carries a goose, it lies obliquely on the shoulder, and of course is a cumbrous load, and incapable of being carried very far.

To obviate the difficulties of this process, the beaver has recourse to water carriage, in the same way that man has recourse to water carriage when he goes "lumbering," that is, procuring timber in the wild forest. This is not the case with man in the north of America only, but in all parts of the world; and thus far *reason*, which proceeds on the principle of cause and effect, and *instinct*, which proceeds from a cause which we are unable to comprehend, but which certainly has nothing to do with experience, without which there can be no reason or forethought plan, produces the same end by very nearly, if not exactly, the same means.

And when we come to the mechanical operation, we can see that this must be the case. Neither instinct nor reason can alter the properties of that matter on which it acts, whether it be the substance of which its own members are made, or any foreign substance. If the billet or the log is heavier than the strength can move at all, or over the requisite distance, and the purpose either of instinct or of reason is to remove it entire, neither beaver nor man can bring the strength up to the weight, or the weight down to the strength, as both of these fall within the province only of that power, which made the animal structure and the piece of timber. But in the water, the weight of ordinary timber—of all which grows where beavers inhabit, is wholly destroyed as a pressure on the animal, and there is only the resistance of the water's friction to be overcome.

It is this use of the water which sends the beaver into that element, just as it is the production of his food there which sends him to inhabit the banks; or to speak more correctly, the bank; the beaver and all the circumstances of nature in the locality harmonise with each other. Destroy the harmony, and the animal being the most sensitive of the whole, is the first to disappear,—though when the combination is broken up, all the others depart, in the ratio of their changeableness; and the place assumes, to all appearance, a new character. Thus, in those places of Berkshire where the skeletons of beavers are found in the marl under the peat, the probability is that there once had been standing pools with thickets of deciduous trees on their margins, and banks in which the beavers could dig their burrows or construct their huts, according as they were less or more numerous. To this stage had followed another of green mosses, first in the stagnant pool, become shallow by deposits, but increasing at the top and dying at the roots, as mosses are known to do under such circumstances, until what was once a hollow changed to a level surface or even to a height, and till that height consumed the surrounding thickets and groves, and then, exposed to the frost in winter and the drought in summer, become black and sterile, save here and there a few stunted heaths, and other small plants of the desert. There may have been and in many places there are evidences of changes subsequent to these, in which the powers of life have been brought again into action, in a manner altogether different. Deposits of gravel intermixed with fine particles and finished off with vegetable mould, now lie over many such anterior formations as those alluded to, and by the aid of culture are among the most fertile spots in the island. Thus we see that the beaver, as belonging to what we may consider an early stage in the progressive natural history of countries, has a long and a highly interesting story to tell; and one which, duly studied and applied, might be of vast service to us in that artificial cultivation and fertility, upon which we so primarily depend for our food, our clothing, and very many of the other comforts of life.

Beavers have wholly disappeared from those parts of North America which are settled and cultivated; and upon the frontier, where wild nature and man's cultivation may be said to divide the management between them, they are few, straggling, and solitary, and invariably spend the winter in burrows. The burrow of a solitary beaver is seldom, if ever, accompanied by a dam for the regulation of the waters; and where there are villages or colonies, the dam is used only in those situations where, during the sojourn of the animals in their winter's abode, the water is liable to great differences of level. This depends both upon the nature of the water, and the character of the seasons. It is less in pools and lakes than in rivers; and less where the winter is open, and the spring gradual, than where the snow lies long and the thaw is rapid and violent. The latter circumstances prevail in a much higher degree in those parts of America which are still well stocked with beavers, than in any part of Europe, or perhaps of Asia. The autumnal rains are not so heavy there, and do not swell the water so much as they do in milder and more variable climates. The humidity falls much in snow; and the floods occur when that snow melts upon the return of warm weather. Thus, unless to secure a depth which shall not be frozen to the bottom, or one which otherwise shall conduce to floatage and swimming in the winter, beavers have no great occasion for dams, on the larger and more slowly-flowing rivers in that part of the world. The smaller creeks, however, are in some situations apt to be very low, and indeed almost dry in the autumn, the time when the beavers require water the most, because that is the time at which they float along their provisions and other materials.

These latter situations give occasion for many beavers' dams; and though the accounts of the manner of constructing these and their neatness when constructed, have been as much exaggerated as any part in the economy of the animals, yet they are curious structures. The instinct according to which they are made, both as regards the original necessity for them, and their form, is of course as inscrutable by human philosophy as any other instinct. But still the structures themselves are formed upon what we may call sound mechanical principles. The beavers do not, as authors say, fell a large tree so that it may fall across the river and form a head beam for the dam; and as little do they drive perpendicular stakes, or stakes slightly inclined, so as to bear against the beam. They do not fell great trees at all, neither do they set any timbers on end, or arrange them in what we would consider a symmetrical manner. They do indeed make use of billets of wood much thicker than they can cut at one bite—the maximum of which is only about that of an ordinary walking stick. When they cut these larger pieces, they cut them round the circumference, as wood-men do in the operation which in America is termed "girdling," and after once round, they cut round again and again, until a division is effected.

The construction, and also the necessary repair of their dams, usually takes place during the night; so that the precise manner of their working is guessed at rather than known; but the billets of wood are laid across each other, and kept down by means of stones; and the interstices are filled with mud and clay, until the whole dam is rendered water-tight. In the performing of all these labours, they have no instruments that will come into use except the fore-paws and the teeth; but these, from the description which has been given, are well adapted for the purposes.

The timber which they use in the construction of both their houses and dams, is very generally drift wood, of which large quantities are always to be met with in the rivers of these wild countries. This of course requires no felling; and when they find it in the water they can contrive to tow along a large piece; but if it is on the dry bank at some distance, they must cut in lengths, and bear it on their shoulders in the manner which has been already stated. When they have to fell their own timber, they usually have recourse to soft wood, as willow, poplar, and birch; and they rarely cut any piece even of the drift wood, of more than two or three inches in diameter. Small sizes are indeed preferred; and here again their instinct is true to mechanical principle, because the working is lighter and the work itself is more compact. The dam is formed with a broad base and a slope both ways, till it is considerably narrower at top; but however much the level of the bottom may vary, that of the top is made the same all the way; and while, by means of their dam, the colony of beavers will sometimes obtain a depth of several feet of water, the current over the top of the dam will be so spread in breadth, that a man may cross without very much wetting his feet.

It is said that the position of the dam is tempered to the velocity of the current; and this is certainly no more wonderful than the fact of a dam being made. If the current is slow, the dam is said to be carried straight across; but if it is rapid, the dam is an oblique line, or a curve with its convexity upward to the stream. This again is true to the mechanical principle, and true to the adaptation of means to purpose, and of effort to effect, which we so constantly find in nature. The dam straight across is the shortest possible, and therefore costs the least labour; but it is the one upon which an equal volume and velocity of water would act the most powerfully: therefore it is used in those cases where the force of the current is least. The oblique or curved dam is more laborious in the construction, because it must be longer for the same breadth of river; but as the action of the water upon it diminishes in proportion to the obliquity with which the current meets it, it resists better than the straight dam, and its resistance increases with its obliquity: therefore it is used against the more rapid and powerful currents.

But notwithstanding this perfect accordance of instinct with those principles, on account of a far less perfect degree of which, human engineers are apt to be somewhat vain of their science, the beaver is not nature's master. There are combinations of circumstances, in which the beaver and his dam form no part; and when these occur, the flood comes rolling on in its power, and not only breaks down the dam, but sweeps away the habitation of the beaver, and all the store of his winter wealth. So true is it that when, in the single instance, reason or instinct appears to our understanding of the matter to have done its best, something unknown to us (though not unknown to nature) comes round and hurls to destruction all that reason plans in the one case, or that instinct executes without plan in the other; and when we imagine that we have established our position upon the surest basis, our philosophy is driven to the humbling observation of the poet,

> " The best-laid schemes o' mice an' men,
> Gang aft aglee ; "

while we can say no more about the matter than simply that such is the fact.

The huts of the beavers are constructed of the same materials as these dams. These houses are immediately on the bank, if that is moderately high, and the water proportionally deep, which are circumstances which usually go together; but if the bank is low and the water shallow, they chance a situation a little farther off. This appears to be in order that the floor of the hut, which is always excavated a little below the surrounding surface, may be above the height of the ordinary floods. The securing of a uniform temperature, not too low, appears to be the cause of the partial excavation of the hut; and the same practice is followed by the people of the north, when they form their winter habitations of earthy matters, and not of snow. The houses of Iceland, the Feroe islands, and the original ones of Shetland, the Hebrides, and even many parts of the Highlands of Scotland, are formed by partial excavation; and though they do not accord with southern notions of a comfortable dwelling, they are much more uniformly warm in winter and cool in summer, than houses raised entirely on the surface, or with their floors elevated above it. These houses are generally entered by a long and low porch, which is the case with the houses of the beavers, though the entrances of them are at some distance below the surface of the water.

When a family or society of beavers begin to construct a house (for houses are not made by solitary ones), they at first dig a foundation proportional to the number which it is to accommodate; and the walls are formed of the earth and stones which are dug out of the foundation, mixed with billets of wood, crossing each other, and thus binding or tying the other materials, so as to prevent them from being separated by the weather. The walls are made of considerable thickness, and so compactly put together, and all the interstices so filled with mud, that they are both water and air tight. When the walls have been raised to the proper height, they are closed in by a sort of dome roof, so that the structure is externally something in the shape of a hay-cock. The centre of the floor is a little raised, so that the place where the animals repose may be dry, notwithstanding any moisture which may trickle down the walls. Of this, however, there can be but little, owing to the compactness of the fabric. The principal entrance or entrances (for there are sometimes two, or even more) are below the surface of the water, to which they extend sloping from the edifice itself, and generally have the opening about three feet below the surface, which, in average situations, secures the animals an access to the water, notwithstanding the frost. A water entrance of this description is called "the angle," by the beaver hunters; but besides these, there is usually, and probably in all cases, a smaller opening toward the land. Without this last there would be danger of suffocation. There does not, however, appear to be any current of air, so that, even in very severe weather, the habitation of the beaver must be snug and warm.

Authors have stated that these houses have sometimes more than one story, and that they are divided laterally by partitions; but there does not appear to be any truth in the statement. Their houses are, upon the whole, very rude structures, far inferior to the nests of some birds, which have no working tools, save the mandibles of their little bills.

The winter stores of provisions, which consist of branches of trees, from which the animals gnaw the bark for their subsistence, are placed in the water close by the "angle," or entrance porch. Where there is a current they are placed above the entrance, and fastened with stones ; but where the water is comparatively still, either by being a lake, or from the existence of a dam, they are placed indiscriminately. When the party inhabiting the same house is numerous, the store of provisions is considerable, consisting of a cart load of twigs and branches. The store is said to be a joint collection by all the inmates of the house, but by them only, though the colony should, as it sometimes does, consist of a village of a dozen houses or more. The house is also the work of those only by whom it is to be inhabited ; but the dam is a work of joint labour. The celerity with which they build the latter, and especially with which they repair any injury which it may sustain, is wonderful, as compared with the slow progress of works of proportional magnitude among men ; but it is not more wonderful than that by which ants repair any injury which is done to their hills. There is one circumstance in the construction of these dams which our mechanical knowlege very imperfectly reaches or explains ; and that is, how, considering the light materials of which they are composed, and the total absence of piles, or any other means of protection, they get them to stand till they are closed. It is true that they are never erected in very rapid currents, and that the time of their erection is one in which there is but little risk from floods and inequalities of the rivers ; but still, if even a clever engineer were called upon to build of similar materials such a dam as the beaver builds, and to build it in the same manner, he would find many difficulties in the execution. It does not appear, either, that the current or fall of water over the beaver dams acts behind the foundation, which is very apt to be the case with dams and weirs of human construction, unless they have a "*tail*" of solid pavement carried out to a considerable distance, with its longitudinal section something in the parabolic form ; and even then the duration of the work appears to depend as much, at least, upon the strength of the materials as upon the mechanical skill which regulates the form of the work.

Thus, viewed in all their bearings, the mechanical labours of the beavers are, assuredly, not less wonderful or worthy of study, when we take them simply as animal labourers, than when we strain the imaginary comparison between them and the *contrived* works of man, to the very utmost pitch to which romancing and extravagant fancy has ventured to go ; and there is this advantage in the plain and rational study of them, that they contain something yet to be known, which cannot fail in being useful to us when we do know it, whereas we can learn nothing from the romance which judges of them from human art as the standard. The structures formed by these animals vary with the situations in which they are placed ; but the highly graphic representation by Landseer, on the plate "Beavers," will give a very good general notion of both the scenery and the habitation.

Even in those situations where beavers do not require to range far from their winter habitations during the summer, they do not then make use of them as places of rest. They generally form small detached burrows in the banks, and these, like their winter houses, often have their entrances under water. It seems, indeed, that beavers, as might indeed be supposed by their aquatic powers of locomotion being superior to their land ones, prefer journeying by water in all cases where the journey is of considerable length. They are thus bank animals even at that season when they depend upon the growing produce of the land. In this respect they bear some resemblance to those cetaceous animals (to the lamantines, for instance) which inhabit the large rivers in the tropical parts of the world which reside chiefly in the water during the day, and come on shore to browse the vegetation on the banks, during the night or in the twilight. Like these, the beavers are nocturnal feeders, and are seldom on land during the heat of the day, though they spend more of their time in their resting places than in the water, whereas the herbivorous cetacea take their rest in the shallows of the rivers. Beavers are, indeed, fond of sporting in the water, although it is only a pathway and a means of floatage to them, and not a pasture from which they immediately derive their food. But this is what we might suppose ; for living as the beaver lives, and feeding as it feeds, the water is necessary to its existence ; and it is a general, and, at the same time, a very benevolent and beautiful law of nature, that whatever is in ordinary circumstances necessary to the well-being of an animal, affords it pleasure in proportion to the necessity. This pleasure does not consist in the mere *utility;* as, for instance, the pleasure of the water to the beaver does not arise from the food which that element enables it to reach, or from the building materials which that element enables it to transport. The pleasure is in the mere fact of swimming in the water ; and if it were a case in which we could at all admit the relation of cause and effect, we would be much more correct in saying that the pleasure is the cause getting the food and the materials, and not the desire of possessing these the cause of the pleasure.

And we ourselves may here learn of the beaver : "Go to the beasts, and they shall teach," says an author of high authority ; and one equally high puts this question : "Is not the *life* more than meat, and the *body* than raiment?" This last instruction is put in the form of a question, in order more forcibly to draw our attention to it ; for He by whom it is put knew every instinct of nature and every thought of man, and thus stood in need of no confirmation. When "the life," in man, is in this manner put in opposition to, or as distinct from, "the body" it always means the intellectual part—that which can learn, and know, and think ; and in the passage above quoted, the contrast of "the body" with "raiment," is that of the exercise of our faculties with all those things which, under the name of wealth, the exercise of our faculties procures or accumulates. The first part of the lesson, that which relates to the intellectual power, is to man only : the second is to every creature, though man is the only one to whom it needs to be repeated. Those creatures depart not from their instincts. The pleasure of the beaver, for instance, is on the bank or in the stream, and he attempts not to wander over the thirsty plain, or to climb the rugged mountain. A being of matter, and of such life only as can exist in matter, all his faculties, and all their operations, are as determinate under the circumstances which admits of their existence, as the falling of a rock is when the lightning shatters it from the perpendicular cliff. Accordingly, neither the beaver nor any other animal ever sacrifices its true enjoyment for the purposes of folly or of avarice. The instinct of the beaver leads him to accumulate a bundle of sticks for his winter provision; but the beaver never thinks of accumulating in one year a stock which shall last him for twenty; neither does he seek to become a great beaver among beavers, "in proportion to the magnitude of his heap," and look with scorn upon the rest of the village, because he has a few sticks more than they. Still, when the season requires it, the beaver slackens not the hand of his industry; and unless when a casualty of nature, which his instinct does not reach—such as an excessive frost, an overwhelming flood, a parching drought in the summer, or one of those fearful conflagrations which sometimes lay the natural forests in ashes, and cause the pools to boil like cauldrons, overtakes him, there is plenty, as well as peace and happiness, in his dwelling. Turn from the hut of the beaver to the dwelling of man, and be it cottage or be it palace, say if the parallel holds. The record forbids the affirmative, for, taking it from day to day, or from age to age, a full third of it is the recital of crime, and more than another third the recital of misery.

And wherefore is it so? Clearly for this reason, that in man, and in man only of all creatures, there is a departure from the law, a violation of some of those statutes or principles, the full operation of all of which would make the life of man, as it makes the life of every other creature, one continued scene of enjoyment. This deviation can take place only in the intellectual part of man's nature; for, make a beast of him, and, either there is no consistency or meaning in nature, and no use in studying any thing about the material creation, or he would be as faithful to his instincts as other beasts. Thus man's deviation from the law of nature, as proved by his crimes and their necessary punishments,—(for, though men often remain ignorant of the crime or spare the guilty, nay, though they often raise error and absurdity to the seat of wisdom, and fall down and worship them there, nature never does),— is at once an irrefragable proof of the intellectual part of his nature, and a ground of very bitter self-humiliation—unless the bitterness is made to become sweet, by finding out what should be the course, and steadily following it.

Now, as the things of this world are for this world only, it is clear that the accumulation of them should be a secondary operation with man—inferior to the exercise of the intellectual or higher part of his nature, and therefore it should always be made to give way to that. Not only so, but in the conducting of it, man should follow the general law of the animals; because each of them is for this world as much as he is, materially speaking, and some of them are for it during a longer period. Consequently, even in the acquiring of that which is necessary, the powers exercised in the acquisition, or, in other words, the exercise of those powers, should be man's chief pleasure, and he ought never to allow them to diminish, or in any wise interfere with the natural charities of his kind. The beaver collects his bundle of sticks; but in doing so these animals never abandon their young, neither do they, by gloomy (and blasphemous) anticipations that God shall in time become unable to provide for all beavers that may be born, take moral or immoral means of either preventing an increase or diminishing the present number. Beavers do indeed establish new colonies; but there are no commissioners or land agents among them; they work exactly to the circumstances of the place and the time, and therefore they work all-enjoyingly; and their population can at no time be said to be redundant or defective. We, on the other hand, taking a fraction, and generally a very small fraction, of the case, legislate not only for the laws of nature but for the succession of time, and we need not wonder that the statutes which we thus frame are as senseless as the framers. Such is the beginning of the lesson which the beaver teaches; but we shall not pursue it farther, as the introduction into works on natural history, of such deductions, though really the most useful part of the subject, is not yet sanctioned by the custom of authors.

In an economical point of view, the beaver is a very valuable animal. The fur is more glossy and beautiful than almost any other of the same fineness; it takes a rich black colour, without having its gloss in the least destroyed; it wears well, and is not much subject to injury from rain; and it very readily unites into a strong, though light and flexible fabric, by the operation called *felting*. Hats are put together by that operation, unless very inferior ones, in which glue is applied in supplement, which of course spots the hat, and refreshes with its unctuous droppings the head of the wearer during rain; and the fur of the beaver has those qualities which render it a much better material for hats than any other which is known. Accordingly it was very early used for this purpose; and so exclusively used, when hats were fewer and beavers more numerous, that both the English and the Latin name of the animal became synonimous for the article of dress. At one period it was deemed necessary to enact statutes for preventing the admixture of any other material with the fur of beavers in the manufacture of hats; and at that time the hat outlasted the wearer, and could be washed in the same manner as a piece of woollen cloth; but in more modern times, owing partly to the great decrease in the number of beavers, and partly to the increased demand for hats, the article is so expensive that no hat is made entirely of beaver. The body is formed of wool, and that is plated over with beaver, which is worked fully through the body, or "felt," in good hats, but only very partially in inferior ones. A shower takes the beaver off the latter; and it is not very long in wearing bare, and showing the felt in the former.

The skin of the beaver is also used in the manufacture of gloves, and sometimes in that of shoes, though in the latter case the shoe, like the bad hat, requires a little glue to make it saleable. Even the gloves are of very inferior quality, as the skin is thick and very rough and loose in the texture; so that if it were not for the fur, the beavers would not be deprived of their lives for the sake of their skins.

There is another part of the beaver which is used in medicine, though not so largely at present as formerly. It is a peculiarly unctuous product, secreted by a follicle immediately under the tail of the animal. It has a very disagreeable smell and nauseous taste, but it was once in high request as an antispasmodic, and also as producing an important and specific action on the uterine system. It is still retained in the Pharmacopœia under the name of *castoreum*, or castor. It is not our province to examine its virtues as a drug; but we may observe that it was introduced into medicine at a time when nostrums were held as being beneficial, very much in proportion as they were nasty; and to what extent this may be the case still, is also without our province.

In consequence of these uses in the arts, the beaver has been hunted with great assiduity; and some idea of the total quantity killed in all parts which beavers inhabit may be obtained from the fact that, in the year 1808, there were 126,927 brought to this country from Canada alone.

Many stratagems are resorted to for the capture of an animal so much in request, but we shall notice these very briefly.

The skin of the cub-beaver is more highly prized than that of older animals, as being darker and more glossy; the winter season is preferred for capturing them, on account of the superiority of their coat at that time. There are various means employed in taking them. One of the ways in which they are captured is, by boring a number of holes in the ice, when they are driven from their habitations, which are then destroyed. They remain under water a short time (as they are incapable of remaining in that element for any very protracted period), then by rising to the surface where the ice is broken, they are easily taken. At these times many of them retreat to the holes in the banks, where they lodge in summer; but these vaults are soon discovered by experienced hunters, by striking on the ice with chisels, and they select such spots for their openings as they know will readily lead to the capture of their victims, and they are seldom mistaken. Another way in which they are taken is, to cut the ice both above and below their dwellings, nets are then thrown across, and the animals are driven from their abodes and compelled to enter the nets. It is usual, in summer, to take them in their houses, by what is called staking them. To effect this purpose the hunters first make an opening in the roof, in order to discover the exact position of the angle, and having adapted a number of stakes to the opening, so as to completely blockade it, they cover in the top and leave the stakes on one side ready for use. This done, they drive the beavers, by means of dogs, from all parts of the pond or river; and when the affrighted and hunted animals have succeeded in reaching their homes, they again put up their stakes before the door-way, take off the temporary covering from the roof, and either take them in a living state or spear them in their habitations. When they inhabit a sheet of water, which is merely kept up by a dam, they are still more readily taken, by letting off the water, and leaving their huts quite dry. The gun is also sometimes, though not very generally, used; and log-traps, baited with poplar sticks, are now and then made use of, to commit havoc among them.

The following account of a tame beaver was furnished by its owner, Mr. Broderip, to Mr. Bennet of the Zoological Society, when that gentleman drew up his account of "The Gardens and Menagerie;" and we have quoted it because Mr. Bennet's work is not so much known to the public as its merits deserve:—

"The animal arrived in this country in the winter of 1825, very young, being very small and woolly, and without the covering of long hair which marks the adult beaver. It was the sole survivor of five or six, which were shipped at the same time, and it was in a very pitiable condition. Good treatment quickly restored it to health, and kindness soon made it familiar. When called by its name, "Binny," it generally answered with a little cry, and came to its owner. The hearth-rug was its favourite haunt, and thereon it would lie stretched out sometimes on its back, sometimes on its side, and sometimes flat on its belly, but always near its master. The building instinct showed itself immediately it was let out of its cage, and materials were placed in its way; and this before it had been a week in its new quarters. Its strength, even before it was half-grown, was great. It would drag along a large sweeping-brush, or a warming-pan, grasping the handle with its teeth, so that the load came over its shoulder, and advancing in an oblique direction till it arrived at the point where it wished to place it. The long and large materials were always taken first, and two of the longest were generally laid cross-wise, with one of the ends of each touching the wall, and the other ends projecting out into the room. The area formed by the crossed brushes and the wall he would fill up with hand brushes, rush baskets, books, boots, sticks, cloths, dried turf, or any thing portable. As the work grew high, he supported himself on his tail, which propped him up admirably, and he would often after laying on one of his building materials, sit up over against it, appearing to consider his work, or, as the country people say, 'judge it.' This was sometimes followed by changing the position of the material 'judged,' and sometimes it was left in its place. After he had piled up his materials in one part of the room (for he generally chose the same place), he proceeded to wall up the space between the feet of a chest of drawers which stood at a little distance from it, high enough on its legs to make the bottom a roof for him; using for this purpose dried turf and sticks, which he laid very even, and filling up the interstices with bits of coal, hay, cloth, or any thing he could pick up. This last place he seemed to appropriate for his dwelling: the former work seemed to be intended for a dam. When he had walled up the space between the feet of the chest of drawers, he proceeded to carry in sticks, cloths, hay, cotton, and to make a nest; and when he had done he would sit up under the drawers and comb himself with the nails of his hind feet. In this operation, that which appeared at first to be a mal-formation was shown to be a beautiful adaptation to the necessities of the animal. The huge webbed hind feet of the beaver turn in so as to give the appearance of deformity, but if the toes were straight, instead of being incurved, the animal could not use them for the purpose of keeping its fur in order, and cleansing it from dirt and moisture.

"Binny generally carried small and light articles between his right fore-leg and his chin, walking on the other three legs; and large masses, which he could not grasp readily with his teeth, he pushed forwards, leaning against them with his right fore-paw and his chin. He never carried any thing on his tail, which he liked to dip in water, but he was not fond of plunging in the whole of his body. If his tail was kept moist, he never cared to drink; but if it was kept dry, it became hot, and the animal appeared distressed, and would drink a great deal. It is not impossible that the tail may have the power of absorbing water, like the skin of frogs, though it must be owned that the scaly integuments which invests that member has not much of the character which generally belongs to absorbing surfaces.

"Bread, and bread-and-milk and sugar, formed the principal part of Binny's food, but he was very fond of succulent fruits and roots. He was a most entertaining creature, and some highly comic scenes occurred between the worthy, but slow beaver, and a light and airy macauco that was kept in the same apartment.

"An animal so sociable in his habits ought to be affectionate, and very affectionate the beaver is said to be. Drage mentions two young ones which were taken alive and brought to a neighbouring factory in Hudson's Bay, where they throve very fast, until one of them was killed accidentally. The survivor instantly felt the loss, began to moan, and abstained from food till it died. Mr. Bullock mentioned to the narrator a similar instance, which fell under his notice in North America. A male and female were kept together in a room, where they lived happily till the male was deprived of his partner by death. For a day or two he appeared to be hardly aware of his loss, and brought food and laid it before her; at last, finding that she did not stir, he covered her body with twigs and leaves, and was in a pining state when Mr. Bullock lost sight of him."

Notwithstanding the length of time that the beavers have been known to commerce, the numbers of them that have been captured, and the long accounts which have been drawn up of the parallel between their dam and hut building, as compared with the same operations in man, there are some parts of their real and proper history which still remain in a great measure undetermined.

Among these are, the length of gestation in the females, and the season at which the young are brought forth. The general habit of the order is short gestation; and from the size of cub beavers when brought to this country, and the season at which they have been brought, it is natural to suppose that the young are brought forth in the very warmest season of the year. There is another reason why that should be the case. Animals in a state of nature, generally produce their offspring, or have them in a very young state, at that season when their proper food is in the greatest abundance. The apparent exceptions to this, are in reality no exceptions at all. The bears, which, at first consideration, appear to be the most striking exception, as the females not only bring forth their young in the winter retreats, but suckle them for some time there, not only have an accumulation of fat sufficient for the support of both dam and cubs, till they are able to follow her in ranging, but they come abroad when the "harvest" of the winter's desolation, the ruin occasioned by the storms of winter, is the most abundant and most easily found.

Winter directly produces no superabundance of food for the rodentia; nor is it till the season of growth has made some advances, that there is moisture in the bark. When, in the latter part of the year, the *cambium* ripens, the bark is dry, until the leaves are so far developed that their action commences. This may be one reason why beavers cut their winter provision before the bark has attained its most sapless state, and it is also a reason why the whole period of gestation in the rodentia is thrown into the spring season, and their bringing forth into the latter part of the spring or the autumn.

In the absence of certain information, we cannot, of course, speak positively, but the probability is, that beavers, to a considerable extent, follow the law of shore birds, which congregate in winter, and disperse against the pairing time. The period of their gestation is, of course, longer than that of the incubation of birds; and that carries the time of their bringing forth, nearly to that season at which the young twigs are in the fulness of their growth, so that when the cubs begin to seek their own food, they find it in the greatest abundance and perfection.

This is rendered probable, nay certain, by the immature state of the cub beavers during the prime of the hunting season, which is the latter part of the winter; and it is confirmed by the stage of growth at which they have been imported to this country, as established by the case of the individual of which we have quoted the account.

Though beavers, and indeed most of the class of animals to which they belong, are easily tamed, they are, when brought alive to this country, sometimes subjected to the wantonly cruel operation of blinding. This is said to be done with a view of keeping them from the water, into which, if they once escape, they do not readily return to the state in which they previously are.

Those which are at the Zoological Gardens have been nearly blinded, though one of them still possesses the sight of one eye, at least partially. They are provided with water and a house, and also with food, so that they can only indicate their natural propensities; and the loss of the eyes makes those indications very imperfect. Still they show the building propensity; and at the season when beavers, in a state of nature, construct or repair their habitations, these not only carry sticks which are thrown into the water for that purpose, but carefully inspect their artificial house, fetching clay and mud from the bottom of the pond, and plastering every crevice so carefully over as to render their habitation not only weather-proof, but air-proof at all places except the entrances.

It is to be regretted that these, the most accessible to the public of any specimens of this interesting species to be met with in the country, have been blinded, because that must necessarily prevent the display of some of their habits, though fewer of them, perhaps, than in most animals, as beavers perform their most curious labours during the night. It were to be wished that some of the proprietors of land who have large parks intersected by such streams, or containing such sheets of water, as beavers frequent in a state of nature, would establish beaver preserves. The creatures would be highly curious and ornamental; their flesh, if fed upon succulent plants, would probably be found more nutritious than that of hares, and their fur is certainly far more valuable. Now it should seem that, even as a matter of economy, it would be much wiser to give up a few acres of osier-holt along the margin of the waters to a colony of beavers than to keep preserves of hares and pheasants, which animals plunder the crops for miles round.

BEDEGUAR. An excrescence frequently found growing upon various species of roses; especially of the wild kinds, of a fine green or pink colour, and covered with branched hairs. This excrescence is a species of gall, caused by the deposition of the eggs of a small fly, belonging to the genus *Cynips* of Linnæus, in the substance of the twig, and when opened is found to contain the grubs or pupæ, in considerable numbers, of the fly. It is perhaps one of the most singular circumstances in the economy of the insect world, that a fly, scarcely more than one-twelfth of an inch in length, is able to inflict a wound, from which an excrescence often a couple of inches in diameter is produced. The subject, however, will more appropriately come under our notice in the article CYNIPS or GALL FLIES.

BEE. The English name for all those species of hymenopterous insects which compose the very extensive Linnæan genus *Apis*, or the section *Anthophila* or *Mellifera* of modern classifications; and which, as already stated under the article *Apis*, consists of two distinct families. In the present article we purpose confining ourselves to the domestic bee, the *Apis mellifica* of Linnæus, and which, with some exotic species possessing similar habits, constitutes the restricted modern genus *Apis*.

It may be convenient, in the outset, to state that the hive-bee is distinguished from all the other species of bees, by having the shanks of the hind legs furnished with a smooth and concave pollen plate on the outer surface, and destitute of spines at the extremity; by the basal joint of the tarsi, in the workers, being of an oblong form, with its inner surface clothed with fine hairs disposed in transverse layers; by the oblong shape of the body; by the maxillary palpi, or the feelers of the sheaths of the tongue, being almost obsolete and formed of a single joint, and by the oral apparatus being of an elongated form.

The hive-bee may be regarded as one of the most perfectly social species of insects, and one, whose economy is regulated by the possession of a more perfect degree of instinct than is perhaps possessed by any other invertebrated animal. Another peculiarity, necessarily dependent upon the social habits of these insects, is the existence of individuals which have been regarded by many as a third sex, but which modern investigations have ascertained to be female insects, whose internal and sexual organisation is in an undeveloped state. These individuals, neu-

Neuter Bee.

ters or mules, or workers, or female non-breeders, as they have been termed, constitute the great mass of the population of a society: they are the smallest members in the community, a circumstance probably dependent upon their imperfect organisation (if we may be allowed to use the term to an animal possessing such perfection of habits); and it is to them that the internal economy of the hive is committed, and upon them the whole labour of the community devolves.

> How skilfully she builds her cell,
> How neat she spreads her wax,
> She labours hard to store it well
> With the sweet food she makes—
> She gathers honey all the day
> From ev'ry opening flow'r.

Moreover it is their duty to guard and protect the hive and the queen, to feed the young, and to kill the drones at the appointed season.

In a single hive, there are sometimes not fewer than 30,000 of these individuals. They are distinguished from the fully developed females by having a longer lip, the jaws not notched at the tip, and the sting straight.

The perfect female, of which there is but a single individual in a hive, is termed the queen, and is distinguished by her greater size, more elongate form, brighter colour, shorter tongue, notched jaws, and curved sting. Her duty principally consists in the laying of eggs, and in her proceedings she is attended by a body guard of workers, who pay her the greatest attention; hence, she is the mother of the hive, not indeed of the contemporary generation, but of the future inhabitants of the hive, as well as of the swarms of the following summer. It is one of the most curious points in the history of this insect, to notice the immense influence which this solitary female has upon an entire population of many thousand bees. And, indeed, did not the accounts which have been given respecting it, depend upon authors of the most undisputed veracity, it would be next to impossible to consider them to be otherwise than as most marvellous and impossible *fables*. Reaumur, however, by dividing a hive, clearly proved the existence of the more than careful attention and respect with which the queen is regarded. He inclosed the two portions of the society in glass hives, and ascertained not only that such was the case, but also, that whilst in that division which possessed the queen, and but a small proportion of workers, the latter quickly made two combs, the portion without a sovereign, although far more numerous, did not construct a single cell; whence it is evident that the instinctive proceedings of the workers depend on the love of progeny; and what is the more remarkable, it is not for their own offspring that they are content to undergo all their labours, being totally incapacitated from becoming the parents of a hive.

Queen Bee.

The absence of the queen deprives the workers of no organ, paralyses no limb, yet in every instance that they are deprived of her they neglect their duties, and unless provided with another queen they refuse food and quickly perish. How difficult is it to attribute these wonderful proceedings to any other cause than the possession of the most perfect reason.

The male bees, of which there are several hundreds, sometimes even two thousand, in a full hive, are idle creatures, doing no work:—

> On other's toils, in pampered leisure thrive
> The lazy fathers of the industrious hive.

Their only duty is to impregnate the female, and this effected, they are driven from the hive and killed by the workers, who thereupon also destroy the male larvæ and pupæ remaining. They are generally termed drones, a term which has been misapplied to various species of flies which indeed much resemble bees, but which may at once be distinguished by having only one pair of wings.

These drones are of a more bulky size than the other bees, and they are not armed with a sting. Their antennæ are composed of thirteen joints (those of the females and workers having only twelve articulations); the head is more rounded, with the eyes larger, and meeting behind; their jaws are smaller and very hairy; and the basal joint of the posterior tarsi has neither pollen plate nor brush. They make a much greater noise in their flight than the others, and at the extremity of the body two small corneous appendages are to be observed of a yellow colour, which, with some other internal organs, constitute the sexual apparatus.

Drone Bee.

In addition to these three kind of individuals, it is to be observed, that there appear to be two sorts of females, namely, the large and small. Reaumur, however, attributes this difference of size to the state of the eggs in the body. There are likewise two descriptions of males, one not larger than the workers, and supposed to be produced from a male egg laid in a worker's cell, and the other much larger, above described. Moreover, there are, according to M. Huber, two sorts of workers; the first, which he calls cirières, wax-makers, being charged with the collecting of food and secretion of materials for the building of the nest; and the second, which he calls nourrices, or nurses, smaller and more weakly, whose cares are directed to the feeding of the young and the domestic concerns of the nest*. Huber also noticed another kind of bees, which he terms black bees, and which appear to be only casual inmates of the hive, from which they are always expelled, and often killed by the workers, with which, however, except in having the head and thorax of a darker colour, they agree both in their external appearance and internal structure, having, like the workers, perfect ovaries, although not furnished with eggs. Messrs. Kirby and Spence threw out the hint that those black bees may be superannuated workers, which have lost some of the hairs from off their bodies, and which, being incapable of contributing to the labours of the nest, are banished by the younger members.

Such are the inhabitants of the hive—the chief products of which are bees-wax and honey. The former is secreted by the worker-bees from a peculiar apparatus on the under-side of the belly, as occasion requires†, and is employed for constructing the combs in which the family-provision and the young brood are deposited. These combs are boiled in water, after the honey is extracted, until melted; the wax is then separated from the water, and being remelted, it is poured into moulds, to form the bees-wax sold in our shops. It has been said that there is hardly enough of this article produced in England to answer the demand for lip-salve alone, the greater portion employed being annually imported from the Baltic, the Levant, the Barbary coast, and North America. Humboldt informs us that not less than 42,670 arobas of wax, worth upwards of 130,000*l.* were exported from the island of Cuba in a single year. This product is for the most part obtained from the common hive bees; a quantity by no means inconsiderable is, however, procured from various species of wild bees.

Honey is obtained by the bees from the nectaries of flowers, which, as is well known, are constantly secreting a sweet nectarial fluid. This is sucked up by the tongue of the insect; a portion of it is consumed at once for its support, but the majority of the supply, although taken into the stomach of the bee, is again regurgitated and poured into the cells of the hive for the food of the grubs and the use of the community during winter. These cells are placed in the most inaccessible parts of the hive, and are closed with waxen lids, but the honey destined for the use of the nurses, workers, and drones, is deposited in unclosed cells. Some difference seems to exist whether the honey, whilst retained in the stomach of the bee, does not undergo some change, and this idea is strengthened by Reaumur's experiment, from which he obtained honey from the nests of bees fed upon sugar. Moreover, in each honey-cell there is a cream-like layer or covering of a thicker consistence than the honey itself. This layer is perforated by the bee, when it deposits its honey in the cell, through a hole made by the fore-legs, and which is closed before the bee flies away. The quality and taste of honey depend, therefore, upon the plants frequented by the bees; thus, the finest flavoured and most delicate honey is collected from aromatic plants, and has been stored in clean and new cells, for which reason, and not because it is elaborated by a fresh swarm of bees, it is termed virgin honey. The peculiar taste of the fine Narbonne honey has been attempted to be imitated by adding an infusion of rosemary. Hence it is advisable to have large patches of such plants as borage, viper's bugloss, mignonette, lemon thyme, and sage, in the neighbourhood of bee-hives. Lime trees, furze, heath, and clover, are also desirable auxiliaries.

Honey, however, occasionally has been found to have acted like poison, a circumstance probably owing to the bees having extracted it from poisonous plants. Many of the ancient writers contain facts on this subject, and in particular Xenophon has recorded in his Memorabilia that a number of Greek soldiers, during the celebrated retreat of the ten thousand, were violently affected by honey, which they had eaten near Trebizond. Tournefort, when travelling in Asia, made some inquiries upon the subject, and discovered a shrub growing in the neighbourhood of that place, which is well known to produce similar effects. He says, "There is a kind of rhododendrons about Trebizond, whose flowers the bee feeds upon, and the honey thence drives people mad." Moore has employed this circumstance,

* Much difference of opinion has prevailed amongst naturalists as to the origin of wax, it having been generally supposed that the yellow matter, which in fact is the farina of flowers, and which is collected upon the thighs of bees, was its prime constituent. More recent investigations have, however, pretty clearly demonstrated, that wax, by the organic intervention of bees, is produced from honey having been repeatedly secreted when the bees have been confined in rooms, where they could not possibly obtain the least particle of farina, which has been termed bee-bread, or the ambrosia of the hive, and which having been collected by the workers, is deposited by them in the cells. The wax is secreted by a singular series of organs between the abdominal scales, Mr. John Hunter having detected the genuine reservoir of wax under the bee's belly.

† It is not improbable that the assertion of Father Tanoya, mentioned by Monticelli, that in every hive there are three sorts of bees independent of each other, namely, male and female drones, male and female monarchs, and male and female workers, originated in these several kinds of bees; but that each construct their own nests, as he asserts, is certainly unfounded in fact.

in his "Lalla Rookh," in a most forcible and poetic manner:—

> Just Alla! what must be thy look
> When such a wretch before thee stands
> Unblushing, with thy sacred book,
> Turning the leaves with blood-stained hands,
> And wresting from its page sublime
> His creed of lust and hate and crime?
> Ev'n as those bees of Trebizond
> Which from the sunniest flowers that glad
> With their pure smile the gardens round,
> Draw venom forth that drives men mad.

It is probable that the plant in question is the *Rhododendron ponticum*, or the *Azalea pontica* of Linnæus.

Dr. B. S. Barton, in a valuable paper in the Fifth Volume of the Transactions of the Philosophical Society of America, after detailing the statements of classical authors upon the subject of poisonous honey, has stated that, in the autumn and winter of 1790, the honey collected near Philadelphia proved fatal to many, in consequence of which it was discovered, after an inquiry instituted by the government, that the honey had been chiefly collected from the flowers of the *Kalmia latifolia*. He also mentions that a party of adventurers removed some hives of bees from Pennsylvania to New Jersey, in the hope that the savannahs of the latter country might be favourable to the increase of these animals, and, consequently, to the making of honey; they accordingly placed them in the above situations, and where the *Kalmia angustifolia* was the principal flowering shrub; the bees increased prodigiously, and the enterprise appeared successful, but it was soon found that every one who ate of the honey became intoxicated to a high degree. It was then made into metheglin, but with a similar effect to those who partook of it. The usual symptoms were a dimness of sight, or vertigo, succeeded by a delirium, which was sometimes mild and pleasant, and sometimes ferocious; intoxication, pain in the stomach and intestines, convulsions, profuse perspiration, foaming at the mouth, vomiting, purging, and, in a few instances, even death. Sometimes vomiting was among the earliest symptoms, and in that case the patient was readily relieved, although a temporary weakness of the limbs was not an uncommon result.

Dr. Hosack has recorded two cases in which this substance produced violent vomiting, a coldness at the extremities, and a livid appearance of the countenance. The pulse was reduced to about twenty in a minute; the spontaneous vomiting, however, being followed by a dose of castor oil, together with the application of fomentations, relieved the sufferers. In these cases the honey was of a dark reddish colour, and a thicker consistence than usually sold in the market.

From the facts mentioned above, Dr. Barton is of opinion that the poisonous nature of the honey is owing to the bees feeding on poisonous plants, such as the *Kalmia* of various species, the *Andromeda Mariana*, which is injurious to sheep, the *Rhododendron*, the *Azalea mediflora*, and the *Datura*, and he recommends that every fœtid or poisonous vegetable should be removed from the habitations of these animals.

Thus it will be seen that, as Dr. Barton observes, there is more of poetry than philosophy in the following lines of Pope,—

> In the nice bee what sense so subtly true,
> From poisonous herbs extracts the healing dew?

Adding, "It is, however, much to be questioned whether this noxious honey proves so to the bees themselves." This, it may easily be conceived, does not take place, since the bees would most undoubtedly have the instinct to avoid the plant, and in the case of the Philadelphia bees, they are said to have thriven prodigiously. The case is, however, very different with them in respect to other flowers and fruits, which act upon them in a manner greatly resembling the effects of intoxication. Thus an elegant modern writer, cited by Dr. Bevan, after defending animals in general against the impropriety of the expression that a man who has drank to such an excess as to lose his reason, has made a beast of himself, observes, that it may fairly be said that he has made a *humble bee* of himself, for those little debauchees may often be observed round the nectaries of hollyhocks, quaffing as pertinaciously as though they belonged to Wilkes's Club, whilst round the flower on the ground several of the *bon vivants* will be found lying inebriated and insensible. Other observations have been made to the like effect.

Various plans have been of late years adopted to obtain the honey from bee-hives without resorting to the cruel, and, as it seems, unnecessary practice (which is, however, still usually adopted in this country) of sacrificing the lives of the bees, by placing the hive at night over a hole, in which lighted brimstone matches are placed, the fumes from which in a short time kill the bees.

> Sudden the dark oppressive steam ascends,
> And, used to milder scents, the tender race
> By thousands tumble from their honey'd dome,
> Convuls'd and agonising in the dust.
>
> THOMSON.

The plans chiefly adopted have had for their object the expulsion of the bees from the old nest, after the combs are well filled with honey, into adjacent boxes, in which they then recommence their labours, or after the removal of the honey, they are again returned to their old habitation. We shall take this opportunity of mentioning a plan adopted by Mr. Nutt, an intelligent and practical apiarian of Lincolnshire, whose apparatus was lately exhibited at the Museum of National Manufactures in Leicester-square. By arrangements which, although very simple are very complete, a secretion of a much larger quantity of honey is caused than can be produced by any other mode of management. Three collateral boxes are placed side by side, with a single entrance in the centre box, which, however, communicates with the side boxes by apertures, which are easily closed by a tin slide. The bees are first introduced into the centre box; when this is filled with honey, which is allowed to remain for the use of the bees, in order to obviate the necessity of swarming, Mr. Nutt removes one of the slides, and establishes a communication with one of the side boxes, the temperature of the latter being regulated by a perforated tin tube, which acts as a ventilator, and by which means these additional store boxes are kept at a proper working temperature, and *below the generative heat*, in consequence of which the queen bee is always retained in the middle box. The heat of these side boxes is kept at 70° or 80°, whilst the natural temperature of the working hive is 90° or 100°, increasing even to 120°. When the temperature of the side boxes rises towards the latter point it is evident that they are full, and the necessity which exists for establishing a connexion with the centre and the other end box is thus shown. The bees are easily driven from the full side box by the action of the ventilator, when the communicating aperture is closed by means of the slide, and the first full side box is then removed; and the bees, finding the middle box full, soon make their way into the other side box. The ingenious action of the ventilator is designed to retain the queen in the middle box, since the reduced temperature of the side boxes prevents the queen from rendering them her domicile, whereby a great superiority both in the quantity and quality of the honey is obtained, as it contains none of the eggs, larvæ, pupæ, pollen, or bee-bread, which is found in the centre box in considerable quantities for the support of the young. By this means Mr. Nutt has procured the amazing quantity of 296 lbs. of honey from one stock of bees, the general average product being from 100 to 130 lbs.

But Mr. Nutt's own statement is so fully illustrative of the advantages of his system, that we furnish it in a tabular form:—

Pounds.			Pounds.
	First swarm on the 10th June, 1823.		
127	Union of the present stock,	14th Aug. 1823,	28
132	Collection of honey,	12th June, 1824,	30
109	Ditto .	16th July, 1825,	58
125	Ditto .	10th Aug. 1826,	106
105	Ditto .	10th July, 1827,	219
114	Ditto .	6th Aug. 1828,	296
712	For the bees' support during five years.		
737	Contribution	Contribution	737
1449			

Hence it is evident, that by this and other "humanity" systems, the comparative estimate given by Dr. Bevan of the advantages which are thereby obtained over the old single-hiving system is well founded; namely,

"Firstly, an economical division of labour, which causes a larger quantity of wax and honey to be collected than if the bees were to swarm and to carry on their operations in separate families.

"Secondly, the facility with which the bees may be deprived of a considerable portion of their honey without destroying their lives, or communicating to the honey any unpleasant flavour from the sulphurous gas.

"Thirdly, the power which is afforded to the bees of employing themselves usefully during wet weather.

"Fourthly, the saving of that time which is unnecessarily spent in the construction of the fresh combs in the new habitation, at a period of the year, it may be observed, when nature is most lavish of her flowers for the development of their sweets.

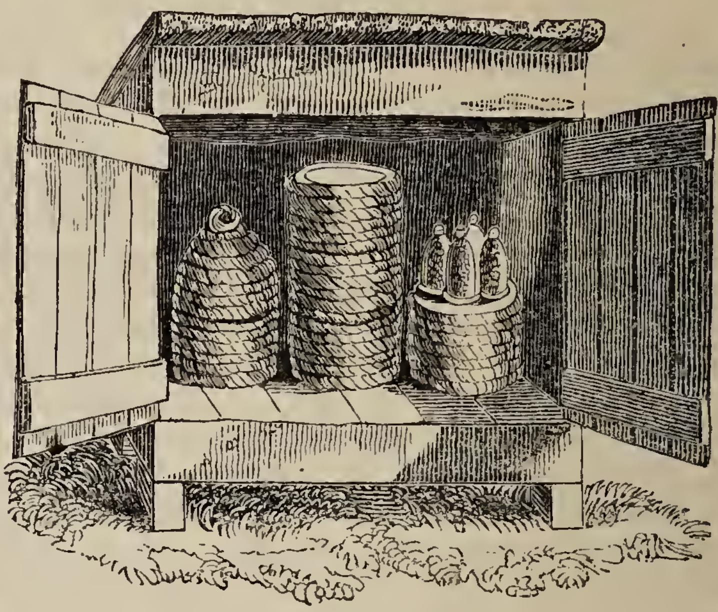
"Fifthly, the saving of room; for as every family has more warehouse room than its respective necessities require, the division into small families must multiply the proportion of this superfluous room.

"Sixthly, the saving of time usually lost in the preparations for swarming, when the bees hang inactively in clusters on the outsides of the hives for many days, sometimes for weeks, particularly if the weather prove unfavourable."

From honey is prepared a vinous fluid, heretofore much used in England, called mead, metheglin, or hydromel.

> Fill the *honey'd beverage* high,
> Fill the skulls, 'tis Odin's cry—
> Fill the *meath*, and spread the board,
> Vassals of the grisly lord.

This was, indeed, the chief wine of the old inhabitants of Britain. It was prepared in various ways, one of which may serve as an example. "Into twelve gallons of water slip the whites of six eggs, mix these well together, add twenty pounds of honey. Let the liquor boil an hour, and when boiled add cinnamon, ginger, cloves, mace, and rosemary; when cold put a spoonful of yeast to it, and tun it up, keeping the vessel filled as it works; when it has done working stop it up close; and when fine, bottle it off for use."



Apiary.

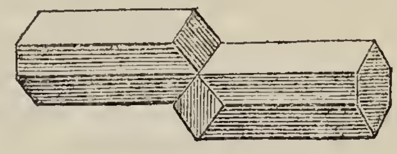
In the above engraving we give a representation of one of the modes resorted to for facilitating our acquaintance with the economy of the hive. Many of the most important discoveries connected with the habits of the bee have been made by the use of a glass-hive, and the one represented in the engraving combines all the comforts of a common apiary, with a complete facility of examination.

Having thus noticed the inhabitants and the products of the hive, we may now turn our attention to the hive itself. "The most profound philosopher, equally with the most incurious of mortals, is struck with astonishment on inspecting the interior of a bee-hive. He beholds a city in miniature. He sees this city divided into regular streets, these streets composed of houses constructed on the most exact geometrical principles and the most symmetrical plan: some serving for store-houses for food, others for the habitations of the citizens, and a few much more extensive than the rest destined for the palaces of the sovereign. He perceives that the substance of which the whole city is built is one which man, with all his skill, is unable to fabricate; and that the edifices in which it is employed are such as the most expert artist would find himself incompetent to erect." Such is the general description given by Messrs. Kirby and Spence; but we will descend to more minute particulars, observing that, although the hive and its inhabitants have formed the subjects of investigation from the earliest periods, its mysteries are not yet fathomed—it "is a miracle which overwhelms our faculties." In the first place it is to be observed, that the hive is but a convenience, not essential to the establishment of a nest, since bees, after swarming, will form their city in the hollow of a tree, or other cavity. Thus the scriptural riddle, "Out of the eater came forth meat, and out of the strong came forth sweetness" (Judges, chapter xiv.), may be solved by supposing that the carcass of the lion had become dried up, and formed a convenient cavity for the reception of the nest. And Montgomery, in his Pelican Island, also notices the propensity of these insects of establishing themselves in the dried and capacious skeletons of animals—where, speaking of the hugeness of the skull of the elephant, he says,—

> Bees, in the ample hollow of his skull,
> Piled their wax citadel, and stored their honey;
> Hence sallied forth to forage through the fields,
> And swarmed in emigrating myriads hence.

The nest, as constructed by the insects, consists of a continued series of combs arranged vertically, each of which consists of a vast number of cells, forming two ranges, backed against each other, and consequently placed in a horizontal position. A sufficient space is left between each of these double layers of cells to allow a couple of bees, busied upon the opposite cells, to work without incommoding each other. In addition to these spaces, the combs are perforated in various places, so as to allow a passage for the bees from one street to another, thus saving them much time ; but it is in the construction of the cells themselves that the most admirable instinct is displayed. These are formed of wax, a material not secreted in very great quantities by the bees ; whence it is essential that not only the least possible space should be occupied in the nest, but also that the least possible wax should be employed. Geometricians are aware that, in order to occupy a given space with solid objects of equal size and similar form without any useless interstices, three figures only can be adopted, namely, the equilateral triangle, the square or cube, and the regular hexagon. Of these three geometrical figures the hexagon most completely unites, as Dr. Reed observes, the prime requisites for insect architecture. The bees appear, says Reaumur, to have had a problem to solve which would puzzle many a mathematician. " A quantity of matter being given, it is required to form out of it cells, which shall be equal and similar, and of a determinate size, but the largest possible with relation to the quantity of matter employed, whilst they shall occupy the least possible space."

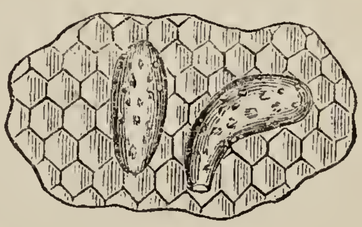
The bottom of each cell is formed of three lozenge-shaped pieces, whence it is obvious that their junction might have been formed at any imaginable angle. Like the slated roofs of houses, it might have been of any inclination. Reaumur, however, suspected that as the bottom of the cells had an uniform inclination, this particular direction was the one which also caused the least expenditure of wax. He therefore asked M. Kœnig, a skilful geometrician, to determine by calculations the following question. Among all the hexagonal tubes with pyramidal bases, composed of three similar and equal rhombs, to determine that which can be constructed with the least possible quantity of matter. Kœnig, ignorant of the object which Reaumur had in view, worked out the problem and found, that if three rhombs or lozenges were so inclined to each other, that the great angles measured 109° 26′ and the little angles 70° 34′, this construction would require the least quantity of matter. Now M. Miraldi had actually previously ascertained by a very accurate admeasurement, that the great angles of the cells were in general 109° 28′, of the smaller ones 70° 32′. Admirable geometricians, which without compasses or figures, not only adopt the most advantageous form for your cells, but build them with that minute precision which insures the employment of the least quantity of materials, and form them of those precise dimensions which will suit the size of the future inhabitant! But there is still another instance of geometrical instinct exhibited in these cells ; a common base serves for two strata of cells, which base is so disposed as to form a pyramidal cavity at the bottom of each, being composed, as above stated, of three distinct lozenge-shaped pieces : hence it follows, that the base of a cell on one side of the comb is formed of portions of the bases of three distinct cells, on the other. By this means, a greater degree of strength and a smaller consumption of materials is obtained, than if each set were first thoroughly formed, and then the two cemented together, whereby each of the cells would have a distinct pyramidal base, or than if the two cells had been a single hexagonal tube, intersected in the middle by a flat instead of a pyramidal division.



Cells shewing manner of uniting at base.

It is a remarkable circumstance, that in a new colony the design of every comb is sketched out and the first rudiments laid by a single bee, which having disengaged itself from the swarm, commences the building of cells, which is then taken up by the other wax makers, and subsequently by the nurse bees, which give the finishing stroke to the cells. And so expeditious are the proceedings of these indefatigable creatures, that a comb, twenty-seven inches long by seven or eight inches wide, is built in four and twenty hours, and in five or six days they will half fill the hive. The combs are attached to the roof and sides of the dwelling, the hives or boxes to the floors and roofs, the cell-work of the combs varnished, &c. with a resinous, very tenacious, and transparent substance, termed propolis, which the bees collect from various trees, as from pines and other trees of the fir tribe, according to some authors, but from the wild poplar, according to Huber.

There are three sorts of cells, the first are for the larvæ of workers and for containing the honey, these are of the ordinary form ; the second are for the grubs of the males or drones,—being considerably larger and more substantial, they usually appear near the bottom of the combs ; the third are the cells for the females, of which there are usually three or four, although Mr. Hunter observed as many as thirteen royal cells in one hive. They are attached commonly to the central part of the comb, having very little wax in their composition, the remainder being considered by Mr. Hunter to be farina. One of these cells considerably exceeds in height the ordinary ones, and they are not interwoven with them but suspended perpendicularly, their sizes being nearly parallel to the mouths of the common cells, several of which are sacrificed to support them : they are of an oblong spheroidal form tapering gradually downward.



Hexagonal Cells with Royal Cells attached.

After the queen bee has quitted her cell, it is destroyed by the workers, and its place occupied by a range of common cells. A beautiful and gradual transition is established between the small-sized ordinary cells and the larger ones, or vice versa, the bases of the connecting cells being composed of two rhombs and two hexagons, instead of three rhombs; the rhombs and hexagons varying in form and relative proportions until the required size is obtained.

Although the general form of the cells is hexagonal that of those first begun is pentagonal, the side next the top of the hive, and by which the comb is attached, being much broader than the rest; whence the comb is more strongly united to the hive than if their cells were of the ordinary shape. It of course follows, that the base of these cells, instead of being formed, like those of the hexagonal cells, of three rhomboids, consists of one rhomboid and two trapeziums.

The bees, observe Messrs. Kirby and Spence, appear to give the proper forms to the bottoms of the cells by means of their antennæ, which extraordinary organs, they seem to employ as directors, by which their other instruments are instructed to execute their very complex work. They do not remove a single particle of wax until the antennæ have explored the surface that is to be sculptured. By the use of these organs which are so flexible and so readily applied to all parts, however delicate, that they can perform the functions of compasses in measuring very minute objects, they can work in the dark, and raise those wonderful combs, the first productions of insects.

The diameters of the cells, intended for the larvæ of the workers, is always two lines and two-thirds, that of those meant for the larvæ of the males or drones three lines and one-third. It appears to be the oviposition of the queen which decides the kind of cells that are to be made, as whilst she lays the eggs of workers, no male cells are constructed, but when she is about to lay the eggs of males, the neuters appear to know it and act accordingly.

The queen deposits her eggs separately in the bottom of each cell; the egg is of a lengthened oval shape, with a slight curve, and of a bluish colour; when laid it is covered with a glutinous matter, which enables it to adhere to the bottom of the cell, where it remains for four days. The workers' eggs, which are the only ones laid by the queen during the first eleven months, hatch in a few days and become little white maggots, which, as they grow, assume a curved position, till the two extremities touch one another and form a ring. Each is now fed with bee-bread by the workers very assiduously, and at the expiration of six days, having attained its full size, it is roofed in by the workers, spins a silken cocoon, which occupies it for thirty-six hours, and then becomes a nymph or pupa; and at the further expiration of eleven days, the insect quits the exuviæ of the pupa, eats through the roof of the cell, and comes forth a perfect worker bee.

The male bee passes three days in the egg state, six and a half in the larvæ, and makes its appearance at the further expiration of fifteen days.

The development of the queen bee requires a more lengthened notice, involving some of the most interesting points in the economy of the hive. We have said that for nearly twelve months the queen bee deposits only workers' eggs, after which period, however, she commences laying those of drones. As soon as this change takes place, the workers begin to construct royal cells, in which, without discontinuing to lay male eggs, she deposits now and then, about once in three days, an egg destined to produce a future queen. This laying of eggs commonly happens in May, lasts thirty days, and regularly on the twentieth or twenty-first day, royal cells are founded. The queens pass three days in the egg state, and five as larvæ; they are then occupied twenty-four hours in forming their cocoons, their cells having been previously closed by the workers. During nearly the whole of the three following days they repose in their cocoons, after which they are transformed to pupæ, in which state they remain between four and five days, appearing in the perfect state on the sixteenth day after the eggs are deposited; thus a worker, or abortive female requires four more days in which to undergo its preparatory state, than the perfect female, whilst four more days are required for the perfection of the male, than for the workers. The cocoon of the queen, however, is incomplete, covering only the head, thorax, and basal segment of the abdomen, a peculiarity probably dependent upon the form of the cell in which she is born, since if a female larvæ be placed in a worker's cell, she will spin a complete cocoon, and if a worker be placed in a royal cell it will form an incomplete cocoon.

The food of the royal grubs has been termed royal jelly. It is a pungent food, prepared by the workers, exclusively for the purpose of feeding such of the grubs as are destined for queens, and is more stimulating than the food given to the common grubs, having a perceptibly acescent taste.

Should it happen, as is sometimes the case, that the queen be killed, or the hive in any other manner deprived of her, during the first eleven months of her existence, and before she has deposited any royal eggs, the most extraordinary circumstances occur. If such an event takes place amongst the wasps, they are said to become restless and idle, wandering away from the nest, and never returning; but with the bees it is far different. For twelve hours little notice is taken of the loss; it appears unknown, and the work of the hive proceeds as usual. Presently a hubbub commences, work is abandoned, the whole hive is in an uproar; every bee traverses the hive at random, with the most evident want of purpose. This state of confusion sometimes continues for several days; then the bees gather in knots, clusters of a dozen or so, as though engaged in consultation, shortly after which a resolution appears to have been taken by the whole population. Some of the workers select one of the worker eggs, which had been previously deposited by the lost sovereign. Three cells are thrown into one for its reception, the eggs in the two other cells being destroyed. The grub, when hatched, is fed with royal jelly above described, and a queen is produced. Even if the grub had been hatched, and partly fed as a worker, and had only received two or three days' allowance of royal food, the result would be the same. They emerge from the pupæ perfect queens, whereas had they remained in the cells which they originally inhabited, they would have turned out workers, having their form, instinct, and organs of generation entirely different.

This is a most extraordinary fact; but if we consider the subject, especially with reference to the worker bees, we must admit that their case is still more extraordinary. Its ordinary occurrence, as is too generally the case, taking off its apparent singularity.

The queen, as we have seen, is a perfect female, the workers imperfect ones. The queen is fed with peculiar food, and comes forth perfect: her food is therefore what we may call naturally perfect food.

But with the workers it is different; for the production of an imperfect animal a peculiar weakened kind of food is given. Here then is the great and extraordinary economy of the hive shown. If every grub were fed with the naturally strengthening food, every bee would be male or female, and perfect; but in such case how would the hive be formed, the honey gathered, the young bees fed? These are the peculiar duties of those bees, which, having no sexual duties to perform, are employed throughout their entire lives in the duties of the hive. Hence, it is far more remarkable that, for the due regulation in the internal arrangements of the hive, the greater portion of the inhabitants should be stinted in their growth, and rendered sterile members of the community, than that a maggot, well supplied with wholesome nutriment, should arrive at that perfect development which is the characteristic of its sex. If the case were reversed—if, for the performance of some singular duty, it were requisite, that in a nest of 20,000 or 30,000 insects, some half a dozen should annually be produced, which should, by the greatest care, be supplied with impoverishing food, so as to become unfruitful, how much more remarkable would the production of the barren bee be considered than it is, because nineteen-twentieths of the community are abortive.

In this light the non-development of the worker bees becomes a new matter for wonder. It may be asked, Can a smaller and more moderately heated house, a less stimulating kind of food, and a horizontal instead of a vertical posture in the larva state, give an insect a differently shaped tongue and mandible, render the surface of its posterior thighs concave and flat, provide them with a fringe of hairs, forming the basket for carrying pollen, furnish them with an apparatus at the extremity of the tibiæ and base of the tarsi, enabling the insects to use their legs as pincers, or furnish them with the pollen brush which lines the inside of their basal tarsal joint? Can they shorten its abdomen, alter its colour and clothing, straighten its sting, furnish it with wax pockets and vessels secreting that substance, and render its ovaries abortive. Can, in the next place, the circumstances above noticed, altogether alter, as Messrs. Kirby and Spence observe, the instinct of these creatures? Can they give to one description of animals address and industry, and to the other astonishing fecundity? Can we conceive them sufficient to change the very passions, tempers, and manners? That the very same fœtus, if fed with more pungent food, shall become a female, passing her time without labour—that this very same fœtus, if fed with more simple food, shall come forth a worker,—this, and more than this, is so contrary to what is known in other branches of natural history, that unless it were perfectly authenticated, we might deem it as fabulous as the stories circulated amongst the ancients respecting the very same insects.

In man and the higher animals it is well known that numerous differences, both as respects the form and relative proportion of parts, occurs frequently, although their causes are difficult of explanation. In many instances these may originate in the difference of the nutriment which the embryo derives in the womb, or from the degree of confinement or temperature caused by that organ; a case that analogically would not be very wide of that of the grub or embryo of the bee inclosed in its cell. These and similar instances which have been adduced, are, however, of rare occurrence, and the result of accident, so that they can scarcely be considered as strictly analogous to the case of the bee.

We are now to suppose that the period of the year is arrived that the queen insects, having undergone the change to the pupa state, are nearly ready to burst forth to life. It is now that the old queen-mother, losing all her parental feelings, becomes infuriated. She rushes to the cells wherein are deposited the future queens, her offspring, and instantly begins to tear them open; the guards which surround the cells make way for her approach, and suffer her to act as she pleases, whereupon she slaughters the inmates with her stings without remorse. As the cells, however, are thicker than those of the workers, she is soon fatigued by her labours; and after she has opened one or two she languidly attempts to gnaw through a third. The sight of these cells agitates her to such a degree that she runs about the hive in a state of delirium. This excitement she soon communicates to the workers by touching their antennæ; and, after scampering about in all directions, a great portion of them, accompanied by their old queen, rush out of the hive, and seek another house. In every instance it is the old queen which leads the first swarm. Experience enables the apiarist to foretell this event, for on the evening previous to swarming the bees suddenly leave off their labours, as if aware of the approaching change, whilst a few scouts are sent out in search of a new colony. Something very like concerted action and foresight are evident in these proceedings. It is always in calm weather, when the sky is serene, between nine in the morning and four in the afternoon, that they quit their habitation. If the female is not found amongst the first which issue forth (in general, however, the swarm drags the mother-queen with them out of the hive), she is not long in repairing after them, and in less than a minute she is followed by all the bees which are to compose the swarm. By degrees they fix themselves upon a branch, form a group there, by hooking themselves one to another with their feet, although they are exposed: they remain quiet, and often, in less than a quarter of an hour, we see scarcely more bees hovering round the swarm than are to be observed around a hive in fine weather. If in sallying forth they fly toward some large tree, there is reason to fear that they may wander beyond the limits of the hive. They are easily brought down by throwing up handfuls of dust. Although the swarm remain tranquil, it must not be left long in this position without offering to it a lodging, especially if the sun be warm, because it would speedily go elsewhere in search of a new habitation. Thus, therefore, in the swarming season, it is necessary to have hives quite ready to make use of as occasion requires. The interior of a hive should be well cleaned before it be presented to the bees, since they are fond of cleanliness. To render it agreeable to them the sides are rubbed with flowers of melissa, bean flowers, &c., of the scent of which they are fond. Some parts of it are also moistened with a slight layer of honey. Thus a fresh hive is established, chiefly consisting of insects lately hatched, which in the course of a very short time commence their labours with all the zeal of the inhabitants of the hive from which they have swarmed. Let us return, however, to the old hive thus bereft of their queen. The bees that remain take particular care of the royal cells, and prevent the young queens successively hatched from leaving them, except at an interval of several days from each departure. This results, in a considerable degree, from the different period at which the royal eggs are deposited. Thus several queens are successively produced, and several swarms thrown off. As soon as a young queen is produced she proceeds instantly to attack the other royal cells; but here there is a remarkable difference in the conduct of the workers, for although they permitted their ancient queen to pursue her own instinct, they by no means extend the same courtesy to her successor; but the moment she attempts to approach a royal cell, the guards surrounding it immediately attack, bite, and drive her off. Irritated at this behaviour the young queen stands upright, and utters a shrill and clear sound; and no sooner is it heard than the bees appear to be paralysed; they remain motionless, and hang down their heads. She then attacks the cells, but in doing so ceases to pipe, when the bees, recovering from their stupor, drive her away. This is continued until the queen is irritated to such a degree that she follows the steps of her predecessor, and in a state of delirium, which is communicated to a portion of the workers, she quits the hive with a second swarm.

In this manner several swarms take place in the course of the summer, between the months of April and August—a necessary consequence of the great increase in the population of the hive, owing to the fecundity of the queen in the spring months far exceeding the loss occasioned to the hive by the cold of winter, which is estimated to destroy six or seven eighths of the inhabitants.

A good stock of bees ordinarily produces three swarms in favourable seasons, and even a swarm of the current year will occasionally throw off another swarm. Five swarms have, indeed, been recorded to have been thrown off; and Bosc, the celebrated entomologist, has stated that, whilst in Carolina, he had eleven swarms in the course of a year from one stock, each of which, during the same season, threw off the same number of secondary ones. Each swarm contains not only young bees recently hatched, but also a portion of the old inhabitants. There are generally from seven to nine days intervening between the first and second swarm; between the second and third the space is shorter; and where there is a fourth, it may depart the day after that which precedes it. Hence it is essential that this space of time should intervene between the flight of the old queen and the appearance in the perfect state of the new one, and this is produced in the following singular manner:—

After the royal cells are covered in, in order that the inclosed grub may undergo its change to the chrysalis state, the workers immediately remove here and there a portion of the wax from the surface, so as to render it unequal; and immediately before the last metamorphosis takes place the walls are so thin that all the motions of the inclosed pupa are distinctly visible. On the seventh day the part covering the head and trunk of the pupa is almost entirely unwaxed, whereby the inclosed insect, on arriving at its winged state, would be enabled to make its exit with perfect facility, were it not for the proceedings of the attendant workers, who are guided therein entirely by the wants of the society. As soon, therefore, as the workers perceive that the young queen has cut circularly through her cocoon, they immediately solder the cleft up with some particles of wax, and so keep her a prisoner against her will. Upon this, as if to complain of such treatment, she emits a distinct humming sound, which excites no dread nor pity in the breasts of her subjects, who detain her two days longer than nature has assigned for her confinement. During this period she sometimes thrusts her tongue through the cleft she has made, drawing it in and out until she is noticed by the workers, who thereupon feed her with honey, till, her hunger being satisfied, she draws her tongue back. At the proper period she is released, and proceeds as her predecessor had done.

Shortly after the swarming has taken place, the impregnation of the queen takes place. Upon this subject such differences of opinion have prevailed amongst naturalists, and such absurd theories have been broached, that, now that the subject has been cleared of all its mystery, the reader cannot but smile at the errors which a minute investigation and an unbiassed mind could not fail to have detected; and thus it has generally been with every question of natural history which required any thing beyond the most commonplace attention. Mankind has been too prone to indulge in the marvellous; and hence, without stopping to inquire into the precise nature of things, well observed effects have been attributed to the most ridiculous causes. Thus it has been with the impregnation of the queen bee; but we will not waste our space, nor the time of our readers, by citing the opinions which have been entertained upon the subject. Similar to the case of the ants, amongst which it is well known that fecundation takes place in the air at the period of swarming, the female bee being preceded by the drones, and having previously reconnoitred the exterior of the hive, rises aloft in the air, wheeling upwards in large circles, until she is out of sight. She returns from her excursion in about half an hour with the most evident marks of impregnation, although occasionally these excursions are of shorter duration, and are repeated, the female, in such case, exhibiting no such marks. Now it is that a new stimulus to exertion is given to the workers; every thing is then done with the greatest care. They hasten to finish the cells which they have commenced, laying new foundations, and appear to be fully conscious of the importance of their activity. The progress of their labours is the signal by which the female is directed in laying her eggs.

According to M. Huber, a single coupling is sufficient to vivify all the eggs which the female shall deposit in the course of a couple of years, and probably for all those which she shall lay during her entire life. According to Huber, the queen ordinarily lays about 12,000 eggs in the months of April and May, which is termed the great laying, as it is from these that the swarms are produced, one of which, of a moderate size, is calculated to consist of from 12,000 to 20,000; hence, as there are several swarms in the course of the summer, it is probable that the calculation of Reaumur, which is double that of Huber, viz. 200 per day, is more correct. Another great laying takes place at the beginning of autumn.

But it is not the queen alone which deposits eggs, since it has been well ascertained that the worker bees occasionally lay them; but it is remarkable that these fertile workers never deposit anything but male eggs. It has been supposed, however, that they must have been small queens (noticed above) mixed with the workers, whose office it was to lay male eggs in old hives. As, however, this is so contrary to the known proceedings of the real queen, it is perhaps to be considered more probable that those fertile insects, which are smaller and more slender than the common workers, may be common workers which have derived their fertility from the circumstance of some royal jelly having been casually dropt into their cells when grubs, as they uniformly issue from cells adjoining those inhabited by grubs that have been raised from the plebeian to the royal rank; of course, therefore, they are never found in any hives which have had the misfortune to lose their queen.

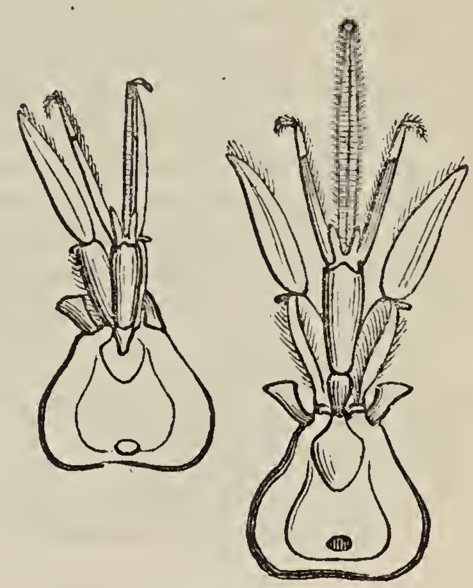
The duration of the life of the different individuals of the hive is various. Without recurring to the fabulous accounts of the old naturalists, who thought that bees lived as long as the hive lasted, were it never so long, it is to be observed, that a male bee's existence is not more than two or three months. The female has been known to live five years, although the general term of her existence is more probably from two to three years; and the workers, from the observations of naturalists, do not appear to be so long-lived as the queen, probably little longer than a year being the term of life.

Thus have we, in a connected form, laid before the reader the " birth, parentage and education, life, character and behaviour" of the honey-bee. The numerous experiments which have been performed upon these insects, although possessing the greatest interest, scarcely seem to fall within the limits of a moderately long article in a work like the present; recourse must therefore be had for them to the Memoirs of M. Huber, to the Introduction to Entomology of Messrs. Kirby and Spence, and to the intelligent volume recently published by Dr. Bevan.

We shall conclude this article by a more detailed account of the structure of the larva and pupa of the bee, and of two organs of the perfect insect, which cannot but be regarded with peculiar interest, namely, the tongue and the sting.

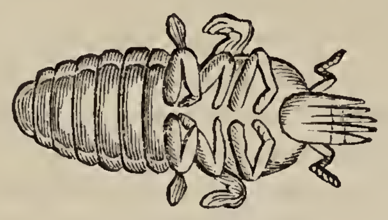
Bee grubs natural size and magnified.

The larva of the bee is a soft fleshy grub, with a wrinkled skin, and is generally to be observed in an arched position in the cell. Swammerdam, who dissected these grubs very minutely, states that they are composed of fourteen annular incisions, including the head; his figures, however, exhibit only thirteen, which number is found in all other insects, one segment being occupied by the head, three by the thorax, and nine by the abdomen of the perfect insect, although in the latter some of the segments of the abdomen of the larva become obsolete, forming, in fact, the organs of generation. The head comprises the eyes, which are transparent and white, resembling the ocelli of other insects, a small transverse upper lip, two small organs placed at the anterior angles of the head, which Swammerdam conceives afterwards become the antennæ, and two " little parts, situated under the former, which seem as if they were articulated and afterwards grow into teeth. Moreover between these two little parts, and consequently under the lip, is presented to view another small and somewhat prominent part, which resembles a trunk or tongue, and this increasing by degrees at length indeed constitutes the trunk of the bee; moreover there is something that hangs out of this little part above like a small nipple, by which the worm discharges its thread to make the web when it has eaten for a sufficient time, and is going to be transformed into a nymph. In some other worms I have seen, besides the tongue, the resemblance of a small and tubular proboscis, situate in the middle, between the tongue and the lip, by the help of which the worm can probably take in its meat. Again, in other such worms, I observed a horny or bony little part immediately under the lip." Their colour, however, which is whitish, prevents their being accurately viewed together.



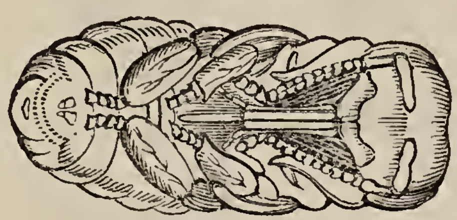
Bee's mouth.

From a careful examination of the structure of the mouth of the grubs of other bees, it appears that the two side organs, or " little parts which seem as if they were articulated," do not correspond with the " teeth" or jaws of the perfect bee, but with the sheaths of the tongue or maxillæ, whilst the former organs are represented in the grub by a pair of horny acute teeth, which Swammerdam has overlooked, if indeed they be not what he has noticed as " a horny or bony little part, immediately under the lip." The body is furnished on each side with ten minute circular spiracles, or breathing pores, a pair being placed on each segment of the body, with the exception of that which immediately follows the head, and the terminal one which bears the anus. The worm being unfurnished with legs, has a very slow motion, and whenever it is disturbed, it merely draws its head and tail, or the posterior part of the body inward; when more roughly handled, however, it sometimes twists and bends itself forwards, and sometimes backwards: but if it be not disturbed it lies in its cell without motion. Although it increases rapidly in bulk, it has not been ascertained that it sheds its skin as the caterpillars of moths do, except when on the point of becoming a nymph, at which period the pulmonary tubes also change their skin and throw out, through the orifices of the body, a thin pellicle. Previous to shedding its skin, the first three segments of the body begin to swell, since it is to these segments that the locomotive organs in the perfect insect are attached. At length the skin of the grub splits along the back, and the skull is divided into three pieces, whereupon the pupa is seen within, which, in a short time, disengages itself from its exuviæ; the organs which a short time previously were but slightly indicated by the swellings on the grub's body, but which, if the skin be stripped off, are nevertheless easily discernible,



Grub stripped of skin.

are now more clearly visible, and indeed may be observed more easily than in the perfect state, since at this period they are not covered with hairs as they are subsequently. The pupa of the bee, in fact, exhibits "an elegant disposition and well-ordered representation of all the limbs and parts of the future bee;" the various organs, however, remain immoveable until the humours are exhaled and dissipated, and hence it is that the bee, whilst in the pupa state, weighs considerably more than in the perfect state. In this state, therefore, we are able to see the eyes, the antennæ, and the tongue lying along the breast, as well as the rudimental wings and the legs, which are extended from the sides of the body along the belly. If all these parts be after-



Pupa.

wards removed out of their places, then the divisions of the head, thorax, and abdomen, appear distinctly, and we may ascertain the manner of the insertion of the legs, which is rendered more difficult in the perfect insect from the great quantity of hairs with which the parts are covered. If the insect be inverted, the three great divisions of the body are equally manifest.

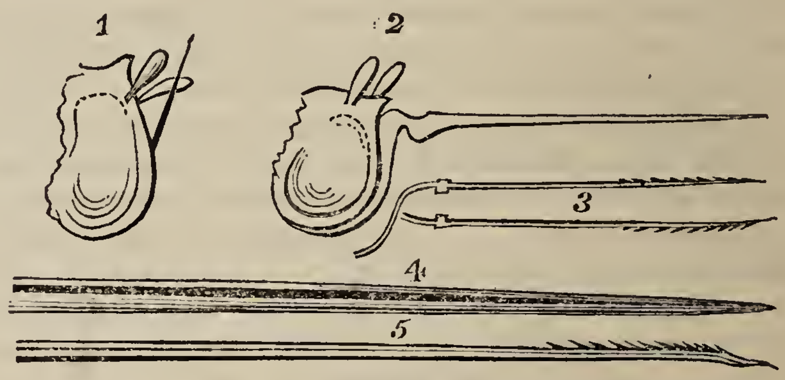
The tongue of a bee, by which is understood the apparatus with which it laps the nectar of flowers, is a very complex instrument, and possesses great powers of motion. As this organ has been very incorrectly described in a modern popular work, we have thought that it might not be without service to describe it in detail. If we hold a bee by its wings, the mouth at first sight appears to consist only of a small transverse lip, and a pair of strong jaws having a lateral motion. (See fig. 1).

Bee's tongue.

On further examination, however, a flattened instrument, of a shining brown colour, is perceived extending from the lip towards the throat—this is the tongue, and at the pleasure of the bee it can be projected forward, either in a straight or a curved form, so as to resemble the beak of a bird, as is shown in figs. 2 and 3. It in reality consists of no less than five distinct branches; 1st, a central piece of very delicate structure, transversely ringed along the greater portion of its length, having a small circular orifice at the extremity; this is the true tongue or lingua, and from the base of this ringed portion arises a pair of feelers, which are scientifically termed the labial palpi, and which are composed of four joints, the basal one being the longest; these organs, when at rest, are defended by a pair of scaly instruments, convex outwardly, and concave inwardly, each of which consists of a basal and terminal portion, articulated near the middle; conjointly, these latter are termed the sheath, and separately the demi-sheath. They correspond with the maxillæ of other insects possessing jaws, and near the middle are furnished with a small lobe-like joint, which is the only rudiment of the maxillary feelers, which in many other bees are very visible, and sometimes six-jointed.

In the third figure the parts are seen from the under side of the head, and one of the demi-sheaths is drawn aside in order to show the manner in which this part protects the tongue, the last joints of the palpi are observed at the extremity of the tongue.

From these figures, and especially from fig. 1 and 3, it will be perceived that when unemployed, the terminal portion of the demi-sheaths, the whole of the labial palpi, and the ringed portion of the tongue, are folded back upon the basal parting of the tongue and demi-sheaths.



Bee's sting.

The *sting* is an instrument scarcely less complex in its structure than the tongue. The whole of its mechanism is exhibited in the above figures. If a bee be held in the fingers, a dart, not finer than the point of the finest needle, is seen to be protruded from the extremity of the body. If this delicate instrument should be plunged into the finger by the infuriated bee, it will in all probability be left there before the bee can disengage itself, and the pain is too well known to need any descriptive comment.

It will be seen, from the above figures, that, like the tongue, the sting is composed of five parts; first, a pair of elongated flattened organs, between which, when unemployed, the extremity of the sting is lodged; second, the instrument itself, which is so frequently seen protruded from the tail of the bee, and which, upon a close examination, is found to consist of a canal having a gutter along its upper edge, within which two darts of the most exquisite construction play backwards and forwards, and which are armed with fine teeth set backwards; the sting, by means of the strong muscles at its base, is thrust forward, as in fig. 2., and, from its strength, forms a support for the interior serrated darts shown at fig. 3, which are plunged still farther into the wound, whence, from their structure, it is impossible to withdraw them without force; the poison, which is conveyed through the canal of the sting, is contained in a reservoir near the dilated base of the apparatus, and is connected with it. The channelled sheath with its serrated weapon are shown on a large scale at figs. 4 and 5; and it will be obvious that its structure admirably fits the possessor to protect the fruits of his laborious industry from any enemy less powerful than man, and even to the "lord of the creation" it becomes an instrument of terror.

BEECH TREE (*Fagus sylvatica*). A tree belonging to the Linnæan class and order *Monœcia Polyandria;* natural order *Amentaceæ*. Generic character: male flower—calyx bell-shaped, five-cleft; corolla none; stamina five to twelve. Female flower—calyx four-cleft; corolla none; styles two or three three-cleft; seeds an angular or three-corner shaped nut, one or two contained in each muricate capsule, which opens with four valves, and emits the nuts. The beech is indigenous to Britain; many extensive natural woods of it are found on the Chiltern Hills and other chalky districts of England. It is a highly ornamental tree; and very much cultivated for its timber, which is of a fine close grain and very durable when converted into Tunbridge-ware, turnery, mill and wheelwrights' machinery, cabinet-makers' articles, &c. It is also used in the dock-yards for wedges; by musical-instrument makers for sounding boards; by coopers for clap-boards. It is very much used in the manufacture of charcoal, and no kind of timber is more used, or better adapted for billet wood. It is also extensively used for sheet-piling of canals, and for round or square piles for the foundations of bridges, or other buildings standing in water, as it is very durable when kept constantly under water.

The tree being very hardy is well calculated for planting in bleak situations where the shelter of woods would be beneficial. It withstands the sea breezes as well as any other; and, though a native forester, is a very suitable tree for park scenery; its fresh green tint in spring, graceful form in summer, smooth silvery bark, and its many rich and mellowed hues of autumn, adds greatly to the beauty of the landscape.

As a rustic fruit tree it is of great value; the fine flavour and fattening qualities of its mast or nuts afford the highest treat to deer and vast droves of swine. To some of the wild inferior animals, both birds and quadrupeds, the nuts are a constant feast; the woodpigeon, jay, and nuthatch, among birds, and the badger, hedgehog, squirrel, rat, and different species of mice, not only live on the mast during autumn, but lay up winter stores of them in their nests and burrows. Even man himself, in some places on the continent, makes the kernels a part of his diet, roasted and used as coffee, and the expressed oil serves instead of butter. This oil is considered next in fineness to the olive, is employed for lamps, and many other useful purposes in the arts, and by mechanists. According to Michaux, "the forests of Eu and Crecy, in the department of the Oise, have yielded, in a single season, 2,000,000 bushels of beech-mast." The oil millers readily buy up whatever quantity of the nuts they can procure; but the lords of manors seldom allow the nuts to be gathered, as their tenants have generally a right of pannage.

The beech tree as well as the hornbeam was formerly much used for hedges in pleasure grounds and gardens as sheltering boundaries; and, being clipped in summer, the remaining leaves die, without falling from the tree till late in the spring On the continent fields are fenced with beech trees. They are planted when young near together, and when grown up five or six feet high are intertwined right and left, and tied together where the stems intersect. In a few years they become engrafted with each other, and then form a very durable fence.

The bark contains a little of the tanning principle, but far inferior to that of the oak. It is also the thinnest of, perhaps, all forest trees; that on a tree of a century old being hardly one quarter of an inch thick. This is the more surprising when we consider that the bark receives an addition of liber in every year of its age. But these annual layers of liber are as thin, and being constructed like fine gauze, are compressed so closely together by the internal growth of the wood, that they occupy but little space. Add to this, that the bark of a beech is not rent into exterior fissures, like that of the oak, to make room for the new layers of wood within, but is stretched horizontally like the lateral spreading of a net, the opened meshes of the cortical tissue being filled up by the parenchymous matter in which the fibrous tissue of all the libers lie imbedded.

With reference to the cultivation, it may be proper to state, that no forest tree is easier raised than the beech. A bed of light loamy earth is prepared, by digging and levelling with the rake; about an inch of the surface is drawn off to each side, the nuts are then spread regularly over the bed, and the earth drawn over again from the sides that the seeds may be covered about an inch deep. This sowing may be done any time between October and February. The bed must be guarded from mice, jays, &c., as well before as for some time after the seedlings appear. These stand on the seed-bed for a year or two; and are then transplanted into nursery rows, to gain strength before removal to their final stations.

Sir John Evelyn, the great founder of beech planting in this country, in describing his process, says, that "for woods the beech must be governed as the oak; in nurseries, as the ash; sowing the mast in autumn, or later, even after January, or rather nearer the spring, to preserve them from vermin. They are likewise to be planted from young seedlings, to be drawn out of the places where the fruitful trees abound." A later author says, "The season for sowing the mast is any time from October to February, only observing to secure the seeds from vermin when early sowed. The sooner they are sown the better, after they are fully ripe."

Besides the common there are several ornamental species or varieties, viz. the purple-leaved, than which no tree is more conspicuous in a pleasure ground, being so great a contrast to the general colour of trees. Of this there is a sub-variety called the Golden Stripe-leaved, which is planted in shrubberies; next there is what is called the Copper-leaved, allied to the purple, and only different in the colour of the foliage. Another from North America is called the Broad-leaved, seemingly a distinct species; as also two others from the same country, viz. the White and Fern-leaved beech trees.

All these are propagated by layers or grafting in this country; and all are admitted into arboretums, or for diversifying ornamental plantations.

Beech Tree.

As the beech kernel is so agreeable to the palate, and perfectly wholesome to the human constitution, it has been suggested whither it be capable, as the hazel has been, of improvement by domestication and culture. If by the art of cross impregnation, or extremely high garden management, the nuts could be advanced to the size of its congener, the sweet chestnut, the result would be of importance to the nut-eating mortals of the south of Europe. Such a result may rationally be expected; and it is one which should not be lost sight of by the fruit cultivator.

BEE-EATER (*Merops*). A genus of *Alcyonian* or *Syndactylous* birds, remarkable for the bright colours and metallic lustre of their plumage, as well as for the nature of their food. They get their English name of "Bee-eaters" because bees form a large portion of their prey, though they also feed upon wasps, hornets, and various other insects of long and comparatively rapid flight. The order or group are called *Alcyonidæ*, from the resemblance they have in their structure and some of their habits to the kingfisher (*Alcedo*); and they are called *Syndactyli* from the structure of their feet, which are the least used in finding their food, and the least efficient for any species of locomotion which are found among the feathered tribes. Syndactylic means "having the toes together;" and these birds have the exterior front toe united to the middle one as far as the second joint, and the inner united to the same as far as the first joint. In the genus under consideration, the hind toe is enlarged at the base, and the claw upon it is very short.

Feet of this description are neither well adapted for walking nor for perching; and few of the birds which have them perch for any other purpose than that of rest, for which the foot is, on account of its stiffness, and the shortness of the tarsus, well adapted. But these feet answer well for another purpose, that of digging in the ground, which is a habit not of this genus only, but of most of the order, in the construction of their nests, which are frequently made as deep as six or seven feet, in steep banks of soft earth.

The generic characters of the bee-eaters are: the feet, as already described; the bill of mean length, triangular at the base, slightly arched, having an elevated ridge on the culmen, sharp pointed, and strong and hard in the tomia or cutting edges; the wings long and pointed, the first quill generally short, and merely supporting the second, which is the longest in the wing; the form of the tail varies with the species, being square at the end in some, forked in others, and in others again with the middle feathers produced, but in all the species it is of considerable length. There is a double hollow anteriorly on each side of the sternum, and the keel of that bone is very much produced, as in all birds of powerful wing.

The plumage upon these birds is not only beautiful in its colours, and rich and metallic in its lustre, but it is remarkably close and firm both in its texture and in its adherence to the skin; so that it is difficult either to deplume or ruffle the birds by any ordinary casualty. Even the skin is much tougher than that of birds generally; and though the flesh, at least of many of the species, is said to be both palatable and wholesome, the birds have to be skinned before they are dressed, in the same manner as such of the omnivorous birds as are eaten.

The nests, as has been said, are placed deep in the ground, so deep as not to be very much affected by changes of atmospheric temperature; and as the birds are day-feeders only, both male and female are in the nest during the night, the one on the eggs and the other between and the entrance, acting as a sort of screen. The temperature of the eggs of these birds during the incubation is consequently much more uniform than that of the eggs of surface or of tree breeders. At the same time, it is a low temperature as compared with the temperature of the atmosphere during the day in the places which these birds inhabit; the greater number of them being found in the hottest parts of the eastern continent, and only one making its appearance in Europe, and that one not found to the north of the forty-eighth parallel of latitude, except as a rare and accidental straggler. The eggs which are deposited in the deep excavations made by these birds are placed, upon only a little moss. They are of a white colour, and vary in number from five to seven.

Eggs so placed, and of such a colour, are not subject to much heat from surrounding objects; and the smooth and glossy plumage of the birds renders them less capable of imparting heat to the eggs than those species which have the clothing on the under part more downy. From these circumstances it naturally follows that the process of hatching should be slower in these birds than in species which have their eggs at or above the surface of the ground. In their incubations, birds appear to work to a certain temperature, and the sitting of the bird seems to be for the keeping up of that temperature when the atmosphere sinks below it. If the nest is on the surface the bird may be said to work to the highest temperature which the place and the season afford, as is the case with the partridge among the clods, or the plover or lapwing on the dry heath. If the nest is elevated above the surface, the bird works to a lower temperature, as in the case of the rook on the top of the tree, or the swift in the crevice of the steeple. If again the bird builds in holes of the earth, especially in holes bored so deep as those of the bee-eaters, the bird works to a temperature still lower than that of the birds which build in lofty situations; but though the general temperature in those hole-building birds is lower than in any other summer breeders, it is much more uniform, and the bird may be said to have less labour in the incubation, very much in the same proportion as it has more in the excavating of the nest. And we find very striking differences in the development of life in the eggs, answering to those differences of what may be called the average temperature of the nesting places. This will be further considered in the article Bird; but still as the genus under notice may be considered as one of the extremes, a short glance at the differences may be useful here, upon the well-known principle that the mention of a law is most effective when accompanied by a practical case which proves its existence.

Now, if we compare the birds which have been mentioned, we shall find that there are striking differences in the rate at which the young are developed, and also in the texture (when matured) of that portion of the structure of birds which appears to require most labour in the development, namely, the feathers. The length of time during which the incubation lasts, until the young break the shell, is not very clearly determined, even in the species to which allusion has been made; but the state of the young birds at that time is satisfactorily known.

The partridge and plover come out of the shell in full activity, and may be said, in part at least, to find their own food in the very same hour. It is true they do not come out of the shell as fliers, neither can they be said to be fledged; but they run very rapidly, and have what may be called an infant clothing of down, which protects them from changes of temperature in their non-age, as completely as they could be protected by feathers.

The rook comes forth of the shell callow and in a helpless state, so that it would perish if it were not fed by the parent bird, and in the early stage if it were not sheltered by that bird during the night. Its feathers are not preceded by a downy coat; but first appear like little tufts issuing from those sheaths in which they are produced. The young rook is accordingly fed by its parents for a considerable time, and does not "branch" or perch apart from the nest for a week or two, neither does it take flight, or in anywise provide for itself until it is fully fledged.

The bee-eaters, and, in common with them, all the order or group to which they belong, and all birds which build in deep holes of the earth generally, are much less matured than even rooks are when they come out of the shell; and they continue still longer in the nest, and are fed there by the parents. Indeed, as compared with young birds which are met with in nests on the surface of the ground, or even above it in trees, and whether the nests be of rude or of compact structure, the young of the hole-building birds, and especially of the bee-eaters, have the appearance of being immature and untimely productions. Their very limbs seem rudimental; and the only part of them that gives evidence of being complete is the mouth, and the rest of the alimentary system. They have no down on them, neither is there any farther appearance of the future feathers, than little dimples at the places whence they are to issue; and to see them in their then naked condition, one ignorant of the appearance of the mature birds, would never suppose that those naked and helpless little things would in time become clothed in nature's very gayest attire, and fearlessly cross the ocean on lusty wing.

When, however, we come to look at the plumages of the three different kinds of birds which we have mentioned, we find a very beautiful confirmation of that general law both of nature and of art, according to which the result is always valuable or elaborate in proportion to the time and the efficient labour bestowed on the preparation of it. The feathers on the partridge and the plover, are downy or loose and spongy; they are also easily ruffled, and subject to be turned and even torn by the wind, while rain soon wets them. They are also in a great measure clothing feathers only, and can bear up the bird merely in short and apparently laborious flight. The feathers of the rook are more compact; and the rook can accordingly take moderately long flights, remain a considerable time in the air, and bear the violence of the weather, at least to a much greater extent than surface building birds can do on the wing. But still the plumage of the rook gets sadly torn when the season is boisterous and it has to range farther than usual for food; and if the rain descends heavily the rook cannot keep the sky, but seeks a perch on the nearest tree, or if there is no tree at hand, it descends and crouches in the shelter if it can find one, or stands huddled together facing the wind if there is none. The bee-eaters have their plumage far more compact than the rook, and also far more firm, both in respect of stiffness and toughness; so that, range where they may, and be the weather what it will, it is not subject either to be ruffled or torn.

Thus the deep burrowing, the low temperature, and the slow incubation and long infancy of the bee-eaters all conduce to a certain purpose,—a purpose which, according to the properties of matter, and the laws according to which nature acts in tempering that matter to the various organs of living creatures, appears to be indispensable for fitting the birds for that office which they perform. It seems that a feather of the best substance cannot be produced hotbed-wise, but must have time, and also uniform temperature, and temperature not too high. It appears that the action of the sun, alternating with the cold of night, would tear asunder the delicate tissue of vessels which is necessary for this firm structure of feather; and therefore the birds avoid them by burrowing in the ground; but in proportion as these feathers are formed under less violent action they require longer time; and then, when they are once matured, they stand in much the same relation to feathers of hasty growth, as steel which has been long beaten on the anvil does to cast iron. They are so tough they cannot easily be broken, and so elastic that they instantly spring back to their position when bent. These properties apply not merely to the shafts of the feathers but to the fibres of their webs; and thus, from the mere consideration of the feathers we might conclude, that in their ordinary habits the birds must have some arduous labour to perform; and we might further conclude that feathers of so elaborate a growth cannot afford to be moulted twice in the year, which last (as well as the first) is confirmed by observation.

We are thus to consider the bee-eaters, which are very numerous in species as well as in individuals, as birds prepared for a very marked office in nature, and it is of use to examine them well in their preparation before we follow them in their course, and watch them in the performances of their labours. We have seen that their bills are, proportional to the size of the birds, sufficiently large for being powerful, but at the same time not heavy; that they are strong in their cutting edges, closing firmly for the whole length, and sharp pointed, so as to divide the atmosphere like an arrow. The wings are long and pointed, not unlike those of the swallow tribe; and the muscles by which they are worked, have ample support, not only from the deep keel of the sternum, but from the furrows in that bone. The tails are long and strong; and the varied shapes of their terminations would lead us to infer three distinct varieties of habits, or rather of haunt among the genus. Thus those with square tails are for ascent or descent, those with the middle feathers produced for more forward flight, and those with the forked tails better able to wheel and turn in the air. Feet to aid in the capture of them, or in the maintaining of their position on the ground or elsewhere when in search of that food, these birds have none, as those organs merely perform in concert with the bill the operation of digging the burrow. Thus, in their feeding, which is the habit that stamps the leading character upon all animals, the bee-eaters are reduced to two instruments only—the wings to bear them to their prey, and the bill wherewithal to seize it Each of these instruments is, however, of so superior a character that it performs its labour most effectively, and the one does not interfere with the other, for the feeding of the bird never interrupts its flight.

As these birds feed by day only, and chiefly when the weather is fine, they are more completely children of the sun than any birds with which we in our northern climates are acquainted.

The colouring of the plumage of birds, unquestionably depends upon the sun, because they are gay and glossy in proportion as they are exposed to the action of that luminary; but the light of the sun must have a substance upon which it can act; and it appears to act most powerfully upon the firm feather which grows slowly, and, in the first instance, under cover. The colouration is an after process, though an obscure one, and one upon which it does not appear easy to get more information; but it has no apparent connexion with the colour of the egg; for the bee-eaters have, in one or other of the species, all the colours of the rainbow, as brilliant as in the rainbow itself, and yet the eggs are white. Whether the bright colours are less sentient to the sun than the more sober hues of the birds of cold climates, we are unable to tell; but the smooth surface, and metallic lustre must reflect the light, as well as decompose it by that refraction which shows the colours; and we find the same kinds of tint and gloss in the day-insects of sunny climes, as in the birds of the same. We may therefore conclude that the splendent plumage of these birds answers as a sort of protection against the ardour of the sun, just in the same manner as the half-furry clothing of the northern owls protects them against the pelting sleet and the driving snow, or as the down upon sea birds protects them against the action of the water.

Thus formed, thus armed, and thus defended, the bee-eaters are sent abroad to restrain the superabundance of those two-winged and membranous-winged (hymenopterous) insects especially, (though their feeding is not confined exclusively to these), which are abroad during the day in warm climates, and of these insects the numbers are immense; and as is the case with all numerous classes in which the principle of life is more than usually active, and which inhabit regions where the elements second and further that activity, they would in a short time usurp the general dominion, if it were not that their restrainers are in proportion to the excess of their energy. If we take the old continent southward of the parallel already stated, which is the limit northward whereof these birds only straggle, and that rarely, we find them increase in numbers as we approach the tropics, and become most numerous in the intertropical latitudes. They are met with throughout Africa, in Asia, south of the central deserts, in New Holland, in the Oriental Archipelago (which seems to be in an especial manner the head-quarters of the more brilliant air-birds), and they range far and wide among the clustered islands, which so beautifully diversify the wide expanse of the Pacific with their verdant surfaces. None of the numerous species is found in any part of the American continent, the analogous place in nature there being supplied by the genus *Prionites*, which resemble the bee-eaters in some respects, but differ very much from them in others. The comparison of these two genera of birds might, if followed out, lead to some important conclusions respecting the tropical parts of the continents themselves; and one of these would probably be found to be that the eastern continent abounds much more in sweet substances than the western, while the forests in the richer parts are less close and tangled. We have corroborative evidence in some of the characteristic mammalia, as in the long-armed apes of the East, and the sloths of the West; and it is not a little remarkable, that there is something like the same kind of analogy between the genus *Merops*, and the genus *Prionites*, as between these two genera of mammalia; the tree-mammalia of the East have long arms, and the air-birds long wings; and both are rapid in their several kinds of motions; the tree-mammalia of the West have short-arms, and the birds which most resemble the bee-eaters have but feeble wings, and both they and the mammalia of the same localities are rather slow in their motions.

The bee-eaters are nowhere birds of the desert, neither do they remain after drought has burned up the vegetation in districts where that is one of the alternations of season. In order that the insects upon which they feed may exist, there must be vegetation, and consequently humidity. Hence it is only by the banks of perennial streams that they can have permanent abodes, or along the margins of the sea in peculiar situations. The great majority of them are, therefore, in so far at least, migratory; but theirs is altogether a different kind of migration from that of the birds with which we are acquainted. The migration which we know, is northward in the summer and southward in the winter, constant to those seasons, and not varying much as to the period of time at which it takes place. It is a migration, generally speaking, in the direction of the meridian, and its extreme limits are the equator and the poles. The migration of the bee-eaters, (and various other tropical birds, participate in it along with them,) is a migration entirely tropical, and does not necessarily follow any general direction, or take place regularly at the same time of the year. It is true that on their northern limits (their only southern limit appears to be the sea), they in so far fall into the general economy of the place as to be seen in the warm season in places considerably north of any where they could be looked for, or even where, considering the nature of their food, they could exist in winter. Thus, for instance, the species which is found in the south, and more especially in the south-east of Europe, does sometimes straggle into the British islands, though its visits are exceedingly rare. It is generally in the county of Norfolk, or Dorset, where they are seen, and those counties are more remarkable perhaps than any other in England, for the appearance of rare birds. There a flock of as many as twenty has been seen at once, about June, and again (though of course the identity of the birds was presumed, not proved) in October; but where or how they spent the interval is unknown.

But these occasional migrations northward in summer, taking place as they do upon the mere confines of the proper locality of the genus, are to be considered as anomalies rather than as any part of the general habits of the birds. Where they are "at home," so to express it, their migrations are regulated entirely by the alternations of the tropical seasons, that is, of the rains and the drought; and as these depend in a great measure upon situation, it sometimes happens that at the same time of the year, the bee-eaters shall be arriving at the one of two places, and departing from the other, though both places are situated under exactly the same parallel of latitude. Thus it sometimes happens, that in those parts of peninsular India, where the one coast receives only the rain of the south-western monsoon, and the other coast that of the north-eastern, the bee-eaters migrate on the parallel of latitude from the one side of the peninsula to the other.

In the Oriental Archipelago, migration is, upon the whole, less necessary to them, because, for reasons in part explained in the article Atmosphere, many portions of the surface there, are perpetually verdant. Bee-eaters, as well as other species of birds, do, however, migrate from those favoured isles; but they may be said to do so rather for the purpose of gathering in an abundant harvest in other places, and again returning when the pastures which they visit are bare, than from any absolute want of food in their island homes. Many parts of New Holland are totally destitute both of insects and their food for a portion of the year, though they produce these abundantly at other times. This is more especially the case in the north-eastern or most tropical part of that vast island. There there are extensive districts, which, when the rains fall, are laid under water; and as this water evaporates by the action of the sun, a rich vegetation springs up, and then there are insects in myriads. At that season there is food for many bee-eaters; and where food is abundant nature always provides a corresponding abundance of feeders. When, however, the action of the heat, which is there very intense, and as the bottom of the sea reflects heat and light, the sea-breeze does not tend to fertilise even the shore, beyond the mangroves which grow in the water, the earth soon becomes burnt up, and there is no insect food, except for the species which inhabit the few hard-leaved trees that can endure such a climate, and these are not the proper food of bee-eaters. Of course there is an arrival and a departure of the birds annually in that country, and in all countries in which the seasons are similar.

In places where, though the plains are burnt up, the rivers do not run wholly dry, the seasonal movements of the birds are confined to the country itself. Thus, in southern Africa, where the *karroos* are rich with leaves, gay with flowers, and abundant in honey, which they always are in the fertile season, the bee-eaters find ample supplies of food over them; but when the karroos are burnt up, the birds must betake themselves to those places along the banks of the rivers where vegetation is still vigorous, and food is to be found; and all places which have their seasons analogous to those of southern Africa, whether they take place at the same time of the year or not, must subject the bee-eaters to similar migrations.

From these few hints some knowledge of the general haunts of the genus may be inferred; and, as is the case with all birds, they may be presumed to breed at that place and time of their range where food is most abundant, and the succession of it of longest continuance.

These migrations give the birds much exercise for their powerful wings, but these are also in constant exercise while they are feeding. Thus, if we except the swallow tribe, we have no birds in temperate climates which find their living by such severe and continuous labour as the bee-eaters. Many of the birds of prey have, no doubt, harder work while they are engaged in it; but then the capture of an individual furnishes the greater number with a hearty meal; and the smaller hawks, which occasionally feed on beetles, catch these right and left with their claws as they are flying. But the bee-eaters have no auxiliary to the bill; they have not the *vibrissæ* to it like the goat-suckers; they do not appear to have any glutinous secretion in the mouth; and the probability is that they do not, like many insect-feeding birds, fly with the mouth open when they are feeding. They capture their prey with a snap of the bill, as the swallows do; but as the food of the swallow is generally stingless, and many of the species on which bee-eaters feed have stings so powerful and so much envenomed, that it would not be very pleasant for the birds to take them alive into the mouth. Any one who has had the mischance to shut his lips on a live wasp can tell how awkward a matter it would be to attempt subsistence by swallowing these creatures alive. It is thus to be presumed that the bee-eaters invariably kill their prey by the snap of the bill, that is, by bruising it between the tomia the instant it is touched.

This renders their hunting (or hawking, if the word is more appropriate) a matter of course. Those insectivorous birds which hawk sightless, or at random, as one may say, must receive the insect in any way and in any part of the open gape to which the current, produced by the flight of the bird, happens to direct it. But the bee-eaters, and probably also the swallow tribe, must follow their prey by sight. The vision of swallows, and especially that of swifts, is known to be exceedingly delicate, especially as regards length of distance at which a minute object may be seen. But is probable that the power, especially the near-sight, or microscopic power of the bee-eaters, is much greater, because they have to seize the insect in a particular manner, which is not necessary in the others; and if we suppose a bird careering at the rate of fifty miles an hour, or probably of more, seeing a bee at the distance of probably a hundred yards, and coming up with it with such certain aim as to snap it instantly between the cutting edges of its mandibles, we may easily perceive how wonderful must be the power both of vision and of flight in the bird.

No human ingenuity could perform such an exploit, even though we leave the prehensile or snapping part of it out of the question, and that is the nicest of the whole. The arrow of Robin Hood or William Tell, or the bullet of the surest marksman that ever drew the trigger of a rifle in the back-woods of America, would have been, or be, altogether unequal to such a feat; and when we consider that the all-flexible atmosphere is the bow from which the arrowy bird shoots itself, our wonder may well be increased. There is, of course, leeward motion both in the bird and the insect, varying with the strength and direction of the wind, and also of the different specific gravities of the pursuer and the pursued, and the different rates of their motion. When the wind is beyond a certain strength, neither the one nor the other can "take it sideways;" but bees do fly, and bee-eaters capture them during light breezes, though, as we find swifts most assiduous in their lofty hawkings in that tranquil state of the atmosphere which immediately precedes rain, we may conclude that such weather must also afford most successful sport to the bee-eater.

But even granting that the air is perfectly still, except in so far as the forward rush of the bird produces a current—the capture is a very nice, and to our knowledge of mechanics, apparently an impossible operation. The pointed wings, the produced feathers in the tail, the lightness of the feet, the smoothness of the plumage, and the muscular quickness of the bird, together with the obedience of the whole to the eye which guides it to its object, work beautifully in concert; and when we consider what the bird has to perform, we may well cease to wonder both at the superiority of its organs of aërial motion, and the great length of time, compared with that of mere ground birds, which is spent in elaborating and perfecting them.

The space to which this article must necessarily be restricted, prevents us from following out this remarkable instance of the beauty and perfection of animal mechanics as it ought to be followed; but we trust that enough has been said to arouse the attention of the reader to a subject, than which there are few more worthy of being studied. The forms and colours of birds force themselves upon our notice by their gracefulness and by their beauty; and we may rest assured that nature never entices us to our disappointment, but that whenever she is more than usually attractive, the lesson which she has to teach us is certain to be, when fully studied, more than usually instructive. Fine as is the organisation of these birds, and perfect as are their movements, they are still wholly made of matter, and moved by such means as matter can be moved by; and therefore though their action involves a degree of mechanical perfection which we can never hope to equal, or ever nearly approximate, yet still it is mechanical action, and we may learn much by studying the bird as a model.

The details of species in this highly interesting genus form a department of study sadly different from the contemplation of the general structure and the habits. The real species, or those which possess all the generic characters, are numerous; and different describers have added to the perplexity by mentioning as bee-eaters, birds which may with more propriety be included in other genera; besides, other than mere size, colour, and locality, the specific distinctions are few, or, strictly speaking, none; for, though the different terminations of the tails would lead us to suppose that there are differences both in place of abode and in manner of flight, yet these differences are not established by observed facts; and though it be true of some other birds that those with square tails are most expert at ascending or descending in their flight; that those which have the external feathers of the tail much produced, can wheel in the air by turning upon them as pivots; and that those which have the middle few thus produced, so that the tail is wedge-shaped, are the steadiest upon a line in forward flight; yet these act in accordance with the general structure of the bird, so that we cannot implicitly rely upon the analogy in any other. But yet further to perplex us in the details of this genus, the habits of the birds are such that in wild nature the sights of them are but momentary. They are in the air, driving about like fine brands, or pieces of rainbows, according to their colour; and they will not perch and occupy themselves so situated till we can minutely examine them. Hence, not a few of the recorded species are no further known than the museum specimens; and thus, though there is no question that they exist and exist plentifully in nature, yet all that we know of their history may be learned by simply looking at them. There is, however, one slight advantage in the specific arrangement of these birds, an advantage in which all the birds of warm climates, which have rich and boldly contrasted colours, may be said to participate. It is this: their glossy plumage and gay colours are subject to much less variety either in different individuals of the same species, or at different ages, than in birds which are less gorgeous in their attire. The young come forth in mature plumage; and when they moult afterwards, the process appears to be so gradual, that there is little difference arising from season. Both of these might be expected; the preparation of the first plumage seems too laborious a process for being expended upon that which is soon to be replaced by a different one; and the necessity of these birds to be on the wing when they feed, renders it indispensable that they should be at all times in flying order. Even if they belong to those latitudes in which we could presume a short period when little food is required, still that is not the time at which birds moult; and in the latitudes which these birds inhabit, there is not even an approximation to any thing like hybernating on the part of any of the feathered tribes.

From the number of the species, the little that is known of many of them, the similarity of their habits, and the length at which the chief of these have been noticed, we shall give little more than a list of those which are most interesting, beginning with the European species.

Common Bee-eater (*Merops apiaster*). This is a very beautiful species, and certainly one of the finest of all the rare and local birds of Europe. It is about eleven inches in length, but the female, as is the case in most species of the genus, is rather smaller than the male. The extent of the expanded wings is about seventeen or eighteen. The colour on the upper part is of a maroon red, fading into yellowish rust-colour on the middle of the back; the front of the head white, shaded with green; the eye-streak large and of a black colour; the quills and coverts olive green; the neck golden yellow, marked in the middle with a half collar of black; and all the rest of the under part clear aqua-marine, or sea green. The bill black, and the feet brown. These are the colours of the male bird. In the female, the tints, where they resemble those in the male, are duller; she has a yellowish band underneath the eyes, and the breast shaded with reddish. In the young, the upper part is greenish brown; they have a reddish streak under the eyes, and are without the collar which marks the mature bird. The coverts are in them also nearly all of the same length, while in the old birds the middle ones are longer than the rest.

These birds are very rare in western Europe, as the southern parts of it are too dry for their habits; but, during the summer, they are by no means scarce in the south-east, and they range as far northward as the Don and the Volga, the steep and soft banks of which are drilled as thick with their holes as some banks with us are with the holes of sand martins. They are also abundant on the Lower Danube and the larger branches of that river—much more so, indeed, than nearer the Mediterranean, where the weather is more unsettled in the summer, and therefore not so well adapted to their habits. But though they do not take up a regular abode westward of the centre of Russia, northward of the Carpathian mountains, or generally much higher on the Danube than Hungary, they sometimes pay straggling visits to other parts of Europe, as has been mentioned in the case of those seen in Norfolk. Beyond the limits which we have stated they are, however, to be considered as mere stragglers, and the appearance of them in any place one year is no ground for even presuming that they will be found in that place the year following.

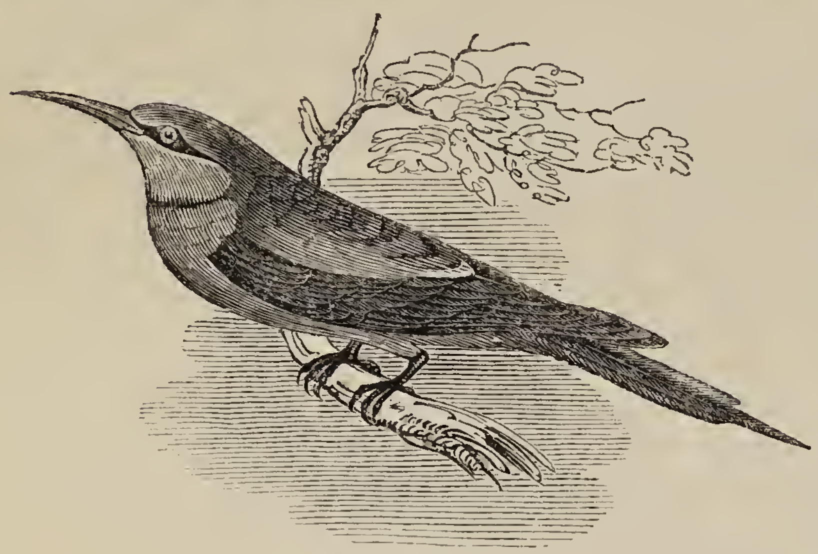
In all places of Europe they are to be considered merely as summer migrants, and as migrants in longitude more than migrants in latitude. They range from east to west, or rather from south-east to north-west, along the great internal basin, which may be said to extend from the Hindû Koosh to the Carpathian mountains, and only partially interrupted by the ridges of Caucasus. It is also probable that from the Oxus, which rises in the Hindû Koosh, and discharges itself into the sea of Aral in a direction nearly the opposite of that by which the Volga descends to the Caspian, they may pass the gorges of these mountains, and descend the Indus and the other rivers of India, upon the banks of which it is probable that many of them winter. They cannot winter in the country south-eastward of the Caspian, because though that country is very hot in summer, as is the case with the south and even with the north of Russia, it is cold in winter, the rivers being sometimes completely frozen over as far to the southward as Bokhara, where of course bee-eaters could not find food. The migration of birds along this basin is not confined to bee-eaters, but applies to many of the most interesting of the rarer insectivorous and aquatic birds which are found in eastern Europe in the summer, but quit that part ere the winter sets in. The pratincole and several of the herons belong to this migration, and some of them occasionally straggle into western Europe, as well as the bee does. The subject is, however, too extensive and too intimately connected with the general economy of nature in the wide region to which it refers, for being advantageously noticed while discussing the habits of a single species of bird.

This is the species which has been longest known, and the one to which the name of *merops* was first given, probably on account of the black streak or division across the eye. The habits of the bird were, however, much misrepresented by the ancients, who made it the type of filial affection, asserting that the young birds fed the mother while she remained at her ease in the security of the nest. There is no bird, and indeed, so far as is known, no animal which has that habit; and it would be contrary to the general rule of mere animal nature if they had. The old animal feeds and rears the young ones; and when it can feed and rear no more, its use in the economy of nature may be said to be at an end, and it speedily dies. This general rule is not departed from in the case of the bee-eater, for the old birds of these have to feed their young for a longer period than almost any other species.

The common bee-eater is also the only one which may be said to have a northern history, as the others have been met with chiefly at the other extremity of what may be considered the zone of their inhabiting.

The common bee-eater is so abundant in all the islands of the Archipelago and the Levant as to be one of the most common summer birds. The climate of those islands is very fine; and as, from their comparatively small size, no part of them is at any great distance from water, they abound with insects, which afford subsistence to all the species of insectivorous birds, especially those which prey on the wing

In these islands the species under consideration is as plentiful and as familiar in his habits as swallows are with us, only it builds, or rather burrows, in banks remote from human habitations. But, in search of its food, it flies in the close vicinity of houses; and, in Crete especially, the boys are said to angle for it in rather a curious manner. They catch locusts, or any of the larger winged insects, which have considerable power of flight; fasten the insect to a crooked pin or small fish-hook at the end of a line; and, letting the insect fly from the window, retain the line in their hand. The insect mounts up and endeavours to escape, notwithstanding the weight which it has to drag after it; and the bee-eater perceiving it in the air, snaps at it, is caught by the hook, and dragged home. This is perhaps one of the most singular modes of bird-catching, and yet anglers in this country sometimes catch swallows involuntarily, in a manner nearly similar, by means of their artificial flies; and the writer of this article has sometimes been astonished in casting his fly, at throwing a swallow on the water, instead of raising a trout. The swallow in this case no doubt catches the artificial fly while in motion through the air behind the angler; which in part proves, by the way, that swallows do not catch flies knowing them to be flies, any more than fish do, but that they merely pursue that which they see in motion. Water birds often do the same thing, especially with the larger kinds of flies; and it is not impossible to catch one of those birds while trying for a salmon. Indeed it appears that most animals which capture prey when it is in motion follow it just because it is moving; for boys sometimes catch the common bat by means of the heads of burdock, dipped in powdered whiting to render them more conspicuous. The hooks of these substances grapple the flying membrane of the bat, and thereby destroying its balance, by making one side heavier than the other, bring it to the ground. These circumstances, especially those of the bee-eater and the swallow, show how very slight a resistance can make even a bird of powerful flight lose command of itself when on the wing; and the consideration of them may well heighten our admiration of that dexterity with which birds, as they fly along, avoid, and that apparently without an effort, those numerous obstacles which are in their way.



Merops apiaster.

Merops Castaneus of some authors. This name has been given to two distinct species or varieties, or the one species has been found in two places pretty far distant from each other, and varying considerably in size.

One of these is named "Adanson's bee-eater," and is found on the Senegal and Gambia, in Western Africa. It is said to be sixteen inches long; to have the bill black, and the head red. The upper part of the body reddish-brown; the under part, the rump, and the lesser coverts, sea-green; the throat, the sides of the neck, and the breast, bright blue green; the quills green; the upper coverts of the wings blue, and the under ones ash-colour: the two middle feathers of the upper coverts being two inches longer than the others, and having their tips black.

The other has been described as the "Mauritius bee-eater," and is found in that island. It is much smaller than the former, being only eleven inches in length. Its colours are described as being almost exactly the same.

Many of the African species are of much smaller dimensions. Among these are the

Angola Bee-eater (*Merops Angolensis*), which, as its name implies, is found in Angola. Its length is about five inches and a half. Its colours are, golden-green on the upper part, and sea-green on the under. The neck and throat rich reddish-brown; eye-streak ash-colour, dotted with black; quills and coverts green on the upper side, and ash-colour on the under; the bill ash-colour, and the feet black.

Two-coloured Bee-eater (*Merops bicolor*). About the same size as the preceding; having the upper part reddish-ash, and the under part red. The eye-streak brown, the cheeks and sides of the head pure white; the wing-coverts black; the quills blackish-brown on the upper sides, and ash-coloured on the under. The bill and feet black.

Bullock's Bee-eater (*Merops Bullockii*), of which a figure is annexed, is also about the same size. The upper part is green mixed with fawn colour, in clouds or spots; and the under part brown. The crown of the head blue; the nape of the neck fawn-colour; the eye-streak black, and very conspicuous. The neck red; and the belly and under tail-coverts blue. The bill and feet black.

There are ten or a dozen other species, nearly of the same size, but differing considerably in their colours and marking, described as inhabiting different parts of Africa and the larger African islands; but it does not appear that they have any peculiarities of character which can render them interesting as subjects for popular description.

The physical circumstances of Africa make it peculiarly favourable for these birds, and indeed for all birds which have the power and the habit of ranging to considerable distances in search of their food, so as that when it fails in one place they can seek after it in another. Countries in which the rivers flow among mountainous ridges and with rapid courses, so as not to flood their banks, do not suit these bank-inhabiting birds. Their favourite localities are in those places where the floods, during the rains, fill the entire channel, and back water stands in pools behind those natural dykes which such rivers generally form for themselves. The mud on the banks and in the bottoms of those hollows where the water stagnates is just the proper nidus for very many species of insects; and when it becomes hot during the warm season, and approaches to dryness, it becomes literally alive with larvæ, which are very speedily on the wing. The same heat, too, and the same moisture upon which that heat acts, call up, in very brief space, an exuberant vegetation, which is in full flower in shorter time than is required by the lagging vegetation of our moderately-working climate to cover the clods. Thus as the dry season sets in, in such situations, a plenteous supply of insect food and insects, both of the kinds which gnaw the leaf and which suck nectar from the flower, is produced so rapidly, that to us, who are accustomed to watch the slow progress of the season for months, it would appear like magic. To-day the surface is a lake; one week passes, and it is sludgy mud, heaving with the motions of millions of living things; another week, and it is a flowery meadow, the air over which is literally cumbered with little wings. It is then high feasting-time with the insectivorous birds; and so rich is this feast on the banks of the African rivers, that all the migrant tribes which make Europe lively with their activity, and joyant with their songs during the summer, congregate to partake of it. The swallow from our chimneys, the martin from our sand-banks, the swift from our towers, the cuckoo from our thickets, the nightingale from our groves, and many others, turn their wings on the southern shores of England, and then onward with rapid flight to the Senegal, the Gambia, the Niger, or the Congo, there to wanton under an ardent sun, and fare sumptuously upon the fruits of an all-teeming earth, while with us the bud is wrapped up in its winter tunics, and the insect is in an egg so small and so well-concealed that it eludes the microscopic ken of the titmouse. There they meet with birds of southern Africa and of western Asia, all intent in the following of their own instincts, and all at peace with each other; and while the rays of the sun, striking perpendicularly downward, heat the earth like an oven, the air, which might else breed putridity and death upon the surface, is literally winnowed into healthy motion by the operation of wings.

All the great rivers of Africa, with the exception perhaps of the Congo, have this character. The places where they rise, or at least where they assume the majesty of rivers, are not very elevated, and therefore their currents are slow; and what they take from the uplands in which their feeders rise is not borne onward to the sea, as is the case in such turbulent floods as the Mississippi and the St. Lawrence, but deposited in fertilising mud along all the meadows on their banks; and, while those floods bring soil they bring vegetation, and also the smaller kinds of life. We have seen that the birds come to perform their portion in this work of exuberant activity; and the antelopes (see ANTELOPE) bound forward to browse the lighter vegetation, while the elephant, the rhinoceros, and the hippopotamus, are also welcome, and well-served guests at nature's universal table.

During this season, when there is plenty, and plenty unknown almost in any other clime, by the banks of the rivers, the plains are gradually becoming dry and scorched. There ceases to be food even for a bee in situations where, only a few weeks before, there was abundance, and consequently the bee-eaters betake themselves to the margins of the streams, and there remain while the dry weather lasts; but the excessive action of nature exhausts the humidity of the soil by a threefold waste: one part of it is evaporated, spreads in the air, and forms dew upon the margin of the desert, so as to preserve for a time there that hard and scattered vegetation which is the food of the antelope and of some other mammalia; another part of it is taken up by the action of living vegetables; and a third portion goes for drink to the animated tribes, from the mite upward to the elephant. This rapid action, in many instances, exhausts and withers the surface almost to the river's brink, before the turn of the season comes; but in the more favoured situations, the pause in nature arising from this cause is brief, and the second flood comes while something yet remains of the abundance of the first

As that flood swells, and the birds would be driven from their holes in the banks by the rising waters, the uplands, erewhile sterile by the drought, enjoy the rain, and profit by it for some time before it causes any alteration in the river; so that, by the time the birds are driven from the one locality, the other locality is prepared for their reception and maintenance. The same agent which forces them from the one place fits the other place for receiving them: that agent is the rain, distributed in its season by those periodical movements of the air, a short account of which will be found in the article ATMOSPHERE.

The bee-eaters form only one part of this great seasonal action in Africa; but they form a beautiful and interesting part, and their movements cannot be well understood, or their uses in nature appreciated, without some such allusions as those which have been made. In their other localities, as in India and the Oriental Isles, they are not quite so characteristic of the succession of seasons, neither are they so much so in the narrow part of Africa, southerly toward the Cape of Good Hope, as in the middle latitudes, where the continent is broader. The seasonal action there is chiefly between the sea and the land, and in great part between the one hemisphere and the other; whereas, in central and northern Africa, the action is chiefly between the thirsty desert and the fertile plains along the rivers. Therefore, all the birds and other animals which resort to Africa by migration, or migrate seasonally from one part of it to another, have an African history somewhat different from that which even the same species have in other parts of the world.

There are still some African species, which we may notice on account of the beauty of their colours.

RED-HEADED BEE-EATER (*Merops ruficapillus*). This species is about eleven inches long, and eighteen in the expanse of the wings. Its colours are: the upper part bright green, with metallic lustre; the under part greenish yellow, glossed with rose-coloured reflections; the head maroon red, with green reflections, which colour also extends in part over the nape; the eye-streak black, a portion over the eyes white, and the throat bright yellow. This species, which, from the measurement stated, is of considerable size, is one of the most beautiful of birds. Its colours are equally remarkable for the purity with which they show an entire tint in some directions of the light, and for the contrasts which different positions of the light bring out. It is also very compact and handsome in its form. The colours of the female are not so bright as those of the male, and the size is rather inferior.

TARVA BEE-EATER (*Merops hirundinaceus*). This species gets its trivial name from flying rather higher, and having more the habits of a swallow than many of the genus. It is by no means rare in southern Africa, and is the species which is there known as the "gnat-snapper," though that name is given to bee-eaters generally by the colonists at the Cape. This species is of a clear yellowish green on the upper part, and pure green on the under; the throat yellow, with a blue collar; the rump and wing coverts blue; the eye-streak, the bill, and the feet, black; the tail is very long, and much forked; and the bird wheels about in the air much in the manner of the swallows.

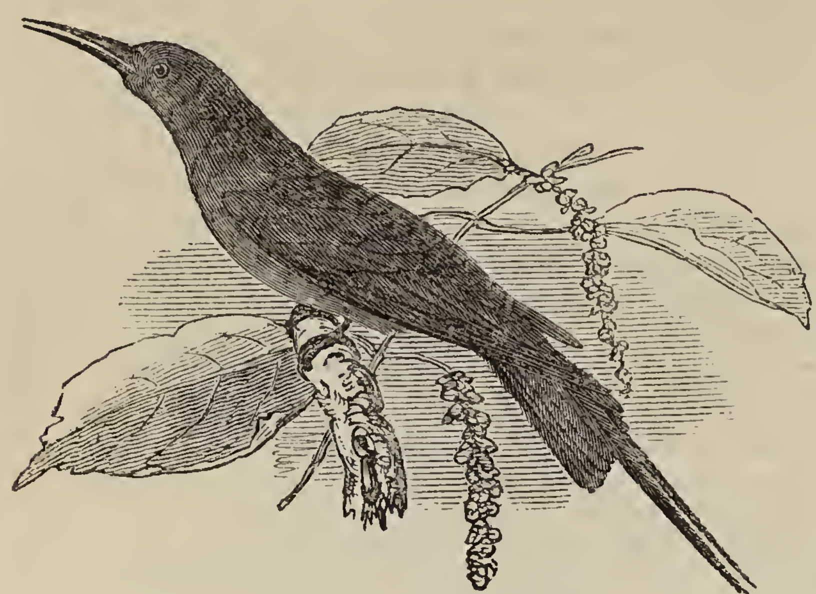
THE EYE-BROWED BEE-EATER (*Merops superciliosus*) is an inhabitant of Madagascar, and about eleven inches in length. The upper part is dull green, but brighter towards the rump. There is a large streak of black proceeding from the base of the bill over the eye to the throat, where the streaks unite and form a gorget of maroon brown, the throat being pale yellow, and the border of the streak greenish white. The top of the head is brown, with reflections of very brilliant green. The quills are green; the covert green, margined with brown and tipped with black; the bill is black, and the feet brown. This is also a very beautiful species.

We shall now notice one or two of the species which are described as being natives of the Asiatic isles.

FIVE-COLOURED BEE-EATER (*Merops quinticolor*. This species inhabits the Spice islands. It is about eight inches in length, bright maroon brown on the upper part, and blue mottled with yellow on the under; the scapulars and coverts are bright green; the rump and part of the quills blue; the throat yellow, with a black collar; the bill black, and the feet yellow.

GREEN-COLLARED BEE-EATER (*Merops viridis torquata*). This is an Indian species, about eleven inches in length. It is green on the upper part, but clouded with ash colour, and greenish white on the under; the forehead sea-green; the throat pale yellow; the upper coverts green, bordered with brown; the under coverts paler; the bill and feet black.

SUMATRAN BEE-EATER (*Merops Sumatranus*), of which the following is a reprentation, has the head and upper part of the neck rich brown; the throat, rump, and tail coverts, bright blue; the breast and wing coverts green; and the quills, tail feathers, and bill, black. It is a native of Sumatra.



Merops Sumatranus.

There are many other Asiatic species, but as nothing is known of them beyond the museum descriptions, a transcript of these could afford no information, and consequently give no pleasure to the general reader.

BEETLE. The English name used to designate insects belonging to the order coleoptera. In general it has reference to those particular species which are of obscure colours and found in dark or damp situations; but the term is by no means exclusively employed for coleopterous insects, since the black beetle, or, as it is more specifically, but not more elegantly, termed the cockroach, belongs to another order, namely, the orthoptera, distinguished at once from the coleoptera, by having the wing-cases of a less firm consistence, and not meeting along the back in a straight line. If it be deemed advisable to employ English names to designate the orders and genera of insects, and indeed any other of the less known groups of animals, it must be admitted that the English names ought to be as restrictedly employed as the scientific ones in the stead of which they are used; hence, the term beetle ought to be confined to coleopterous insects alone.

These animals are exceedingly numerous; and though there is a sort of general character which runs through the whole, in consequence of which they cannot be mistaken for or confounded with any other tribe, they vary very much in the details; and the forms of some of them are exceedingly curious. The greater number of them are a very sturdy race in proportion to their size; and in the perfection and strength of their horny covering, not only in the cases of the wings but upon the body and limbs generally, they are among the most perfect instances of that peculiar kind of strength and action which characterises the articulated animals. See Articulata.

Though the greater number of beetles, even of those which inhabit the waters, can fly, yet flight is with most of them rather the means of change of place than of the immediate search of their food; and even the aquatic ones are chiefly breathers of air rather than breathers of water; but as insects do not breathe by the mouth, but by stemmata, or spiracles, which are often on the abdomen, the water-beetles do not raise the head above the water in breathing, as is the case with aquatic mammalia, they elevate the opposite part of their bodies, as may be seen in the case of the dytisei, or plunger beetles.

Generally speaking, they are obscure animals, living in the earth, or otherwise in concealment, for the greater part of their lives. They are mostly very voracious both in the larva and the perfect state; and, though there are exceptions, their general function in nature appears to be that of scavengers. They consume indiscriminately in the different species, all manner of substances, animal or vegetable, which would otherwise be wasted; though there are several species which prey directly upon living animals, and others upon living plants.

The quantity of substances that they consume, which would otherwise become offensive, might appear almost incredible to those who do not consider their numbers and their activity; and, though none of them are very large animals, perhaps there is no race more useful in the economy of nature than the beetles, especially in warm climates, where the action of life and also of putridity are peculiarly strong.

They are also great favourites with those who form collections. Their forms are not, in general, handsome, according to the commonly received notions; but their colours are, in many of the species, the most splendid that are met with in nature, on account of the richness of their tints, the brilliance of their metallic lustre, and the iridescence of their varying hues as the light falls differently upon them. In consequence of the firmness of their covering they also alter less in the dead state, either by shrivelling, or by the fading off of their tints, than almost any other animals; so that a collection of the bodies of dead beetles, comes nearer in appearance to a collection of living ones than is the case in almost any other animals, the shells of the mollusca not excepted, as the tints of these when living are often in the epidermis.

Of animals which are so numerous there are of course many subdivisions, which cannot conveniently be explained under the English name beetle. Therefore it will be more convenient to refer them to the general article Coleoptera, and the subordinate ones which are referred to from that.

BEGONIACEÆ. A natural order of dicotyledonous plants, allied to the Polygoneæ, containing one genus and about forty species. The characters of the order are: flowers unisexual; tube of the coloured calyx adnate with the ovary, limb of the calyx, in the sterile flowers, consisting of four species, in the fertile of five; stamens distinct or united into a solid column; anthers collected into a head, two-celled; ovary winged, three-celled; stigmas three, two-lobed, sessile, somewhat spiral; fruit capsular, winged, three-celled, with numerous minute seeds.

The plants of this order are herbaceous or shrubby, furnished, like the Polygoneæ, with an acid juice, and having pink or white flowers growing in cymes. They are common in the East and West Indies and in the warmer parts of South America. No species are met with on the African continent, although some exist in Madagascar and the Isles of France and Bourbon.

The Begoniaceæ require considerable heat and humidity, and are easily propagated by seeds or cuttings. Few of them are used either in an economical or medicinal point of view, being chiefly prized as ornamental plants. They yield an acid juice as has been already stated, and their roots are bitter and astringent.

The only genus is Begonia, whence the name of the order is derived. Many of the species are cultivated on account of the neatness of the foliage, and the showy nature of their flowers. The silver-spotted and two-coloured Begonia are the most beautiful species.

Bicolour Begonia.

The genus is remarkable for the peculiar obliquity of the two sides of its leaves, which, in the Begonia bicolor, resembles the ramifications of the blood vessels in the human frame.

Begonia grandiflora and *tomentosa* are mentioned by Decandolle as being used in Peru, on account of their astringency, in fluxes of blood and diseases of the chest.

BELEMNITES. A fossil found in great abundance in most of the formations from the lias upwards. The origin of these singular productions has at all times been involved in great obscurity, as nothing analogous to them in form has been observed among living animals; and it is curious to observe the different opinions which mankind in various ages have held respecting their production.

They were known to the ancients. Ovid, in the 15th book of his Metamorphoses, assigns them a very fanciful origin; whence they received the name of *Lapides Lynces, Lyncurium,* &c. They were also known by the denomination of *Idæus Dactylus,* possibly from their resemblance to fingers, and also from their having been found on Mount Ida.

Among the northern nations it was a common opinion that these stones were petrified fingers, fabricated by demons, in order to be used in those mysterious rites of supernatural agency of which their fierce and gloomy superstition fostered the belief. By them they were designated by terms referring to such agency, their common names being those of "Devils' Fingers"—"*Spectorum Candela,*" &c.

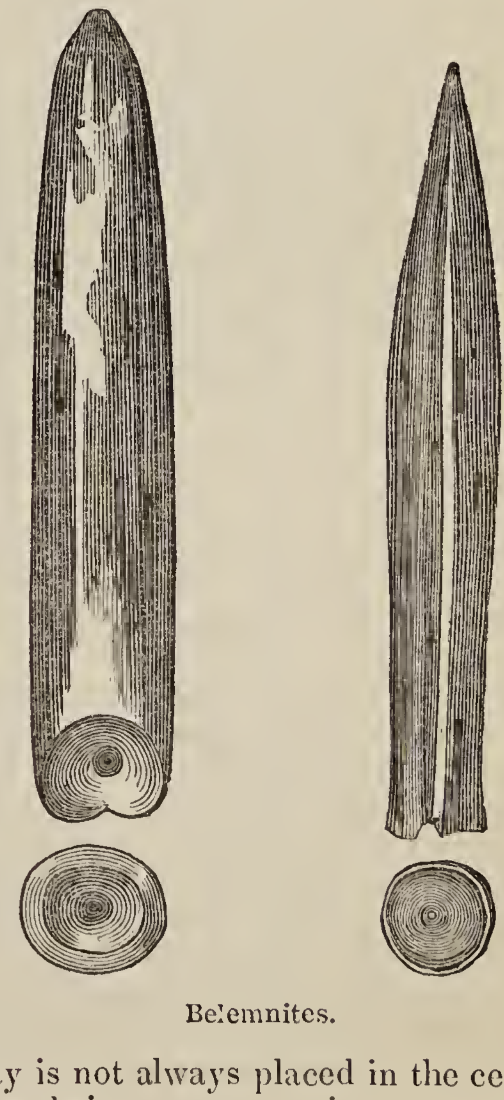
As fossils came to be better understood, the belemnite was supposed, on account of its conical cavity, either to be the remains of the tooth of some unknown animal, or, as it was usually found associated with marine productions, a spine similar to that of the echinus.

When at length, with the advance of science, it came to be considered as the remains of a testaceous animal, new theories and conjectures arose. It was first supposed to be a dentalium, then a limpet; but further observations at last proved it to be the remains of a univalve shell, divided into chambers, pierced by a tube, and similar in their construction to those of the nautilus, which was inclosed in an outer case or sheath, having a sparry mineral structure, radiating from an axis, passing perpendicularly through the fossil, which, in its most perfect state, is formed of carbonate of lime.

When perfect, it presents the appearance of two conical shells, the apex of the one being inserted into the base of the other.

Its general appearance is that of a straight, elongated, conical shell, formed of two distinct and separate parts. The external being a solid sheath, having a conical cavity in the upper part, which contains an internal conical nucleus, which is pointed and chambered transversely through its whole length. The chambers are slightly concave on the one side, and convex on the other, perforated by a lateral siphuncle.

The outer case is most commonly found without the nucleus, being merely the sheath, of the internal conical mass; its form is that of a long cone, more or less pointed; and it often has a lateral groove; it becomes solid as we approach the apex, whilst the base is perforated by the conical cavity before mentioned, for the reception of the multilocular nucleus.



Belemnites.

This cavity is not always placed in the centre of the cone, there being numerous instances of its being placed on one side, and a division passes from its point to the apex of the cone.

The very valuable researches of the late Mr. Miller have thrown much light upon the probable origin of these very singular fossils. They are detailed in an interesting paper read before the Geological Society, and which is published in the second series of their Transactions, vol. ii. He observes, that "the chambered structure of the conical shell of the belemnite and its siphuncle exhibit a striking analogy with the orthoceratite, the nautilus, and the ammonite. It differs, however, essentially from the orthoceratite in the circumstance that all the parts of its shell present, on fracture, a laminar, fibrous, spathose substance, in its being provided at its posterior end with a more or less elongated and encompassing guard or sheath, and in the siphuncle of the chambered cone being situated near the margin. This last character, combined with the fibrous and spathose texture of the shell, at all times affords a discriminating character between the chambered cone of the belemnite, even when occurring separated from its guard and the orthoceratite."

From this analogy of the belemnite to the nautilus in the chambered parts of its shell, he considers that no doubt can remain of this shell having been, like that of the nautilus, intended to increase the buoyancy of the animal to which it belonged; and also that the chambers of the internal cone were formed at various periods, as the growth, &c., of the animal required. This chambered part appears to have extended very much beyond and above the upper extremity of the guard or sheath, and also to have been in the upper part of much larger dimensions. He also conjectured that the last, or outer chamber, did not appear to have possessed, at any time, any great depth; but later observations have shown this opinion to be erroneous, specimens having been found in Germany in which the outer chamber is of considerable depth. The guard or sheath varies much in different species; in some being fusiform, in others concave; in some it is but slightly elongated, in others of considerable length; in some it has a round, in others an elliptical circumference; its termination is either acutely pointed, conical, compressed, mamillated, or even slightly hooked. In some species one longitudinal groove is found, in others two or three; and in some impressions, may be traced which are evidently the marks of muscles which have encompassed this part of the belemnite, and which show the impressions of branching vessels. These appearances are more particularly to be seen upon those which are found in the chalk. In those which are transparent the guard appears to be formed of two or three nearly equal longitudinal portions, which may be easily separated along the line of their adhesion by a slight blow of a hammer. The edges of these longitudinal portions are irregularly waved, and adhere closely together.

If we examine a longitudinal or transverse fracture of the sheath, we find it to be formed of several concentrically superposed laminæ, perfectly corresponding in structure with those in the chambered cone. Its general appearance is that of a substance radiating in lines from a centre to the circumference, which centre is formed by the prolongation of the point of the conical cavity in the upper part, and is supposed to have been produced by the decomposition of the nacreous matter of which it was originally formed.

From various circumstances it is concluded, that this shell was secreted by the animal much in the same state as it is now found, and that it was like that of the recent, and, with respect to its chambered divisions, analogous genus Spirula, inclosed in the body of the animal; and thence it is conjectured that the animal to which this shell belonged was like that of the Spirula, one of the cephalopodous division of Mollusca, that it held an intermediate place between the two subdivisions of those animals, the Nautilaceæ and the Sepiaceæ, uniting the internal multilocular shell of the former with the laminated calcareous mass of the latter, and that in form it resembled the sepia, or cuttle-fish, having a body of an abbreviated form, partly inserted into the first or upper chamber of the internal cone, and connected to it by a duct extending from it to the end of the siphuncle, and also having powerful muscles extending over the guard for its whole length, having secreting surfaces, and capable of encompassing it.

The figure given in plate 2, Fossil Remains, is that of the *Belemnites elongatus*, a species which is found in the oolite and lias. It is taken from a remarkably fine specimen in the possession of J. S. Bowerbank, esq., F. G. S., and exhibits in a very beautiful and satisfactory manner the upper or chambered portion, with its divisions or septa, inserted into and extending beyond the elongated conical sheath, which in this species is long and narrow.

BELVISIACEÆ, or BELVISIEÆ. A natural order of plants, containing only a few genera and species: it seems to be allied to the Styracineæ. The characters of the order are:—calyx of one piece, with a divided limb, persistent; corolla monopetalous, plaited, deciduous; stamens inserted at the base of the corolla; ovary adnate with the tube of the calyx; one style; stigma lobed or angular; fruit, a many-seeded berry.

The plants included in this order are shrubs which are found in South Africa and Brazil. Their properties are as yet unknown. The chief genus is Belvisia, whence the name of the order is derived.

BEMBECIDÆ (Leach). A family of hymenopterous insects belonging to the division Aculeata, and section of burrowing sand wasps (Fossores). In the Linnæan system the species were arranged with apis, on account of the length of the tongue. The legs are short, or but of moderate length; the fore legs of the females being furnished at the sides with very strong spines for burrowing in the sand. The collar is transverse, not extending to the base of the wings. The head appears transverse from above, the abdomen is of an elongated semiconical form, and the upper lip is exposed. These insects are chiefly inhabitants of warm climates, and their bodies much resemble those of wasps, being generally variegated with yellow, and black, and smooth; the antennæ are inserted close together, and the jaws are long, narrow, and toothed at the tips. The abdomen is generally armed beneath with one or two spines in the males. The perfect insects appear in summer and fly with great rapidity from flower to flower, making a sharp buzzing noise. Many of them emit a scent similar to that of roses. The habits of these insects have lately been investigated with much attention by the count de Saint Fargen, whose observations we shall here introduce to the English reader. The females form oblique cylindrical burrows in sandy situations, and provision them with perfect dipterous insects; *Bembex rostrata*, for this purpose, indifferently collects drone-flies (*Eristalis*), the species of Stratiomys, and large species of common flies (Musca, such as

Vomitoria). *Bembex tarsata*, according to Latreille, selects *Bombylii*. As each cell is capable of containing five or six flies, the female frequently follows her prey during the period of deposition of her eggs. Each time she quits her burrow, she shuts up the mouth with sand to prevent the entrance of enemies. Although these insects work singly, and not socially, the same bank generally contains the nests of many females, thirty of the latter having been observed in the space of twenty feet. When a sufficient quantity of flies have been collected and imprisoned in the cells at the end of the burrows, the female deposits a single egg in each cell, carefully closing its mouth; the grub, when hatched from the egg, devours the flies, and then passes into the pupa state, from which it soon afterwards emerges as a perfect insect. Certain species of Chrysidida or golden-tailed flies, including the *Parnopes carnea*, seize the opportunity of the absence of the female bembex to deposit their eggs in the already-provisioned nests, the spined structure of their legs enabling them to make their way through the entrance. The Parnopes have been observed entering the burrow tail foremost, when it is evident that her object is to deposit her eggs therein. When hatched, the grubs (one only being found in each cell), in the following spring, attack the legitimate inhabitant of the cell, which had attained its full size in the autumn, and destroy it. Thus it is throughout nature. The bembex larvæ feeds upon flies; the parnopes larvæ devours the bembex larvæ.

One species of this family alone has been introduced doubtingly into the British catalogues; no decided instance of its capture having occurred. It is the *Apis rostrata* of Linnæus. The family comprises three genera; namely, *Bembex*, tongue long, upper lip triangular, palpi short; *Monedula*, tongue long, upper lip triangular, palpi long; *Stizus*, tongue short, upper lip short and rounded.

BEMBIDIIDÆ (Stephens). A sub-family of coleopterous insects, belonging to the section, and forming portion of the great division constructed upon the Linnæan genus *Carabus*. Mr. MacLeay united the insects composing the sub-family, but they appear to be at once distinguished from all the other groups of carabideous insects, not only in their structure and diminutive size, but also in their habits.

They may be characterised by their fore-shanks being furnished with a notch, the elytra rounded at the extremity, the abdomen not attached to the thorax by a footstalk, and the external feelers of the lower jaws terminated by a very minute and acute joint, and the antennæ are of moderate length. Unlike the majority of the Carabidæ, these insects are generally found in damp, low, and marshy situations. They are, for the most part, to be met with under stones, beneath which they hide themselves, most probably because it is in such situations that they meet with their prey; the structure of the mouth evidently indicating sufficiently predaceous powers. It is supposed that they feed upon still more minute insects than themselves. They are of a very small size, of highly-polished and metallic colours, and often ornamented with spots of pale colour upon the dark ground-work of their wings. Some of the species, especially those that constitute the restricted genus *Bembidium* of Latreille, have very much the resemblance of small tiger beetles; indeed they were placed in the genus *Cicendela* by Linnæus. This family is rather extensive, upwards of seventy species being recorded as natives of Great Britain and Ireland. These have been arranged by Zeigler, Megerle, Stephens, Leach, &c., into ten genera: namely, *Lymnæum*, 1 species; *Cillenum*, 1 species; *Tachys*, 8 species; *Philochthus*, 6 species; *Ocys*, 3 species; *Peryphus*, 16 species; *Notaphus*, 9 species; *Lopha*, 11 species; *Tachypus*, 9 species; *Bembidium*, 4 species. These genera, with few exceptions, rest upon minute differences in the form of the thorax and other slight characters, which, however, it seems necessary to have recourse to for the purpose of distributing the extensive group into convenient divisions.

BERBERIDEÆ. The Barberry Family. A natural order of dicotyledonous plants, containing seven known genera and forty-seven species. It is nearly allied to the Menispermaceæ, or coculus tribe. The essential characters of the order are:—sepals or leaves of the calyx, three, four, or six, deciduous, in a double series, accompanied by scales; petals hypogynous, equal in number with the sepals, and opposite to them; stamens equal in number to the petals, and opposite to them; filaments short; anthers oblong, two-celled, opening by valves; ovary solitary, one-celled; style oblique; stigma orbicular; fruit, a berry or capsule, containing from one to three seeds.

The plants in this order are shrubs or herbs with perennial roots, found in temperate and cold climates in both hemispheres. Species have been met with in Europe, Asia, North and South America, but none have as yet been detected in Africa or the South Sea Islands. They are propagated by cuttings, layers, and seeds. Their properties will be best shown by a few examples.

The chief and most interesting genus is *Berberis*, whence the name of the order has originated. *Berberis vulgaris*, the common barberry or pepperidge bush, is common in the hedges and woods of Great Britain. It presents a beautiful appearance in spring, when covered with its yellow clusters of flowers. As the season advances, these are succeeded by bunches of red oblong-shaped berries, which are familiar to all. These berries have a sour taste, owing to the malic acid which they contain. They enter into the composition of various sweetmeats and tarts, and when prepared with sugar they form an excellent jelly. When pickled in vinegar, they are used for garnishing dishes. In consequence of their acidity and astringency they are refused by birds. They form a grateful cooling drink in fevers, and are said to be useful in biliary fluxes and internal hæmorrhages. The leaves of the barberry are yellowish or bluish-green, and possess a considerable degree of acidity. The stem and bark are very astringent, and are employed in dyeing; the root resembles that of the pomegranate: it is bitter and styptic, and is used in Poland for the purpose of imparting a yellow colour to leather. Cows, sheep, and goats eat the plant, while horses refuse it. Varieties are cultivated, with purple, white, yellow, black, and seedless fruit.

A singular irritability has been observed in the filaments of the barberry. If their inner side be touched with a pointed instrument, such as a needle, they immediately contract, move towards the stigma, and scatter the pollen if it is ripe. A peculiar fungus also grows on the plant, which is said to be prejudicial to corn growing near it, by causing blight or mildew. (See article ÆCIDIUM.)

All the species of barberries are more or less ornamental. The *Berberis aristata* is a hardy evergreen shrub, found in Nepal. *Berberis tinctoria*, a native of India, yields a yellow colouring matter, which is used in dyeing. *Berberis Siberica* (Siberian barberry), is

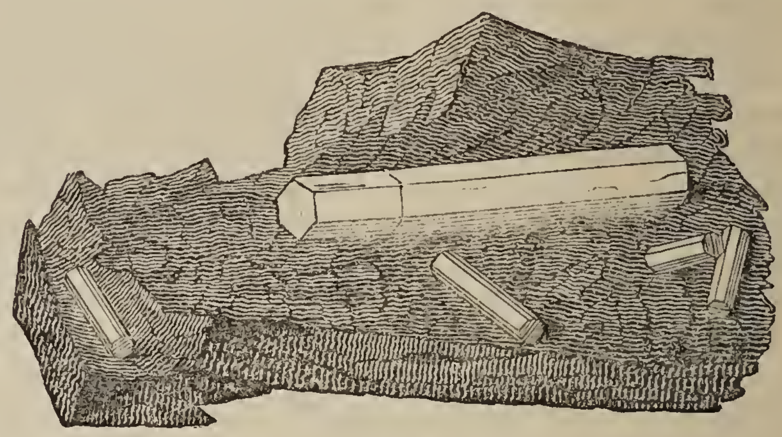
Berberis epimedium, Siberica.

a curious species known among the Mongol Tartars under the name of Yellow-wood, and applied by them both to superstitious and medicinal purposes. It is a native of the Altai mountains, growing in the crevices of the highest rocks, and was introduced into Britain by Sir Joseph Banks in 1790. It produces grey or ash-coloured berries, possessing acid properties. The barberries with pinnated leaves, generally shrubs of great beauty and interest, have been lately referred to a separate genus denominated *Mahonia*. Leontice, or *Caulophyllum thalictroides*, another plant of this order, is remarkable as being an instance of a plant in which the seeds are not inclosed in any covering whatever. *Mandiana domestica* is an elegant shrub, found in Japan. *Epimedium Alpinum*, or Alpine barrenwort is a plant of the barberry tribe, which is found in a few places in Britain. It is a small elegant plant, with handsome dark red flowers, which grows in mountain thickets, and furnishes a considerable quantity of honey.

BERIS (Latreille). A genus of dipterous insects, belonging to the section Notacantha and family Xylophagidæ. These insects, of which there are about a dozen British species, are of small size, lively colours, sluggish in their motions, frequenting aquatic plants, and distinguished by the basal joint of the posterior tarsi being greatly dilated, and the scutellum armed with six or eight spines. In the species forming the genus *Achna* of Meigen, the scutellum is only furnished with four spines. The antennæ have been described as only three-jointed, but the third joint, as it is termed, is distinctly annulated and composed of eight distinct articulations. These organs are but a little longer than the head. *Musca clavipes* of Linnæus is the type.

BEROSUS (Leach). A genus of coleopterous insects, belonging to the section Pentamera, and family Hydrophilidæ. These insects are of small size, and reside, like the rest of the family, in stagnant waters and ponds, in which, from the imperfect ciliation of the hind legs, they swim but slowly. The genus is distinguished by having the clypeus entire, the antennæ eight-jointed, the eyes very prominent, and the elytra are broader at the base than the thorax. Four British species, the *Dytiscus luridus* being the type.

BERYL. A very beautiful mineral, frequently, though improperly, called Aquamarine. Its principal colour is green, from which it passes on the one side into blue, and on the other into yellow. The beryl occurs massive, and it is often crystallised in long equiangular six-sided prisms. The crystals are sometimes jointed like basalt, having a concave surface at one extremity, and a convex surface at the other. They are seldom single; generally many occur together, and these cross each other in different directions. A very fine specimen, in the collection of minerals at the British Museum, is delineated in the accompanying figure.



Beryl.

The beryl was the tenth stone in the breast-plate of the Jewish high-priest, whereon Zebulon was engraven. When pure, it is cut into ring-stones, seal-stones, brooches, intaglios, and necklaces, but it is not so highly valued as the jewellers' emerald. The darkest green varieties are set upon a steel-coloured foil, and the pale ones are either placed, like the diamond, on a black ground, or upon a silvery foil. Figures are sometimes engraved on it. In the royal library at Paris, there is a portrait of Julia, the daughter of Titus, engraved on a very large green-coloured beryl. The largest ones are said to be in much esteem among the Turks for the handles of stilettos. The beryl, which is now classed with the rhomboidal-emerald, is found in its most beautiful varieties in veins that traverse the granite mountain Adon-Tschalon, in Asia, from which quarter nearly all the abundant supplies of Russian beryl are obtained. It also occurs along with arsenical pyrites, in a kind of serpentine rock near Nertschinsk, in the mountain Tygirek (Mountain of Snow), in the Altain range, &c. It also occurs in Europe and the United States of America. In our own island it is found in alluvial soil, along with rock-crystal and topaz, in the upper parts of Aberdeenshire. In Ireland, imbedded in granite, near Lough Bray, in the county of Wicklow, and near Cranebane, in the same county.

BERYTUS (Fabricius; *Neides*, Latreille). A pretty genus of hemipterous insects, belonging to the sub-order Heteroptera, or bug tribes, and family Coreidæ. The species are of a very narrow and elegant form, having very long legs and elbowed antennæ, which give them much the resemblance of *Tipulæ*, whence the type was termed by Linnæus, *Cimex tipularius*. The author of this article has captured the *Ber. elegans*, in some profusion upon the *Ononis arvensis*, at the back of the Isle of Wight, upon the tender shoots of which the insect in all its states feeds.

BETHYLLUS (Latreille; *Omalus*, Jurine). A genus of hymenopterous insects, belonging to the section Pupivora and family Proctotripedæ. This genus is at once distinguished by its large and flattened head, the elongated collar, and the elbowed and thirteen-jointed antennæ in both sexes. The insects are of small size and of black colours; the type is the *Ceraphron formicarius* of Panzer. They are extremely active, and are armed with powerful jaws. The proceedings of one of these insects has been related by Mr. Holiday, in a late number of the "Entomological Magazine," in a very interesting manner. This gentleman observed a female bethyllus occupied with a full-grown larva in a small pit of loose sand, formed at the foot of the cliffs on the sea-coast. This larva was at least six times the weight of the bethyllus. The latter employed the greatest perseverance in dragging the larva up the sides of the pit, avoiding or overcoming all the dangers occasioned to its passage by the stems of grass, &c., with the most surprising skill. "When it had ascended two feet, it came upon a fragment of reed, partly embedded in the sand, the stem of which was broken off and open below, a few dry elastic shreds of the leaf only remaining. Having reached the part where these grew, it, by a strong pull, drew its burden about half through, till its body was grasped between two of these as in a vice, then letting go, it began to explore the bank on each side to some distance, tapping with its antennæ the conspicuous object; in a few minutes, seeming to be satisfied, it hastily descended the reed, and entered its stem at the lower end: it did not remain long in the interior, and on its reappearance set off for the spot where it had left the larva, which, after pulling it out of the hold-fast, it seized by the mouth as usual, and began to descend the reed again; it did not complete the journey this time, but taking advantage of the same kind of security to detain its prey, it repeated the *reconnoissance*, then returning, dragged it to the opening, and leaving it there, plunged in itself, but immediately reappearing, drew in the larva head foremost, speedily disappearing in the interior, so that I could not observe its subsequent proceedings, and being obliged to turn homewards, I left them undisturbed. I think, however, it will seem probable that the bore of the reed was employed instead of an artificial funnel for the cells which should contain the progeny of the bethyllus, with its store of provisions. If these insects select only full-grown caterpillars, I can scarcely imagine one of the smaller individuals managing these unwieldy bodies."

BETULINEÆ. The Birch and Alder Tribe. A natural suborder of dicotyledonous vegetables, containing five genera and about fifty species. By some authors it is included along with the willow and oak tribe, under the Amentaceæ. It is allied to the Cupuliferæ. Its essential characters are:—flowers monœcious, growing in aments or catkins; stamens distinct, rarely united together; anthers two-celled; ovary superior, two-celled; style single, or wanting; two stigmas; fruit membranaceous, indehiscent; seeds pendulous, naked.

The plants of this order are trees or shrubs which shed their leaves every season, and which are found abundantly in the temperate and colder regions of the globe. Several species are found in the woods of Europe, North America, and the northern parts of Asia, and some are said to grow on the mountains of Peru and Colombia. The order contains many trees which are used in ornamenting landscapes, and which furnish valuable timber. They are propagated by layers and seeds.

The Betulineæ, like the willows, contain much tannin, and possess astringent and tonic properties.

Betula alba.

The principal genus is *Betula* or birch, whence the name of the order is derived. This genus contains numerous species which are highly interesting, and have been applied to important uses. *Betula alba*, common European or white birch, is an elegant tree familiar to every one. It is found in woods and in moist heathy mountainous situations in Britain. It grows in almost any kind of soil, moist, dry, gravelly or chalky, and it is frequently seen issuing from the crevices of rocks. It endures the cold of northern regions well, and is found even at the seventieth degree of north latitude. It thrives well in Lapland, Norway, Sweden, and the northern parts of Russia. It is seldom met with farther south than the forty-fifth degree of latitude, unless upon lofty mountains. On the Alps it grows at an elevation considerably above that at which other trees thrive, but in such elevated situations it becomes very diminutive in size. In general it reaches a height of fifty or sixty feet, with a diameter of a foot and a half or two feet. It blooms early in spring, and sends forth pendulous catkins of flowers. The wood of the birch is hard, tough and white, and is used by wheelwrights, turners, and carpenters, in the manufacture of various useful and ornamental articles. In some countries wooden shoes are made from it. The bark is thick, and is covered with a white scaly cuticle. It is astringent and bitter, and has been used in the cure of intermittent fever. On account of the resinous matter which it contains, it serves for torches to the inhabitants of the Alps. A decoction of the bark is used by the Laplanders in the preparation of reindeer skins. An empyreumatic oil also is obtained from it, which the Russians employ in tanning, and it is from this oil that Russia leather derives its peculiar odour. The inner part of the bark in its young state contains a quantity of fecula or starch, and from it the inhabitants of the northern regions make a sort of cake, which, along with smoked salt-fish, constitutes their food during the winter. The leaves of the birch are bitter, and have been used as a substitute for tea. They dye wool of a yellow colour. A decoction of them is said to possess vermifuge and diuretic qualities, and has been praised in calculous complaints and scurvy. A spirituous infusion of them is employed by the Russians and Swedes as an embrocation in rheumatism. By tapping the birch in spring, a sweetish sap is procured in great abundance, which by fermentation yields a sort of wine called birch-wine or mead. The tops and twigs of the birch are commonly used for brooms. *Betula pendula*, or the weeping birch, by some considered as a variety of the common birch, is the most graceful of the genus, and is easily recognised by its elegant drooping branches. *Betula nana*, or dwarf birch, is another European species found in northern climates, and approaching, in Norway and Lapland, very near the limits of perpetual snow. It is a small diminutive shrub, and is found on the Scottish mountains in considerable abundance. In summer, when the Laplander lives on the mountains, this plant furnishes his fuel, and, when covered with rein-deer skin, forms his bed. Its leaves dye a finer yellow than the common birch. Several species of birch are found in North America; of these the most important is the *Betula nigra*, or black birch, which furnishes a very hard and valuable wood. This wood when recently cut, has a rosy hue, which deepens by exposure to light. It receives a fine polish, and may be made to assume the appearance of mahogany: hence the tree is often called mountain mahogany. The twigs of the black birch, when bruised, give out a sweet scent. *Betula papyracea* is another useful North American species. From the wood of this species many articles of furniture are made, and its bark, which is white and indestructible, is used for the formation of canoes. On this account the tree is denominated the canoe birch. The name *papyracea*, or paper birch, is derived from the circumstance that the bark, when divided into thin sheets, is used as a substitute for paper. The red and yellow birch, two other American species, are not put to any particular use.

Another genus of this order is *Alnus*, or the alder. The alders in general grow in marshy, boggy situations by the sides of rivers, requiring black mould with plenty of moisture. They are often planted in places which cannot be drained. They are propagated by layers.

Alnus glutinosa, or common alder, is a quick growing tree found in swamps and meadows in Europe, North America and the northern parts of Asia. It attains a height of fifty feet, and furnishes a compact wood capable of receiving a considerable polish. In France, wooden shoes, or *sabots*, are made from it, which are seasoned by fire before they are sold. From being able to resist the action of water, the wood is employed in the formation of durable water pipes, and in Holland it is used for piles, upon which buildings are erected in marshy places. It is said that piles of this nature were driven in under the old London bridge. The wood takes a black colour well, and can be made to resemble ebony. With green vitriol, it dyes wool of a black colour. It yields excellent charcoal, which is employed in making gunpowder. The juice of the alder is astringent, and the bark is used for tanning, and for detergent gargles.

Alnus incana, hoary alder, grows in several parts of Europe, and has received the name of cold alder, from not being found south of latitude sixty degrees. *Alnus senulata*, notch-leaved alder, and *Alnus glauca*, are two species found abundantly in North America.

Carpinus betulus, hornbeam, a tree of humble growth, and useful in the formation of hedges for shelter, belongs to the betulineæ. It is found in woods and hedges in England, growing in damp, tenacious, meagre soil. It forms the principal part of the ancient forests on the north and east of London, such as Epping and Finchley. Its wood is hard and used for furniture, and its inner bark yields a yellow dye. *Ostrya*, another genus of the order, receives the name of hop-hornbeam, from its scaly catkins being similar to the hop. *Ostrya Virginica* is a small tree found in the shady woods of America. It supplies a hard heavy wood, called iron-wood or lever-wood.

Corylus is the fifth genus of this order. *Corylus avellana*, or hazel-nut tree, must be familiar to all, as furnishing the fruit commonly known by the name of filberts. This tree flowers early in spring, and its leaves do not appear till after the blossoms. Its wood is used for hoops, fishing-rods, walking-sticks, &c., and furnishes excellent charcoal for drawing. Squirrels live on the nuts, and an oil is prepared from them which is used by painters, and which is said to be efficacious against tooth-ach or worms. *Corylus Americana*, American hazel, yields also excellent nuts.

We have thus seen that the trees of this important order, are applied to many of the necessities of life. The wood of several of them is used for the construction of houses and vessels, in the works of the wheelwright, turner, and cabinet-maker, and as an article of fuel; the bark is manufactured into canoes and boxes, serves for the covering of houses, and supplies materials for dyeing and tanning; medicinal preparations, useful in various diseases, are obtained from several species; from some a nutritious article of diet is procured, while from others a sap exudes which constitutes a grateful and refreshing beverage.

BIGNONIACEÆ (the trumpet-flower family). A natural order of dicotyledonous plants, containing about a dozen genera, and nearly one hundred species. The order is very closely allied to the Pedalineæ and Cyrtandraceæ, and bears a considerable affinity to the Scrophularinæ and Acanthaceæ. Its essential characters are:—calyx monophyllous, divided or entire, sometimes in the form of a sheath; corolla monopetalous, hypogynous, frequently irregular; stamens five; anthers two-celled; ovary surrounded with a glandular disk, generally two-celled, and many-seeded; one style; stigma formed of two plates; capsule superior, two-celled and two-valved; seeds compressed, often winged, not provided with albumen.

The plants included in this order are trees or shrubs, frequently twining or climbing, and inhabiting the tropical regions of both hemispheres. Virginia and Japan are said to be the farthest points to which they recede from the equator, and none of the species are found in Europe. They are much cultivated and prized on account of their beautiful trumpet-shaped flowers, and their broad pinnated leaves. They are propagated by cuttings or layers, sometimes by seeds. Their properties are scarcely known. The wood of some of the species is said to resist the attack of worms.

The chief genus, and that which gives name to the order, is *Bignonia*, or trumpet-flower. It contains numerous species, most of which are highly ornamental. The name Bignonia was given in honour of the Abbé John Paul Bignon, who was librarian to Louis XIV., and a particular friend of the celebrated botanist Tournefort. *Bignonia grandifolia*, gigantic-leaved trumpet-flower, is a rapid-growing climber, found in the province of Caraccas, in South America. Its flowers are of a deep, bright-yellow colour, and its leaves are occasionally a foot and a half long, and nine inches broad. *Bignonia venusta*, welted trumpet-flower, is a climbing shrub of Rio Janeiro, producing flowers of a vivid orange-vermilion colour.

BIGNONIA RADICANS.—*a*, calyx; *b*, corolla; *c*, section of corolla, showing the situation of the stamens; *d*, pistil.

The bitter juice and tender shoots of *Bignonia leucoxylon*, or white-wood of Jamaica, are supposed to be an antidote against the poisonous juice of the manchineel. *Bignonia telfairiæ* is cultivated in Madagascar for the sake of its fleshy fruit, which has an agreeable flavour, and is prized as an article of food. The leaves of *Bignonia chica* yield by decoction a red resinous-like matter, called chica, which is used by dyers, and is employed by the Indians of Rio Meta and Orinoco to paint their bodies red. In commerce it is met with in the form of round cakes, five or six inches in diameter, and two or three inches thick. To cotton, it imparts an orange-red colour. The tough shoots of *Bignonia heterophylla*, or chirire, a native of Guiana, are woven as wicker-work. The leaves of *Bignonia Indica* are deemed emollient. Several species of bignonia found in Brazil, yield excellent timber, used in the construction of houses and ships, as well as in the manufacture of bows.

Tecoma, formerly *Bignonia radicans*, is a hardy climbing plant of great beauty, which ascends the tallest trees and the highest rocks, and is capable of being reared in the open air in this country against a wall. *Iacaranda*, another genus of the order, furnishes species remarkable for the elegance of their foliage, and their beautiful blue or purple flowers.

Catalpa syringifolia, an American tree belonging to this order, furnishes a most useful and durable wood. This tree sometimes attains a height of fifty feet, with a diameter of a foot and a half or two feet. Its leaves are very large, while its flowers are showy and white with violet and yellow spots. Its bark, which is of a silver-grey colour, is said to be tonic and stimulant. Honey collected from the flowers is said to be poisonous. An old catalpa exists in Grays Inn Gardens, which is reported to have been planted by Lord Bacon. *Catalpa longissima* is a most important timber tree found in the West Indies. The French call it *Chêne noir*, or black oak.

The root of *Spathodea longiflora* has an agreeable taste, and, along with the fragrant flowers of the tree, is used in some parts of India, in the form of infusion, as a cooling drink in fevers. The purple sweet-smelling flowers are considered by the Hindoos as acceptable to their gods, and are offered by them in their temples.

The genus *Eccremocarpus* differs from the other genera in this order, in having a single-celled ovary and capsule. The remaining genera are *Amphilobium*, *Fieldia*, *Chilopsis*, *Calampelis*, and *Streptocarpus*.

BIMANA (two-handed), the appellation which is given to man, considered as an order of mammalia, and without reference to his peculiar character, as possessing an intellectual nature in addition to his animal or material one. In consequence of possessing the intellectual nature, man differs so much from the rest of animated nature that he can hardly be considered as part of the system. It is true that, in so far as he is material, his body must obey the laws of matter, or overcome them only by means of organisations mechanically fitted for that purpose, just as is the case with other animals; but when we come to study the structure of his body, and the functions which it is capable of performing, we find that they are regulated by principles to which there is nothing analogous in the rest of creation.

When we examine the other animals in conjunction with the physical circumstances under which they exist, we find so perfect a coincidence between the animal and the circumstances, that we can at once say the one is made for the other, and that the animal is perfect in its place. One is fitted for one climate and surface, and another for another; but they are all equally well-fitted for their several places: and when we attempt to take them out of these, their nature resists; and, if we push the case to extremities, their life yields. But man is not completely in his element any where in wild nature, and as little can we say that any where he is completely out of it.

Place man in the very richest spot that can be found upon earth, and notwithstanding the richest luxuriance of nature—that luxuriance in which all the rest of the creatures wanton, as it were, in the fulness of enjoyment,—there is so far from being enough there for the full development of his powers, that these seem to remain inert and he to languish, in proportion to the richness of that plenty in the midst of which he is set.

But still the case is not one of merely physical consideration, in which as we move from the one end of the scale to the other the result is subject to a uniform change; for when we take the opposite character, that of the earth where it is the least productive, we find that it is nearly as unfavourable to the full development of the powers of man as that in which natural production is at a maximum.

From this we are compelled to acknowledge that there must be something more in man than merely an adaptation to the general laws and action of material nature . for if not, then assuredly man forms an anomaly in the creation—an imperfect creature, while all else is most admirably perfect.

When we consider the other creatures in a state of nature, and the natural circumstances under which they exist, we find the adaptation of the one to the other, and also the relation of every creature to the whole, so complete, that we can have no hesitation in at once pronouncing that they and all their adaptations are entirely parts of the one system and design of the present world; that their sole end and purpose are accomplished when they have borne their part in that system; and that, in order that the accomplishment of this end and purpose may be sure, we find all the species in all their varieties acting upon, or, as we may express it, governed by, instincts, which are as constant and immutable as the laws of inorganic matter.

The induction is often (generally indeed) a long one, and therefore we become impatient for the conclusion; and filling up, by analogies drawn from ourselves, those chasms which our ignorance leaves void, we come to a wrong one. We impute design on the part of the creature itself, in cases where, if we studied them a little more intimately and attentively, we should find no more self-design than we can suppose there is in the parts of the earth adhering so as to form our globe, or in the motions of that globe upon its axis, and round the centre of gravity of the solar system. All material movements, whether of a planet in its orbit, the mightier movement of a system of planets in space, or the pulse in the smallest insect, or the motion of growth in the minutest body, belong to the same general class; and, how much soever they may vary in their details, they have one law which is general and the same to all—they are not the result of any purposes in those creatures, animate or inanimate, by which they are displayed. We do see the most perfect design in every action which takes place, and every phenomenon which presents itself in nature. We do also find wisdom, and wisdom which, when once we are able to see it, we never can enough admire, in all and every part of nature. But the design which we trace is the Creator's design; and the wisdom which we see is His wisdom.

It is not in the superiority of the design and the wisdom alone that we see that such must be its origin. If the proof rested upon that, its foundation would be very unstable. We are, no doubt, in the habit of saying that we see demonstrations of *infinite* Wisdom, but that is the arrogance of our own self-deceit. We are *finite* in all our perceptions, mental or bodily, and, therefore, we cannot, in the nature of things, perceive or comprehend *infinitude*. The word itself is a *negative*—a name for that of which we are ignorant, and we cannot found a definition or form an explanation upon it. But still we can no more doubt the infinite than we can doubt our own existence; for we are hemmed in by the infinite in all our studies of the finite, whether they be more or less profound. This feeling accommodates itself to the capacity of every one who thinks; for, whether it be more near or more remote, the end of what we know is to us the beginning of infinitude.

The perfect harmony and adaptation to each other of all the parts of material nature is of itself sufficient proof that there can be purpose or will (for what we call will is nothing but forethought purpose) in none of them; because of themselves they could not preserve the harmony, unless each of them knew all that existed or could happen. Either, therefore, we must suppose every creature, nay, every atom of matter, to be endowed with omniscience, in other words to be a god, or we must admit that the whole obey the law of One God, and obey it, not as a matter of knowledge and judgment, but as a part of their very natures, which it would be absurd to suppose that they have, or can have, any disposition or tendency to resist. The doctrine which would endow matter with the attributes of godhead is perfectly untenable; and it is so, for this very simple and obvious reason, that there cannot possibly be two infinitudes of wisdom and power any more than there can be two infinitudes of space, or two eternities of duration. Whatever is infinite, that is, *unknown* and *unknowable*, as the phenomena of matter are known or knowable, must be infinite in all its attributes and in its essence, and that essence must in itself be *one*, in whatever mode or modes, or by whatever agency, its attributes may be manifested to us.

We are, therefore, to consider the material creation as one system, the workmanship of one Author, and sustained by one system of laws, which we may, without impropriety, call the General Providence of that Author. As such, all its parts change together, or at least in proportion as their nature yields to those circumstances which produce the change; and there is not among all the varied creatures a single race that can of itself either hasten its increase or protract its extinction. All creatures which require food can seek and find that food; but not even those which we regard as the most sage and the most powerful can in any way directly augment the quantity of that food, though, taken along with other circumstances they may be, and often are, the causes of its increase. Beyond the range of their instincts they have no power; they yield to circumstances; and when these press sufficiently upon them they become extinct, without any of that self-destruction by means of which the human race, considered as one species, make their lands desolate. When we take this view of material nature, and it is the only rational view which we can take, it becomes necessary to separate man from the other animated tribes; and then the study both of him and them becomes consistent, instructive, and free from embarrassment. To do this is merely taking a step similar to other steps which have been taken, greatly to the advantage of the science, both as a rational exercise for the human powers, and as a means of acquiring facts and principles, the applications of which are useful in the business of life. There was a time when, not only many of the specific distinctions in all the three kingdoms of nature were unknown or misunderstood, but when it was the habit, even with those who were considered as learned, to confound minerals, animals, and vegetables, especially in those obscure cases where the properties of neither are well understood; and not only this, but a disposition has been shown to endow the globe itself with a living, and in some sort an intellectual principle,—an *anima mundi*, or soul of the world, which gave its motions not to our earth merely, but to the whole system of nature, and was at the same time the life of every individual creature. This, though to us it appears an absurdity, was really a direct acknowledgment of the existence of the Creator, and of the operation of that system of laws emanating from him, which we have called his General Providence. It was merely the feelings confessing the power of the Creator, while the mind was too ignorant for forming any thing like a correct notion of him. It was, in short, an idol, only not a material one, or at least one not made by the hands of the artists; and where the light of revelation has not come, it seems to be a general law of human nature that God, when first confessed and sought after, is shadowed forth by idols. Those idols, too, are imagined in accordance with the leading habits of the people: among barbarous savages we have the god all terror and the worship all blood; and so on through the endless succession of names in the various mythologies, till we come to that which may be considered as probably the highest natural effort of man—the idol of the early student of nature—a living principle pervading and acting upon the whole; and though it must be confessed that this conception comes far short of the truth, when that truth is once *revealed*, yet it must be admitted that it is not only in the way of the truth, but the best preparation of the mind for its reception, and the very nearest approach to it which man in his own strength is capable of making.

Nor need we much wonder, though there are transient apparitions of the vision of this idol, upon the misty confines of all the kingdoms of nature, continued downward even to the times in which we live. There is a strong natural disposition to keep the pretension to knowledge quite up to the reality; and, sometimes vanity, sometimes the wings of a name, wherewithal to rise in the world above the proper level of our deserts, push it considerably ahead. In these cases it is easy to see that the whole measure by which the pretension is thus set in advance of the reality, must be composed of idols of some sort or other, inasmuch as there is nothing else of which it can be composed. These little aberrations are, however, harmless, in proportion to the extent of real knowledge, and they are besides a short-lived race; because every succeeding idolator is much more intent upon breaking the idols of his predecessors, and setting up his own idols in their stead, than on studying those truths in advance of which the idols are set.

It is only upon the shadowy confines that such phantoms in natural history can now be conjured up, even by the most fond pursuer of phantom celebrity. But the connexion between man and the rest of material nature, and the distinction between him and that, which coexist and are inseparable, render the study of man, regarded as a portion of that class of animals which in the structure and functions of his body he most nearly resembles, *the* portion of the subject upon which assumptions of this kind are the most likely to be made, and, being made, the most certain to be dangerous. It is for this reason chiefly that we shall treat of that part of the character of man which belongs to natural history in a separate article under the word MAN, rather than under the present article, as the name of an order of mammalia.

At the same time it must be admitted that the separation of man from those animals with which he used formerly to be combined, and in part confounded, in the systems (see APE and BAT), is an important step towards improvement. We thereby get rid of that continual appeal from man to other animals, or from other animals to man, which used so much to disfigure the pages of writers on natural history. When the comparison is one of mere structure or organisation, it is perfectly legitimate, and may, indeed must, be productive of advantage. The human body is made of the same matter, and very nearly the same kind of matter, as the other mammalia; and, in so far as the mere action of the structure is concerned, the analogy holds. Man feeds, and breathes, his pulse beats, and all his merely animal functions are performed, in the same kind of way as those of the other mammalia, though the mode is different, just as there are differences of mode among these; and, as is the case with these, the organisation is adapted to its purpose with the same perfection of form and economy of materials, so that the knowledge of the one leads us to the knowledge of the other, in so far as both are composed of matter, and sustained by those laws of common animal life in matter, which are necessary for enabling the organic being so far to overcome the resistances of inorganic matter as to be able to perform its functions.

But here there is a limit: in the case of every animal, when we have duly studied that animal, and also the earth in its various latitudes and productions, we can lay our finger upon a precise point of the map, which we know to be under given circumstances at the place of our making the assertion, and say, not only with perfect confidence, but in the spirit of the soundest philosophy, "Here is the proper home and dwelling of this animal." But we are altogether unable to pronounce thus in the case of man; for all the earth is his habitation; and though, for the mere support of his animal nature, he is obliged to toil more in some situations than in others, there is no latitude from the equator to the pole but which can be his home and dwelling place.

Man can endure greater variations of temperature than any other animal. He cannot instinctively repel that which would either mechanically crush or chemically decompose the substance of his body; but he can avoid the one, and blunt the virulence of the other by contrivance,—a power which no other animal possesses. He cannot endure boiling water, neither can he bear to be frozen into solid ice; but if the air is dry, he can bear a heat very considerably greater than that at which water boils, or a degree of cold more intense than that which freezes mercury. In the experiments that have been made of exposure to very high temperatures, the length of time has not been so great as to warrant the belief that man could live permanently under so great a heat; but as those experiments have generally been made by immediate transition from common temperatures to the high ones, the oppressive heat, which has soon begun to be felt under them, affords no conclusive proof that man could not exist habitually under such a temperature, if duly and gradually prepared for it. The intense cold is usually guarded against by an increase of thick clothing, formed of materials which are bad conductors of heat; but it is probable that this also is habit, at least in great part. Though we cannot implicitly believe all the accounts which the historians of antiquity have left us of those rude nations upon which, in those times, civilised man showed such a disposition to make war; yet it is highly probable that in the early ages, the people of middle Europe, and those of Britain among the rest, went naked or nearly so, for at least the greater part of the year; and at the present time, the people where the Highland kelt is worn, do not find the exposed parts of their limbs, either more affected by cold, or more liable to become diseased, than those who attire themselves more closely. The fact seems rather the reverse; for it is proverbial, that a genuine *gluine dhu*, which was never once cased in cloth, can stand on the march against the best knee that ever was defended against the weather from infancy upward.

It must be borne in mind, too, that, at the period when the natives of Europe are represented as having gone wholly, or nearly naked, the climate must have been colder, if not upon the average, at least in winter, than it is at present. We have direct evidence, from the freezing of the Tiber, that the Campagna di Roma was much colder then than it is now; and the same may be said, with equal confidence, of the valley of the Danube. If such was the case in those southerly places, which are not much elevated above the mean level, much more must it have been the case in places having a greater elevation, or lying nearer the pole.

It is no doubt not only true but highly probable that the summers were warmer then than they are now; indeed, in Britain at least, there has been a remarkable tendency to equalisation between those two seasons during the last half century; and many places in the north, and towards the wilds, which were, fifty years ago, buried under snow for four months of the year, and scorched by unbroken heat during other three or four, have now comparatively mild winters, and summers refreshed by occasional showers, in consequence of cultivation having forced vegetable action over a greater part of the year. That vines are said to have been abundant in the south of England, and the vintage from them good, in former times, while they do not now bring their clusters to such maturity as to furnish a sufficient quantity of saccharine matter even for tolerable wine, proves nothing as to the general temperature. The vine is a hybernating plant, coming out rather late in the season, but rapidly when it does come; and therefore all that its maturation would prove would be the heat of the summer, which, upon other principles, we may conclude to have been greater in former times than now; and we have a corroboration of this in the wild berries which the country still affords, which are not only not so vinous and racy on the warm bottoms as on the bleak heights where the winter is cold, but refuse to come to maturity at all in such situations.

Many other facts might be adduced, all tending to show that the constitution of man is so formed, or so flexible to circumstances, that he can command all latitudes; and even in those places which are accounted decidedly unhealthy, it is not to difference of temperature that the unhealthiness is wholly or chiefly owing. When that is natural, excessive humidity or excessive drought is generally found to conspire with temperature; and sometimes, as in the case of the *malaria*, on the plains of Italy, along the Mediterranean shore, the pestilent quality of the climate does not appear to have much to do either with heat or with humidity.

It would perhaps be too much to say, that in all places where man finds an unhealthy climate, it is his own fault; because there are phenomena in nature the controlling of which is above any means that the skill of man can use, at least for the production of immediate or even very rapid change. But still, so much has been done in the way of amelioration, that it is not very easy so to fix a limit as to say confidently that nothing beyond it can be done. Farther, it appears, that where the climate is apparently unfavourable to human life, the mode of living has always at least as great a share in it as the mere locality. Thus the conclusion that man is fitted for all the earth, and all the earth for him, or if not so, naturally capable of being rendered so by art, if not altogether universal, is at least very general.

It is much the same with regard to the necessaries of life, as with the fact of living. There are very few situations in which human beings, duly informed and prepared for the purpose, cannot find subsistence. No doubt, there can be no cultivation above the line of perpetual frost, and as little can there be any upon the dry and shifting sand; but the line of frost may be made to retreat upward, if cultivation is pushed vigorously against it; and though the process is often both slow and laborious, the desert is not utterly irreclaimable. There are many instances on a small scale in our own country, and Holland is a remarkable one of the change of a soil naturally bad, under a climate assuredly none of the best, into the garden of Europe. Many of those places which are now desert were formerly the abodes of plenty and activity, and they have been deteriorated through the neglect and misconduct of man, and not through any natural cause. We do not know the properties of all plants, or the modes which are best for improving them into human food, but from the thirsty soils in which water melons, dourrha, rye, and various other cultivated vegetables, come to maturity without almost a drop of rain, we must not say that any one place is utterly hopeless.

It is true that the very principle which enables man to combat with, and, in the end, subdue the climate and the soil, operates against him when he goes to a place the appearance and circumstances of which are wholly new to him. We always proceed by imitation, sometimes by imitating that which we ourselves have observed, but more frequently by imitating others. Thus, those who have been brought up in any society acquire the habits of that society, and cannot shake these off without considerable difficulty when they move to places where they do not so well apply. In consequence of this, the experienced sometimes fail, when those who must depend wholly upon observation succeed.

To guard against the consequences of this implicit and unreasoning adherence to habit, or to following the example of others, which is sometimes unwise, even where very general and of long standing—and when wise, often wise only because it is local—is one of the greatest advantages which result from the counter habit of observing for ourselves, and understanding the cause of success before we imitate that which we observe to succeed in others. The observation requisite for this purpose is nowhere to be found but by attending to what takes place in nature. Considering practical advantage as the good of that which is done, we never can, by observing only the conduct of men, decide whether that conduct is the best possible or not, because we go to measure without any standard; but when we study those substances and events which are the subjects of human action, so as to know the extent of their capabilities, this becomes a standard, by the application of which we may safely try the conduct of others or of ourselves in all cases where it becomes necessary.

The comparison with this standard of knowledge is the process to which the several names of sound judgment, reason, good sense, and various other commendatory terms of similar import, are applied; and the only means which we have of possessing ourselves of the standard, without which there can be no comparison, is *observation*. This, though the organs of the senses are its instruments, is in itself entirely an intellectual operation, and one which no animal possesses, or can possess, in common with man. It is his grand characteristic,—that which, without going into either his physiology or his history, is the purpose to which the whole of his organisation tends. Other animals have senses, and many of them have probably senses different altogether from those of man, or if of the same kind, more acute in degree; but all their senses tend to mere animal preservation: and beyond this they have no speculation; no tendency to notice, or in any way heed, that which is around them. All their organisations tend to these purposes; and this is the reason why the animal, the locality, and the food are reciprocally adapted to each other; but as man is organised chiefly for observation, and for observation of all that nature presents in space or in time, the structure of his body is not an index to any particular locality or climate. If we may so express it, the material or organic part is an inferior portion of a human being; while in the rest of animated nature it is the whole of the creature. The animal is complete in its instincts; and in these it forms a perfect member of the system of material nature; but as we cannot imagine a human body to exist without the mind or intellectual part, how much soever that part may be clouded by ignorance or concealed by disease, we cannot regard the human body as an entire creature at all. It is that wherewith something superior to matter is to work; and therefore if by any circumstances that superior part cannot work, the body is as inefficient as a tool is without the workman.

We have melancholy proofs of this, in those cases of disease to which the name of mental derangement is usually given. The name is evidently a faulty one; because to be diseased or deranged is quite incompatible with the simplicity of essence, and the eternity of duration, which are the essential attributes of the mind. Even those diseases must be bodily; but as they do not necessarily and immediately produce any topical or systematic effect upon the body, which in its material structure follows the general law of material creatures, we are unable to point out where the disease lies, or in what it consists. But we can see clearly that when this connexion between the intellectual and the corporeal part of a human being is disturbed, that being does not descend in the animal scale, and take the habits of some creature in which the organisation is less developed than in the human subject. It does not fall into a regular government of instincts—does not become more uniform and consistent in its acting, than a sane human being. It becomes a fragment—a thing of ruin—unfit for its proper function in creation, and equally unfit for the humbler one of an unreasoning animal.

Thus viewing man in any light, in which with a knowledge of the facts before us, he can be viewed, we find it impossible to class him with the other animals, because we cannot find his peculiar place in merely material nature; and therefore a system which includes him in the same manner as it includes the others cannot be natural. Even when we take the single circumstance of the hands, and call the race *bimana*, or two-handed, as distinguished from the *quadrumana*, or four-handed mammalia, we find that, although there is some resemblance in the organs on which we found the names, they are so far from being similar in their structure or their uses; that we might with quite as much propriety take the distinguishing character from the feet, and style man a *biped*, to distinguish him from those mammalia which are quadruped. The hands of the quadrumana are (see the article APE) feet, and feet limited to peculiar habitations, or adapted for locomotion which answers upon only a limited portion of the earth's surface. No art of man could people with them the pine forests of the North, or even the groves of deciduous timber trees in the latitudes of a mean temperature; nor is it an easy matter to keep a single individual in health for any length of time in our climate, even with the aid of artificial shelter and careful feeding.

It will be said that apes are observant animals, and carry their observation so far as to make it the foundation of imitation. But the observation which we find in these animals is not of the same kind with that which forms the grand distinguishing character of man. It may be more acute at moderate distances than that of many other animals, because that accords with, or is necessary for their natural habit of sitting or climbing among the branches of a tree, and scrutinising the twigs in quest of fruit. But there is no evidence whatever of any observation of events in their succession, which can be made the basis of analogies of cause and effect; and it is this observation of the successions, and not the more simple gaze at the substances or the occurrences, which constitutes in man that observation which is his grand characteristic.

So far as we can feel in ourselves, and judge from analogy, the material organ of sense, whether it belong to man or to any other animal, can perceive matter only; and thus far the perception by the same kind of organ is probably similar in all, because, thus far all are material; but there is an after process in man which has not any material type, and which, therefore, cannot be perceived by any material organ. This is the only part of the process which can be considered as purely mental; and it is the part which is knowledge, or science; remaining with the individual as a guide in future cases, and capable of being communicated from individual to individual, and handed down from generation to generation. The merely animal sensation, or perception, even in man, cannot be thus communicated or transmitted. In itself, and without the mental process which discovers the relations of the sensation to the object of sense, and to other sensations and other objects, the sensation is a mere feeling of pleasure or of pain according to circumstances. This is the case whatever be the sense which is affected. Those who have been born blinded, by means of an opaque film covering their otherwise perfect eyes, who have lived for some time in that state, and who have afterwards had the film removed by an operation, so that they could see, have described the feelings at first resulting from their newly-acquired sense, as if the objects seen touched the eye, bright and especially red colours producing pain similar to that inflicted by a sharp instrument. In the case of hearing, where the relation between the sensation and the sounding body is not so direct and clear as between sight and the visible one, an unexpected sound of unusual loudness has very much the feeling of a blow on the ear; as for instance, when a piece of ordnance is unexpectedly fired, a person not accustomed to the report of cannon, will, if standing near it, clap his hands on his ears, just as persons do upon any part of the body, in which sudden and severe pain is felt. And though this feeling of pain is a mere deception, the sensation is so strong that there have been instances of the party falling down, in the full belief of being shot. The ear does receive an injury, though of what kind it is not very easy to say; because those who are for the first time in a hot cannonade, become deaf to the reports, though after a time the ear recovers its tone, and the hearing returns.

Many other instances might be adduced, all tending to prove that there is no knowledge produced by mere animal sensation; and that, therefore, if there were not in man a principle in addition to the material body, man could not acquire any knowledge capable of being communicated to others, or of forming the basis and guide in future plans and trains of conduct in himself. If the knowledge is capable of being used by the party himself upon future occasions, it follows, as a matter of course, that it can also be communicated and rendered useful to another party of similar understanding,—the only addition required being a means of communication. We need hardly add that language spoken, or expressed by symbols of some kind or other, is the means of communication among man; but it is worthy of remark that while these idiomatic expressions which denote merely local modes can with difficulty be translated even into an analogous language, the truths of science readily admit of translation into all languages, unless where the language happens to be that of a people who are too ignorant for understanding them.

Animals do communicate with each other; but their means of communication are very limited, and there is no ground whatever for supposing that they can communicate any thing at all resembling those truths to which we give the name of science or knowledge. They communicate merely animal sensations, the same as human beings communicate by dumb show and inarticulate sounds; and they are without the reflective sentiments,—the mental emotions, which in human beings may arise from these, just as the mental perception of relation follows the affection of the senses in other cases.

We have preferred this mode of viewing the grand fundamental distinction between man and the other animals, to the other one of arriving at the same conclusion from an examination of the organisation of the human body, because it is more satisfactory, and also admits of being treated in a more popular manner. But when, carrying the distinction which we have attempted to describe along with us, we examine the organisation, we find that it affords as clear and unbroken proofs of what has been stated, as if the body had been framed for the express purpose of demonstrating the truth of the mind's existence, immateriality, and consequent immortality. It could not indeed be otherwise: for, as the truth to be demonstrated by an appeal to the body is the existence of the mind and the adaptation of the body as an instrument for the use of that mind, it follows that every step of the examination must go either to the establishment of that truth, or to its overthrow. This being a case of nature, and not of human invention or contrivance, and nature being in every other case so perfectly consistent, that there never is any conflicting evidence to weigh, other than that which becomes apparently so from our ignorance, and to know being always perfectly synonymous with to believe, the evidence must all go one way in this case also; and a very slight examination may convince any one that the evidence of reason points to the very same conclusion to which revelation invites,—namely, that the principle of action in man is a principle not material, and therefore not liable to death or dissolution. Farther, that no bounds can be set to the quantity of knowledge which this principle is capable of acquiring; and that it is man's own fault, or his folly, if the acquisition does not go on accumulating, in a rapidly increasing progression, age after age. For, though past history shows that in former times there was a dotage of nations, as well as a manhood of intellectual strength, yet, independently of the fact that nations are always physically young, the same history affords evidence that the dotage which brought about the decay and ruin of the cultivated nations of antiquity, was the imbecility of a constitution wasted by disease, and not the effect of any natural decay. In proof of this, one may appeal to the state of modern Europe, and of all those parts of the world which modern Europe influences, and that is now the greater part of the habitable surface. During the last hundred years the nations of modern Europe have had at least their full complement of war, and those wars have certainly been more expensive, and probably more destructive of human life (that is, in proportion to the number of men actually killed, though certainly not in proportion to the numbers composing the nations between which these wars were carried on); but still, even in the hottest of the fight, the course of improvement was never stopped—not totally even at the very scenes of engagement. Nay, the necessities of the war may in many cases have been stimuli, and very powerful stimuli to improvement. Of this we may mention, as one instance, the contrivance by the French chemists to produce nitre from artificial beds in their own country, when the nation was so hemmed in that it could not procure a supply from foreign countries. This is but one instance, out of many, which will readily suggest themselves to every one who takes an interest in this most interesting question.

This view of human nature, according to which the really active part of it is elevated above the nature of material things, and not clogged, encumbered, or bent down, by the resistance of any of the common laws of matter, which restrain and limit the very instincts of all other animals, is calculated to raise high the hope and confidence of man, even, in this world. No doubt the body is subject to the laws of matter; and admirably as the body is constructed, that which man can achieve individually and with the naked hand is very limited—below what we would consider even tolerable subsistence in the most favoured spot upon earth. But the mental purpose and the mental plan are formed and fabricated independently not only of all the trammels of physical nature and its properties, but absolutely unbounded by space or by time. If we carry along with us this single principle, that we cannot in any thing which we attempt overcome a mechanical resistance or dissolve a chemical union, without the application of a power greater than that which resists in the one case, or holds in union in the other, we may not only plan, but absolutely carry into effect, whatever we purpose. The qualities of matter are so numerous too, and they have been disclosed under circumstances often so unlikely, that we can no more set bounds to what shall be discovered in nature than we can to what shall be devised by mind. If our forefathers, only a century and a half ago, had been told that the scientific use of a few bushels of coals and a few gallons of water, would increase the life of man sevenfold in useful duration, they would have deemed the teller fit only for Bedlam; but when we find that, every day, steam ships and steam carriages convey both men and merchandise, with at least seven times the rapidity that they were carried at that time, and also with much more certainty and comfort, we have the demonstration before our eyes, as a matter of daily observation, so common that we pass it over without a marvel, and almost without a thought. And it seems to be with the general progress of discovery and application in nations, as it is with the progress of knowledge in individual man: the more that is acquired, the room and facility for further acquisition become the greater. Nor is it difficult to see that such must be the case: for all true knowledge is of a fertile nature; and every portion of it that we acquire points out, smooths, and shortens the way to another portion.

In this again we have an irresistible proof that that which discovers, and knows, and points out how the discovery and the knowledge are to be applied, can have none of the properties of matter, and therefore cannot be material. The properties of matter are constant. It requires the same effort of strength to lift a pound weight, and the same degree of heat to smelt iron out of its ore at the present day, as it did when the inhabitant of Britain was a naked savage in the woods; and the men of the present time, by whom wonders, compared with what could then be accomplished, are performed with the greatest ease as matters of common every-day employment, are not a tittle stronger, and have not their senses any more acute than these rude people; but are rather the reverse, inasmuch as they depend more on the results of knowledge, and less on their individual bodily powers.

Now, if we consider this unchangeableness of the properties of matter, whether as inorganic, or as in the organised body, this conclusion forces itself upon us—that a material creature, how curiously soever it may be organised, could not, in the nature of things, improve one jot in one generation upon another. External circumstances it might obey, and be by them so far modified, as we find many animals modified by situation and climate; but of itself it could neither improve nor deteriorate, but would necessarily, under the same circumstances, remain, in all its qualities and all its habits, specifically the same creature from the beginning to the end of time. And, when we look abroad, and survey all living creatures, man excepted, in their present state, and in all of their past history of which any thing is recorded, we find that, in respect of improvement, they are as passive as the grass on the meadow or the rocks in the mountain. If circumstances more favourable to their subsistence come round, they multiply in numbers, and are proportionally in better condition; and if the circumstances are reversed, their numbers decline, and the individuals fall off. But those changes, whether in the one direction or in the other, are in exact proportion to the changes of circumstances; and therefore their causes must be wholly in those circumstances, and in no wise and to no extent in the creatures themselves. They bend to the wind of occurrences in the general system of material nature, just as the reed bends to the wind of heaven; but just as the reed, as long as it is a living plant, continues rooted in the earth, so do they continue rooted to those characters which stamp upon them their specific natures; and they can no more escape from or alter those circumstances than the reed can betake itself to a more sheltered spot when the hurricane threatens to tear it up by the roots. To resist the common laws of matter by contrivance—to battle with the elements, as it were, and to overcome—to improve by its own energy, and even, the converse, to deteriorate from the relaxation of that energy, cannot be predicated of matter under any imaginable circumstances; for that would not only be contrary to the whole tenor of what we know and can observe respecting matter, but it would necessarily lead to the conclusion that matter is self-existent; and this is the ultimate belief to which all scepticism as to the existence and immortality of mind in man directly tends; and sceptics who stop short of this have small merit in so doing, inasmuch as it is merely on account of their being too ignorant or too indolent for following out their own argument.

That the classing of man with the other animals, and treating only of the form, structure, and functions of the body in natural history, has some tendency to produce a leaning toward the doctrine of materialism, at least on the part of those who have merely a surface knowledge of the science, cannot be denied. But still much of the raving in which those who appear to exist, or, at all events, to write and publish, for little other imaginable purpose, is the result of mere prejudice, as ignorant as it is arrogant. In matters of speculative opinion which, however important they may be in themselves, do not involve the gaining or the losing of worldly property, men never seek to deceive others unless where they themselves are deceived; and wherever we find a person calling himself a naturalist, and professing sceptical or material doctrines, we need no further evidence to convince us that, whatever he may know of the mere details, he is not, in the more general, useful, and better sense of the term, a naturalist at all, but a mere impostor, though probably a self-deceived one, and therefore deserving pity rather than the exercise of any harsher or stronger feeling.

But still, though when one has made so much progress in the study of nature as to see how perfect it is in its design, how beautifully it works as a system, how true each part is to the laws which have been given it, and yet how readily all co-operate with each other in the support and maintenance of the whole, it is as absolutely impossible to be sceptical of the existence of the author of nature, as it is for a perfect eye to be open at bright noon-day, and not see: yet, in the progress towards this equally beautiful and delightful elevation, there are difficulties to be overcome, and dangers to be avoided; and against these it becomes necessary to put those who are seeking the truth upon their guard. This is more especially necessary in that general knowledge of nature which should form a part of the education of every individual who is so educated as to enjoy the world while performing his duties to society in it, and not to pass his days in dull and unreflecting routine, like a mere tool, than it is for those who study only one department of nature as a trade or profession. The moral and social duties of man depend so much upon the fundamental principle of belief on the points under notice, that if the study of natural history have no other use, as much of it as should suffice to afford demonstration of their truth, would still be among the most valuable subjects on which instruction could be given.

The danger of error lies in the impossibility of bringing the whole subject at once before the mind; and as it is not easy, if the known makes a due impression, to prevent speculation with regard to the unknown, contradictions are apt to appear, which farther instruction would completely explain away, but which remain and ripen into errors if that additional instruction is not given. When the mistakes happen upon points which are connected with material nature only, they are of less moment, as they affect only the intelligence of the parties, and not their moral habits; but still it is very desirable to avoid them even then, inasmuch as mere goodness, without intelligence, is at best but a feeble and even a frail virtue.

Feeling that the error of confounding man with the system of material nature is the grand error, which not only destroys the better part of the human character, but spoils the rest of nature to man's contemplation, we, as anxious to produce a work of popular as well as scientific usefulness, have taken occasion, in our notices of apes, beavers, and other animals, which have, in some parts at least of their economy, been frequently confounded with man, to point out in what the difference really consists; and now, in this article, or at least in one of similar import, where man is usually confounded with the animals, we have gone over some of the proofs of the existence of mind in man, which arise from the mere study of nature, and without reference to that which is revealed in the Scriptures, and which could not have been arrived at by any study of nature, however extensive or however accurate: otherwise revelation would not have been necessary.

We may, however, remark, in passing, that there is that correspondence between the evidence of nature and the evidence of revelation, which shows that they both emanate from the same source—that the God of Nature and the God of Grace is one and the same. In both, partial views are apt to lead to erroneous conclusions; so that, in order to arrive at the truth, we must study the whole revelation of God in his word as well as in his works; and if we do so, we are sure to find not only that each is perfect and conclusive in itself, but that the two are in perfect harmony with each other: with only this difference, that the law of God, as manifested in nature, is for all the creatures which he has made; while the law as revealed in his word is peculiarly and exclusively for man.

It is the omission of the consideration of man as having an immaterial and immortal spirit, in addition to the body, and the consideration of the latter only as part of natural history, which gives the reality or the appearance (for it is the appearance more frequently than the reality) of materialism to this branch of knowledge; this, therefore, is the view we have taken in the present article, the one in which man is more directly considered as part of the general system of animated nature, as the most proper one under which to show that, even in a natural history point of view, man cannot be regarded as a being wholly composed of matter, but that the material body is only the instrument by means of which the mental or immortal part acts. If the arguments, or rather the proofs (for when all the evidence tends one way there cannot, strictly speaking, be any argument) which we have adduced be properly considered, we feel confident that they will be found conclusive. We have endeavoured to express them in plain and simple language, without any of the technicalities which are usually employed upon such subjects, in order that they may be generally understood; and we have made them, in as far as possible, new, both in form and in substance, in order that they may be the more striking.

Viewing what man does, in opposition to what is done by the other animals, the sum of the whole argument for mind is—that man is the only living creature in the world in which there is a principle or capacity of self-improvement, by means of which one generation, availing itself of the experience of the generations which preceded it, can become better informed than they; or which, by failing to exercise the means by which this improvement is attainable, can deteriorate and fall off. That which is formed of matter, in what manner soever that matter may be organised, cannot have such a principle, unless we suppose that matter, in the case of man, is endowed with properties not only different from but absolutely contrary to those which it possesses, either generally, as inorganic matter, or peculiarly, in consequence of the particular organisation and instincts of any animal.

Those instincts are often very curious; and they are, in their operation, perfectly inexplicable to us, not only in those cases in which "an inferior degree of reason" has been inconsiderately ascribed to the animal, but even in those more simple instances which pass under our notice every day without in the slightest degree attracting our attention. That "the ox should know his owner, and the ass his master's crib," is just as wonderful as that the beaver should build a habitation against the winter, or the bee construct its cell so as to have the maximum of room and of strength out of the minimum of materials. The manners and habits of all creatures are useful subjects of study, not only because they are very curious in themselves, and evince purpose and design in the creation, which we can neither mistake nor refrain from admiring, but also because there is in each of them an example which we can always in so far imitate for our practical advantage. The latter must be the case: all the actions of animals, of what kind soever they may be, have for their object the counteracting or opposing of some of the properties or laws of inorganic matter; and as the natural actions of animals are all, upon the average, successful, it follows that they do, upon the average, overcome those properties and laws. Of the principles in which those instincts originate we do not understand, nor can we hope to understand, any thing, because we do not understand the principle upon which the most simple substance in nature possesses its most simple quality; but they all operate by means, and not by miracles; and those means are always open to our investigation. We cannot, for instance, say why one animal flies in the air, another swims in the water, and a third burrows in the earth; but we can always observe the organisation which it employs for that or for any other purpose; and, upon observing it carefully, we invariably find that the end is accomplished by means which are in perfect accordance with the principles of mechanics, as applied to inorganic matter. All the common external actions of animals are, indeed, strictly mechanical, or employed in the overcoming of mechanical resistances; and that is the reason why there is so much practical advantage in the study of them.

But though we cannot tell in what manner the instinctive impulse in the animal acts, or why one particular form of organisation, and one particular class of instincts should invariably accompany each other; yet the constancy of the latter accompaniment, to which in wild nature there is not one exception, at once shows the perfection of the system, and that that system is altogether one of material nature, varying in the instincts which it possesses, and in the actions and habits to which those instincts give rise, in exactly the same proportion as the organisation varies; so that—when we have once made ourselves duly acquainted with the relation between instinct or habit and organic structure—we are never at a loss in assigning to any species its proper place in the system, even although all that we know of it be merely one dead specimen fetched from the opposite side of the globe, about the habits of which the bringer can tell us nothing. But as the instinct and the habit of the organised being are thus constant to the organ, in the same manner as the mechanical and chemical properties of any piece of inorganic matter are constant to its mechanical size and consistency and its chemical constitution, we are warranted in concluding that the animal is nothing more than matter, deriving peculiar properties from a peculiar organisation, just as a chemical compound is nothing but matter, deriving peculiar properties from the peculiar number and proportions of its ingredients.

For some account of the rationale of taming animals, so as to make it appear to superficial observation that their instincts are altered, we must refer to the article Domestication; but we may here remark, that, as animals never tame themselves, nor those of the same species each other (for the use of tame elephants in the capture of wild ones, and some analogous cases, may be explained upon very different principles), and as mankind, taken as an entire race, must be self-educated,—taming and educating are not at all operations of the same kind. We may be said to tame not only vegetables, but inorganic matter, much in the same way, though not of course by the same means as we tame animals. Every cultivated field furnishes us with an example of the taming or domestication of plants; and the products of all the arts show us how inorganic, or, at all events, dead matter, may be tamed. The cases are not the same in their details, because the subjects operated upon are different, but the principle is in all the same: the subject is placed under new circumstances, and the result is a change in so far as the new circumstances are calculated to effect that which man wishes to alter in order to suit his purpose, but not any further. Thus taming, or domestication, is nothing more than a peculiar application of that which is learned from experience, either in simple observation or in experiment; and all that it proves is, that the creature which is domesticated is so far obedient to circumstances, and the right ones have been resorted to; but the change is no more brought about by anything in the creature itself than animals bring about of their own purpose or volition those changes of seasons which are accompanied by changes in their habits, and often in their appearance.

If the dead body of a human being, which bear upon it no marks by which the particular tribe to which it belonged, or of the mode of life which it had followed, were brought before all the naturalists in the world, they could not, by the most profound knowledge of the relation between structure and habit, which is so easily and clearly traceable in every other animal, come to the smallest conclusion as to what had been the habits of that human being when alive. The houseless tenant of the wild wood and the dweller in the most elaborately formed and luxuriant palace, the king and the beggar, the philosopher and the fool, the man adorned with every virtue and the villain stained by every crime, all become the same in death; or if there is any expression on the countenance of the dead body, it is rather that of the means of death than of the manner of life. Every one conversant with the subject knows that if the greatest hero falls by a gunshot wound which is instantly mortal, his features are as much relaxed and subdued as if he had died of fright; while death, produced by transfixing with a spear, will knit and stiffen the features of the veriest coward into an expression of heroism.

The organisation of man has, therefore, nothing farther of a positive nature to tell than that he is man; but the negative eloquence of its silence in other respects is most important as well as most impressive. It speaks of *the man*, the active, the reasoning, and therefore the accountable being, as the empty sepulchre does of the body which was laid therein—"He is not here;" and thus the very death of the body bears testimony to the immortality of the spirit.

We should now proceed to the structural part of the argument, that which shows, from the organisation of the human body, that that body is not in itself a perfect being, and that, without the operation of the mind, it could not maintain its place, or even exist in the world. But this article has already extended to a greater length than could have been wished; though the great importance of the subject, the most deeply interesting which can occupy the human powers, and one in which we are all equally interested, together with the novel mode in which it is treated, and the perfect originality, in so far as the author knows, of some of the arguments, may perhaps be admitted in excuse of an additional paragraph or two. If we omitted or passed slightly over this part of the subject, we should consider our duty to the public but ill performed by any mere account of animated nature, even if it emanated from ten times the knowledge, and were drawn up with ten times the ability, to which the writer of this article can have any pretension. We have often regretted, upon reading works on natural history, which were in every other respect worthy of our warmest admiration and gratitude, that they stopped short of or blinked this question, as if it formed no part of that very subject in the study of which it is almost the first question that arises to an inquiring mind. And when we have found material nature set forth with all the truth of philosophy, and all the fascination of eloquence, with the structure and functions of the human *body* among the rest, but without one allusion to the *immortal part* of man's compound nature, we have momentarily felt that thrill of dreadful and indescribable horror which "the dream of annihilation," how momentary soever may be its visit, never fails to inflict; and we have felt disposed to address our material instructors in language somewhat similar to that in which queen Katharine addresses the cardinals:—

> "Ye *turn me into nothing:* wo upon ye,
> And all such false professors!"

though there was no falsehood in the case, and no desire of concealing the truth, but merely the custom, which has most unwisely crept in, of treating of one of two subjects which are inseparably connected both in nature and in the ordinary course of human thought, and wholly omitting the other.

Besides the length to which it has already extended, there are some other reasons why the structural part of the inquiry should not be included in this article. The *anatomy* of the human body is a distinct science, and will be found treated of as largely as is necessary for popular purposes in the first division of this Cyclopædia; and, as there is no living action in man in which the mind is not concerned, the consideration of the organ can be much more usefully introduced along with its subservience to the mental physiology; and consequently all which remains farther to be said of man, as an object of natural history, can be more clearly as well as more briefly expressed in the article MAN, which the student may read as a sequel or accompaniment to what has been here stated.

BIRCH (*Betula*). A genus of forest trees, of which there are several species; and some of the species, or at least what are considered as species, are apt to run into varieties.

The common birch, *Betula alba*, is very abundant in the northern parts of Europe; and there are still extensive natural woods of it in many places of the highlands of Scotland: nor is it altogether unknown as an indigenous plant in the uplands of South Britain. It is, perhaps, the most hardy of all the forest trees, and the one which is found uppermost upon the mountains, and nearest to the pole—at least it is much more so than any other indigenous tree.

On the mountain-tops it is exceedingly small, and quite the miniature of a tree, with a stem not thicker than a quill, leaves not larger than those of duckweed on a pond, if indeed as large; and altogether not more than from half a foot to a foot in height. Still, however, even where it is most dwarfed it possesses the proper form of a tree, and does not run into a shrub, as on the moors of Sussex and other parts of the south of England.

No tree is, indeed, more liable to have its size altered by situation than the birch; and when it is so altered, all the parts of it may be said to alter in the same proportion. The leaves are small, and the twigs slender in proportion as the height and thickness of the trunk are less. It is only in very peculiar places of the Scottish mountains that the dwarf birch is met with in the full perfection of its littleness and tree-like habit. Those situations are high mountains, the summits of which present not cliffs, but terraces of mould; and the dwarf birches are met with on the southern exposure, a very little below the snow.

In the sheltered dells and bottoms, and especially by the banks of clear running streams, when these do not consist of bog or peat, but of patches of rich mould with rock interspersed, the birch becomes not an unstately tree, and it is certainly a very beautiful one. The bark, which on the specimens exposed to the blast of the hill is torn and broken by cracks and fissures, is, on the rich and sheltered ground, of a delicate white colour. The green, too, is exceedingly delicate, especially in the early part of the season; and scarcely any foliage can rival in tint that of a copse or grove of thriving birches at that season of the year. It has this further advantage, that the scent of birch leaves when they expand, and, indeed, up almost to the period when their vegetable action ceases, have a very fragrant and exceedingly refreshing scent. The tree is one of the sweet-juiced class, though the bark is astringent; and grass grows better under or in its shade, and suffers less by its drip, than in the case of almost any other tree.

The most beautiful habit of the tree is when its branches are slender and pendent, forming what is called a weeping birch. Authors sometimes state that the weeping birch is a different species from the common; but in the wild birch woods of the Highlands weeping birches occur so frequently on the richer grounds, and especially on the banks of the streams, and birches which do not weep, on the more barren exposed places, that it is scarcely possible they can be different species. In confirmation of their being the same, we may mention that it is a saying in some parts of the Highlands, that "The birch is a silly tree, for it weeps most where it has the least cause."

Birch.

On the banks of some of the larger rivers, just before they leave the mountains, birch trees often assume a very interesting character. The fibres of their roots clutch the projecting pieces of rock, as if they were the talons of birds of prey, penetrating downwards to a considerable depth. In effecting this the power of vegetable action within will sometimes open a crevice where the lightest stone it has to move is many tons, they thus draw a copious nourishment for the trees, as well as give them a firm support. In favourable exposures the height may be forty, fifty, or even sixty feet, though the trunk is rarely, indeed, so much as one foot in diameter.

In these situations the pendent or weeping twigs, seldom thicker than packthread, are often forty or fifty feet long, and wave most gracefully in the little winds which are sporting over the waters in those wild places.

The points of those twigs are often bathed in the pools, or they play in the waterfalls, and a cascade among rocky grounds, with weeping birches, is perhaps one of the most picturesque scenes, on a small scale, which the country affords.

It is difficult to say in which places of the Scottish Highlands, cascades and rapids, with their accompaniment of waving birches, are the finest; but the "Dream of Kilmorac" on the Beauly, the fall of Rogart on the Conan, some of the woods at Cawdor Castle, those by Inver Farigag, and other places by Loch Ness, and also many parts on the Dulnan, are worth visiting.

Among the rude Highlanders the birch is the principal tree for country purposes: fences, houses, carts, ploughs, and all sorts of implements are made of birch; and it used to be quite common to see at the fairs in Inverness scores of equipages fully equipped, in which the horses and their riders were the only portions not made of birch. The twigs of the tree are naturally very tough; but, when used as substitutes for cordage, or for leather in harness, they have great additional toughness given to them by peeling off the bark and twisting the wood till it separates into fibres. A birchen "withie," as it is called, thus made, is considerably stronger and far more durable than a hempen cord of the same diameter; and the people use these, not as substitutes for cordage and leather, but as substitutes for iron. The wheels of the old-fashioned carts which were used for country purposes, were small discs of wood, made fast to the ends of a wooden roller, attached to the under part of the frame by two loops of birchen withie, turned round in them, which was the means of rotatory motion in the wheels: the creaking was exceedingly disagreeable, and so loud as to be heard several miles off.

The timber of the birch is white, close, and easily worked, so that it answers well in articles of turnery; but it is generally only of small diameter, and when used flat, it is very apt to warp. It is also very perishable when exposed to alternations of weather in close air, though it stands well in fences and hurdles; it is also much used for hoops, and the smaller twigs for brooms, the demand for which is very considerable. In the early part of the season, when the sap is in the wood, a sweetish juice may be obtained by bleeding the trunk, and this juice, which has an agreeable taste, is sometimes made into a weak wine.

The native birch is very easily raised in the nursery, and is so hardy, that it will grow in almost any soil, though the richer parts of the moorlands are the best adapted for it.

There are many foreign species, the timber of some of which is highly coloured, and therefore more showy than that of the native tree. But these species are generally American; and American trees never yield so solid or so durable timber as European ones of the same genera. Some of their foliages have a deep colour, and therefore make a good variety in ornamental planting; and as the autumnal tints of American trees are remarkable both for their variety and their beauty, they are still more ornamental on these accounts. As timber trees, however, it is doubtful whether they are worthy of cultivation.

The bark of the birch tree is an article of domestic economy, both in the countries north of the Baltic and in America, where it attains a larger size than naturally in Britain. The bark is firm and durable, and it is made into boxes, cups, and various other containing vessels, by sewing it together. It is also the principal material of which the light canoes of the North American Indians and Canadian hunters are made; and those canoes are not only much lighter than our best constructed boats of the same burthen, but they are much stronger and scarcely less handsome.

BIRD (*Avis*, literally "that which flies," or in the plural *aves*, birds). A class of warm-blooded animals, and the second into which the vertebrated animals are arranged by most of the systematic naturalists.

Birds are a well-marked and easily distinguished class, even by their external characters; so that, though they differ much from each other in their appearances and habits, there is not the least danger of confounding them with any of the other classes. They are all produced from eggs, which are very generally, but not universally, hatched by the heat of the parent, which incubates, or sits upon them, warming them with the heat of the breast, which appears to increase for the purpose, and be one of the natural inducements for the bird to sit; and in many cases the breast of the female becomes denuded of great part of its usual covering, by which means the heat is more freely and immediately communicated to the eggs, the natural covering being a bad conductor of heat.

Though birds are not the only animals which are produced from eggs, and though the eggs of some species of reptiles resemble those of some birds both in size and in colour, yet the egg of a bird is very easily distinguished from that of any other animal. The shell is harder, containing more salts of lime and less gelatinous matter than that of the eggs of reptiles, and it is more granular in its surface; it is also more brittle, though from its shape it is strong in proportion to the quantity of matter in it. Farther, the egg of a bird cannot be dinted without a fracture of the shell, while that of almost every other oviparous animal may. The contents of the bird's egg are also chemically different from those of that of the reptile; indicating even in the rudimental state a higher degree of organisation, and along with it, as is always the case, greater energy and activity in the powers of life. The egg of the bird is much more albuminous, so that it "boils hard," while that of the reptile consists more of gelatine. The flesh of the animals has much the same difference of quality. The muscular parts of birds are more dry and rigid than those of even the mammalia; and some of them are so hard and tough, as not to be eatable. The tendons and even the membranes have the same proportional firmness of structure; so that the flesh of an eagle is much firmer than the flesh of a lion. Even the bones of birds partake of that firmness which is traceable in the egg. All those which are elongated and cylindrical are hollow; but there is no marrow in the tubes, and no part of them is cellular with merely a crust of solid bone on the outside, as is the case in many of the bones of the mammalia. They are all remarkably firm in their texture, and the shape of the bone is always such as to give the greatest possible degree both of strength and of stiffness with the least possible quantity of materials.

The distinctive characters which are traceable in the covering and contents of the egg, are found in an especially conspicuous manner in the covering of the bird. All birds are covered with feathers; and they are the only animals which, properly speaking, are so. These feathers are of two sorts,—feathers for clothing, to protect the animal from the vicissitudes of the weather, and feathers for flight. Both of these are beautifully modified so as to suit the different habits of the several species, and adapt them to the climates and the elements in which they find their food.

Some other animals, as for instance the lepidopterous insects—the butterflies and the moths—have a coat of feathers, or rather of fringed or feathery scales; but these have few or none of the characters of true feathers, and in no case, except that of birds, are feathers the instruments of flight. But still we can, in the imperfect feathers of the lepidoptera, discover one of the uses of feathers in birds better than we can perhaps do in the feathers of birds themselves, as in them it is conjoined with other uses. The study of one animal often assists us in acquiring a knowledge of another, especially when the one contains a single part of that which is a compound organ in another; because by this means we get an analysis of the living animal, which is far more satisfactory than any that we could obtain by the dissection of a dead one; for we can, in the one case, actually see the part of the organ in action, whereas in the other we can only infer or guess at the way in which it acts.

Now, every one must have noticed, that bees, flies, and all insects which have membranous or naked wings, must keep those wings constantly in rapid motion while they fly. The motion is often so rapid that the wings cannot be seen, any further than by a sort of tremulous motion in the air; and the action of the wings produces all that humming and buzzing among flying insects, which makes the summer air so lively; for insects do not breathe by the mouth, and have no organ of voice of any description. The action of those naked wings upon the air must be very considerable; because when a common blue-bottle fly (*musca vomitoria*) alights on the window, and marches along one of the dusty bars of the frame, winnowing the air with its wings, in a vain attempt to escape through the glass, it stirs the dust more in proportion than a coach and six driving rapidly along a dry road on a hot summer's day. Insects with wings of this description cannot *hover*, or lean on the air with still and expanded wing.

But the lepidoptera, especially the butterflies, do hover about, and rest on the air, and wheel in various directions, with very little apparent motion of the wings; and when they do move them, it is done much more slowly than the motion of the naked wing, in proportion to the rate of progressive motion. These lepidopterous wings also move in silence, or when they are brought into such rapid action as to produce a sort of noise, it is a low and muffled rustle, and does not ring out, so that the largest butterfly or moth gets along much more silently than the gnat. We may add, as a farther instance of the same kind, that the bats (see BAT for the particulars, and in that article will be found some of the points of difference between bats and birds), when they fly, are obliged to winnow the air with their flying membranes, something in the same way as naked winged insects, though the flight of bats, unless when they are agitated, is comparatively noiseless. So also those reptiles which fly by means of membranous appendages, are obliged to flutter these very much in proportion to the rate of their progressive motion.

Now the difference of action in these two textures of wings in the other classes of animals, shows us the advantages which birds derive from their feathery covering and feathery organs of flight. These feathers, even to the minutest fibre on the plumes or necks, are tubular, consisting of only a thin film of solid matter, filled with air within, though strengthened by partitions of cellular substance, more or less close together, according to the strain which the feathers have to bear. From the mode in which the feathers, and all their parts, are laid upon the bird, it presents a smooth surface upwards and forwards, so that the animal can move in either of these directions, with very little resistance from the friction of the air. When it moves in either of them, the resistance of friction does not increase so rapidly as the rate of motion; because the pressure smooths the feathers, and causes the air to take less hold on them. This property, which arises in part from the texture of the upper surface of the feathers, but chiefly from the way in which they are formed and placed, is of equal service to birds when they must perch, or otherwise remain at rest so as to abide the blast, as when they fly exposed to it. Perching or flying, when a bird is in the wind it always faces the current; and thus offers the least resistance both by its form and its feathers.

When, however, the feathers are taken in the opposite directions, they offer as much increase of resistance as they offer diminution when they are taken above or in front. The wings are always more or less hollow on the under sides, and they take hold on the air by millions of fibres; so that a bird with its flying feathers on the stretch, would fall much more slowly than one would suppose from the difference between its specific gravity and that of the air.

The resistance which all the feathers on the body of the bird offer to motion backwards is still greater; and it increases with the force which tends to move the animal in that direction. The instant that it begins to be so driven backwards as that a current against its body is produced, the points of the feathers rise, and take the wind with so many fibres that the resistance is very similar to that made by a scaly fish, when one attempts to draw one of these by the tail; and every one who has angled, and accidentally caught even a common trout in that way, knows that an ounce weight is as difficult to land when so hooked as a pound weight is when hooked by the head. But the feathers of birds rise much more in proportion than the free edges of the scales upon any fish; and they are every way as well formed for "holding on" in the air, as those are for holding on in the water. Thus the bird may be said to resist motion backwards in the air, by throwing out the point of each feather like the "fluke" of an anchor.

And all this curious complexity of structure is necessary for enabling the bird to perform those motions which, in the case of an "air-bird," or one which is much on the wing, and on it in all weathers, is absolutely necessary. We are so much in the habit of seeing birds fly, and they fly with such apparent ease, that we are apt to overlook the many mechanical difficulties that have to be overcome by their organisation. But when attempts have been made by men to construct flying apparatus, or even to accomplish the apparently much simpler object of directing a balloon, which floats buoyantly without any effort, because it is filled with gas specifically lighter than the atmosphere, the attempters, notwithstanding all their mechanical boasting, and even their mechanical science, have found that they would require to go a long time to school before they could accomplish even the most apparently simple of those objects. A flying apparatus, to be moved by the human arms, is, like the kindred fancy of a perpetual motion, a physical impossibility, and the attempt to construct one is one of those absurdities into which men are apt to fall in the infancy of knowledge, when they have vanity enough to lead them wrong, but want the requisite knowledge for keeping them right. Even if the arms could be trimmed to perfect wings, bearing the same proportion to the weight of the human body as those of the bird of most powerful flight have to its weight, there are not in the human body any muscles by which such wings could receive any thing like a flying motion. Then, if that difficulty could be got the better of (which it evidently could not), the spine would bend, the body cant over, and tumble to the ground on whatever part happened to be the heaviest. Or, if this again could be got the better of, man is not adapted for breathing on the wing, and thus the circulation would stop, and there would be an end of the flier in the very beginning of his flight. In short, it may be said without fear of contradiction that no addition to the human body could make man a flyer.

If the study of the structure of birds had no other effect than the preventing of such fancies as these—fancies which, like the other absurdity mentioned, still sometimes occupy time in which the schemer might do something not altogether useless—it would be worthy of our attention. The writer of this article remembers, long ago, a case in which a young man, in a small country town, had got so much of the formal or colloquial part of science, that he was looked upon as a prodigy, and, among other things, a very Archimedes in mechanics. Earth could not set bounds to his ambition, and he would needs fly: so, after months of labour, he produced a pair of wings, and, mounting the top of a high barn at his father's farm-yard, spread them for flight, and shot boldly into the air; but no shot pigeon, or even pig of lead, was ever more true to the perpendicular; and it was well for his bones that the cess pool of the farm-yard received him on its soft bosom; for the wings barely saved him, till he could be got out, from the triple death of being drowned, smothered, and "*sconfassed*" (that word is untranslatable) in the savoury compost. The consequence of this attempt at flight was not only the loss of all the high reputation which the party had previously enjoyed, but so overwhelming a burden of ridicule that it broke his spirit, and he became literally good for nothing while he lived.

The cases of all who attempt flying by mechanical contrivances may not be quite so disastrous as this one, but they must be all equally unsuccessful. Nor does it appear that the guiding of a balloon, in any other direction than that in which the current of the air happens to drive it, can be more successful. There is no fulcrum from which a purchase can be obtained but the air itself; and the air presses equally in all directions when still, and in the direction of the wind with a force proportional to the velocity of that when it blows.

Still the bird, when it flies, overcomes mechanical resistances, and, according to the general law of matter, it must overcome them by mechanical means. The bird, too, is very simple in its form, and certainly not more complicated in its organisation than the slowest-paced of the mammalia. But the bird, when its habit is to be much on the wing, is all-over adapted for flight, and the system of its mechanics, if we could fully comprehend it, would certainly be the most curious, and far from the least instructive, in the whole of the animal kingdom.

The buoyancy, as well as the upward motion, is not very difficult to understand, because the wing, from its general form, and the structure of the feathers, rises with much less effort than it descends. Thus the constant tendency of the powerfully-winged bird is to mount upwards, and on this account the firmest bird, that which with the same volume of body and extent of wings, has the greatest specific gravity, is the best flyer, flies more steadily, and apparently with less effort. This must, of course, have a limit; because, leaving the incapacity of breathing out of the question, no bird could fly in a vacuum, and thus there must be a certain density of air which is the best adapted for the flight of any given species of bird. This appears, even in the case of heavy birds, to be considerably less than the density of the mean level of the earth's surface. Eagles are heavy birds, even for their powerful wings, and yet they are high-fliers, even when their abodes are at great elevations in the mountains. All birds which take long flights fly high, whatever may be their other habits. Wild geese, herons, all birds indiscriminately "take the sky" when they set out upon long journeys. In some this may be in part done to avoid enemies or obstacles, but the habit is too general for being accounted for upon any principle save that the high flight is the less fatiguing. Even rooks may be observed to adjust the height of their daily excursions from the rookeries, to the distance at which the pasture upon which they are to feed lies; and the swallow tribe wheel about far more rapidly and gracefully when they hawk high before rain, than when they skim the surfaces of the pools in fine weather. If we may judge from their appearance when we see them on the wing (the only means we have of judging), it appears that birds, when they are not in search of any thing upon the ground near them, mount up till they come to that density of atmosphere which is best suited to their weight and wings, and then continue onwards. There may be another reason: those upper regions to which the birds ascend on their long flights are in a great measure exempted from the momentary gusts and squalls which war upon the surface under them.

This buoyancy, arising from the structure of the wings, is a very beautiful portion of the mechanics of birds, but it is one which man would find it very difficult to imitate. The general form of the wing, the characters of the feathers, the articulations of all the joints, the relative power of the muscles, and even the general form and action of the whole body, are concerned in it. They are all living too—all exerting their peculiar animal actions, in unbidden harmony, with each other; for even the feathers are alive, and the skin in which they are inserted can communicate an individual motion to each. Thus the process is one which we cannot analyse so as to bring it within the scope of our very limited notions of mechanics, though there is no doubt that both the compound motion, and all the individual motions, of which it is made up, are in strict accordance with mechanical principles.

The most singular part of the whole process of flying is, however, the ease with which the bird makes the air a fulcrum, from which to leap, in that same element, and that not only by repeated jerks or efforts, which are characteristic of many of the smaller birds, which thus leap from perch to perch, or from thicket to thicket, but in the case of steady onward flight, in which a few movements of the wings will sometimes send the bird onward for many yards without any other apparent movement; and such appears to be the impulse thus given, that the bird will sometimes turn, and almost double back upon its former course, by merely altering the inclination of the body and wings, and without any new stroke or effort on the part of these. The spring of the tiger, or the bound of the antelope, though taken from the solid earth as a fulcrum, and effected by what we consider as the most powerful muscular action among the mammalia, is a mere fraction in point of distance compared with some of these gliding rushes of birds in the air; and it is worthy of remark, that birds cannot take these motions when they rise directly from the ground, or from their perch, but must have a certain quantity of fluttering, or hurried wing motion, to bring them up to their power.

We know that when any thing is projected forwards the resistance from which it is projected must be equal to the projectile force; for no mechanical force can act in one particular direction only, unless by means of resistance in the opposite direction. Consequently, when a bird gives itself an impulse in the air, in which mere gravitation to the earth can bear no part, and that cannot bear a part, unless the direction is downwards, its body must strike the air backwards with a force equal to that which impels it forwards; and, if the body of the bird had not a means of resisting the reaction backwards, it might move its wings ever so long or so vigorously without advancing a single inch. That the bird derives the greater part of that hold on the air, which enables it to take as effective a leap from that element as it could from a solid substance, and even more so, directly by the action of the wings, is true; but there is no doubt that it receives considerable assistance from the general muscular action. When birds are on long and smooth flight, they also acquire a momentum in proportion to their velocity, and the difference between their specific gravity and that of the air. In consequence of this momentum, they continue their progressive motion with much less effort; and the superiority of this momentum, in a rarer atmosphere, may be an additional reason why they fly high upon their long journeys. But there are many birds which proceed by a succession of jerks or leaps, in the pauses of which they are almost or altogether at rest, and these birds can acquire but little momentum, but must renew their whole impulse at every jerk. These are, for the most part, birds of low flight; and it is probable that the greater resistance of the denser atmosphere is as advantageous to them as the rarity of the upper strata is to those species which fly with a momentum. Birds of smooth flight also, however, often shoot onward with great rapidity, after having hovered so long over the same spot, as that all the momentum which they acquired in arriving at that spot must be exhausted; and they must take the whole of their new velocities from the resistance of the air.

The flight of those birds which proceed by jerks affords a good illustration of the fact which has been stated, of there being a buoyant or upward tendency in the mere motion of the wings in flying. They do not proceed upon a level, but by a series of flat vertical parabolas, each as long as one of the jerks; and the motion is upward while the strength of the jerk lasts, and downward as it weakens. The tail feathers of such birds are also frequently flirted out horizontally, so that the tail may either resist too great an upward motion from the jerk, or act as a parachute against the downward motion.

The head and neck also come into action, both in altering the lateral course of the bird, and in shifting its centre of gravity, with reference to the central line of action in the wings; and the last alteration has no inconsiderable influence in its ascents and its descents. Indeed, a bird when flying is so much in action in all its parts, that it is impossible to point out the specific action of each. Thus we cannot explain the rationale of flight in any thing like a satisfactory manner, and therefore though the operation is not only possible, but performed habitually and with ease, the precise mode in which it is done still remains one of the wonders of nature.

We have made these general observations on the operation of flying and the organs of flight, not only because flying is peculiarly the motion of birds, and the one from which they are named, but also to show how much there is to be learned from operations of nature, which we all have daily opportunities of observing, and yet upon which comparatively few of us ever bestow a single thought. But it is not from this species of motion alone that we can obtain any thing like a knowledge of birds, neither can we found wholly or chiefly upon it that classification which is calculated to assist us in our inquiries.

The general definition of a bird, at least as dependent on its external appearance, is so simple and so well understood, that the repetition of it would be superfluous. It is a vertebrated animal; and, be the species what it might, no one would mistake it for one of the mammalia, or a reptile, or a fish. There have been some mistakes the other way, though they have been but few: in the infancy of natural science bats were considered as a sort of birds: and some of the moderns, who have not quite arrived at the years of scientific discretion in physiology, have gone about to make a sort of bird of the ornithorhynchus.

These mistakes show, what we find to be the fact when we make the attempt, that the natural, or even the satisfactory classification of birds according to an artificial system, is no easy matter. The bats were called birds on account of their flying membranes, and the ornithorhynchus because of its mandibles, which are something (but not very) like those of a duck's bill, while both animals had all the essential characters of true mammalia, though mammalia of peculiar form and habits. Thus it appears that neither the bill nor the flight of birds can be taken as the ground of a classification; as little can the feet; and the digestive organs merely point out the general kind of food, and not how or where it is obtained.

The feeding of birds cannot be made so good a means of general distinction as that of the mammalia, because many birds are so very miscellaneous in what they eat that no one article can be considered as their characteristic or leading food. And when we take the three leading characters: the bill and digestive organs as the system of nourishment, the wings as the organs of motion in the air, and the feet as organs of motion, we find that not even any two of them vary according to the same law, so that we cannot form a classification, even upon the relations which they bear to each other.

Thus, while birds are remarkably well defined as a class, while they are among the most interesting of all nature's productions, and while in their individual habits in wild nature, they are more accessible to our observation than, perhaps, any other animals, they are perfect puzzles when we attempt to systematise them; and almost the best that we can do is to go to wild nature, and study them individually in forest, field, or flood.

Their double motion, that of the feet and that of the wings, which is so modified that it becomes the four motions of walking, flying, swimming, and diving, is the chief cause of the perplexity. Some birds, as the common swift, have very little motion, save the aerial one; others, such as the ostrich, have none but the terrestrial one; some again, as the penguins, have very little more than the aquatic ones; and some, such as the pochard ducks, have all the four. Those which have the same kinds of motions have the one or the other predominating in an endless variety of degrees; and the character of the bill, according to the motions which we observe from other species, sometimes agrees more with the one system of nature, and sometimes with the other. All these perplexing circumstances increase the interest of the study of birds, at the same time that they increase the difficulty; and therefore, though none of the systems are quite consistent—that is, though no single character can be carried through the class—there has been no want of systems, or of ability in the formation of them. We have no desire to add another to the number, as the labour would be but of little value, and in this work out of place; so we shall chiefly follow that of Cuvier, though with some slight variations. The necessity which Cuvier, who had studied the structure of animals intimately, and endeavoured to arrange them according to it, found himself under of sometimes using the bills, sometimes the feet, and sometimes the wings, as the leading characters of his subdivisions, shows very forcibly the difficulty which attends this class of animals.

But before any system can be made intelligible to those who do not already understand the subject, we must give some explanation of the structures and functions on which the systematic arrangement is founded; and this will be rendered more easy of consultation by marking it off into portions under separate titles.

I. General characters of the class.—Birds consist of a head, neck, trunk, tail, and four limbs or extremities. The head is in general small in proportion to the whole animal; and the jaws are produced and terminate in horny mandibles, which open and shut horizontally, forming the bill, which, excepting in those species which kill prey, is the chief or the sole instrument in feeding. The bill varies much, both in the form and in the consistency of the mandibles. In some it serves as a pair of strong pincers for tearing flesh; in others it is a spear for transfixing; in others again it is adapted for hewing into timber; or it is fitted for boring into the ground or for dabbling in the sludge at the bottom of shallow waters, in which cases it is understood to have a sentient covering, so that it can both find and seize the food. Sometimes it is borne open as the bird flies, and catches insects as in a net; in other cases it catches by snapping. In some it is fitted for breaking the hard shells of fruits; in others for cleaving pulpy ones, or raising the scales of cones so as to get at the seeds. The modes of using it are indeed exceedingly varied; for birds are almost universal feeders, both in regard of substance and of situation; and wherever a bird's food is to be found, there is generally a bird to eat it, and the bill of that bird is always very well adapted for taking it. But the office of the bill ends with the prehension of the food, or the dividing of it into such portions as can pass the gullet (which is generally capable of considerable distension) into the stomach; and there is no mastication, or chewing by the mouth, of birds, and no apparatus for the performing of such an office.

The organs of smell, sight, and hearing, are placed in the head; the nostrils at the base of the bill, in the substance of it, or even near its extremity, according to the habit; and they are variously defended by feathers, hairs, scales, and valvular membranes.

The eyes of birds are placed in the sides of the head, generally speaking better adapted for seeing under them or laterally than above them or directly in front. But the position varies with the habit: birds which prey only in clear light and under them have the eyes far apart, and shaded; while those which prey in the twilight have them turned more to the front. The eye is better fortified than in the mammalia; the anterior part of the ball has a circle of bone; and there is a nictitating membrane, or third eyelid, which, when not used, is protected from the action of the weather by a lodgment in the inner canthus of the eye. It is thus more soft and moist than an exposed eyelid, and it works over the whole eye in a direction crosswise to the usual opening. The corner of the eye is very convex, and beautifully clear; but the crystalline lens is rather flat. The eyes of birds are in many instances much more exposed to the action of the weather than the eyes of most other vertebrated animals, and they appear to be the organs of sense upon which birds have their chief dependence; and, true to the general law of nature, that the supply is always proportionate to the want, they are furnished and fortified in an extraordinary manner.

The ears of birds, within the bones of the head, are well formed; but, with the exception of nocturnal feeders, which are, of course, much guided by the ear, they have little or no external concha. The nocturnal ones (the owls especially) have external ears; but the openings of the ears of all birds are concealed by feathers, generally of a more downy character than those on the neighbouring parts. These protect the ear from the violent action of the air when the bird is in rapid flight, and also preserve a uniform temperature in that delicate organ.

The neck of birds does not, like that of the mammalia, consist of the same number of vertebræ in all the species, but varies much according to the habit of the bird. In some it is very long, and in others moderate, but in all it is susceptible of much motion, and of motion in all directions; so that, generally speaking, the point of the bill commands the whole space within reach of the extended neck, and also all parts of the body of the bird. The vertebræ are also articulated in such a manner as that the greatest and most rapid flexures of the neck do not in the least disturb the spinal cord or the circulation in the blood-vessels. Neither does it, generally speaking, interrupt the breathing by the windpipe; though, as will be explained in another section of this article, the breathing of birds is not wholly performed through that organ.

As the bill of very many birds has to perform the functions both of a mouth and hand, it becomes necessary that the neck should be, in some respects, an arm; and it is a very convenient and efficient one. The extent to which it can bend, not only without injury to the bird, but with perfect ease, is proved by the fact, that most birds repose either with the neck doubled back upon the shoulders, and forward again on itself, or with the head placed under the wing. Many of the long-necked birds carry a fold of their necks upon their shoulders while they are in ordinary flight, though they stretch them out in case of alarm. The rapidity of motion, both in long necks and in those of moderate length, is exemplified in the strokes of the heron and the bittern, and in those of the woodpecker, which follow each other so fast, that the eye cannot see them, or the ear count their sounds. The rotatory motion of the joints of the neck is seen in the wryneck, which can turn the head quite round, till the chin and point of the bill are in the same line with the middle of the back.

The head and neck of birds, taken together, may, in the average of the class, be considered as the working apparatus, in the finding of food, the constructing of nests, and, generally speaking, in all mechanical operations. Their forms are of course as varied as the habits and haunts of the owners, being, in all cases, the best adapted to them; and therefore they do not admit of general description, though they are good characters of tribes and species, as indicating how and where the food is obtained. Independently altogether of their uses, in enabling us to obtain a rational knowledge of birds, they are valuable subjects of contemplation, as perfect models of mechanical arrangement, and most striking proofs of purpose, and the perfect accomplishment of purpose, in creation, which, labour as we may, will always present us much beyond our power of imitating, and may well command our admiration. And here we cannot help pausing to remark (for though the remark would occur to the reflective reader, we are unwilling that he should rob us of the pleasure of making it: as enough remains for him, and what we state may lead the unaccustomed to reflection)—how superior the models which we find in nature, are to those of human contrivance. We study the latter; we soon find out all their principles; and there, in so far as we are concerned, instruction, and with that mental pleasure, ends, so that, be it the steam engine, the chronometer, or any other *chef d'œuvre* of science and art combined, the mental improvement and pleasure are soon at an end; and we have nothing but the cold consideration of money value and utility, which, however necessary to our bodily existence and comfort, is always blight and mildew to the mind when uppermost there. Or, if we carry our observation further, we find faults and imperfections which we cannot remedy, and these spoil our enjoyment.

But when nature is the model, we find no fault or imperfection, and we never can exhaust the information which it affords. The Macedonian conqueror is said to have wept when the world was won; but if he had followed out the path of his tutor the Stagyrite, so far as to study the mechanism of the head and neck of a bird, he would have found, in that single specimen, a world of wisdom which he never could have conquered. There is not a projection or a hollow in all their curiously-shaped bones, or a tube, or membrane, or a fibre, in all the soft parts with which they are invested, but has its use, and is more beautifully adapted to that use, and fashioned with more perfect economy, than the most finished production of human skill. The motions which the point of the human finger can perform (see Articulata) are almost infinite to our arithmetic, but they are nothing compared to those of the point of the bill in some birds; and when we consider that, by the aid of its other mechanism, and without any apparatus but what God has given it in its own structure, it will strike prey under the birch in Lapland, and again perform the same feat under the palm by the bank of the Niger, before the same spot of earth has thrice seen the sun, it is passing wonderful, and should, even under the worst of the little casualties of life, make us grateful to God for giving us such things for our contemplation.

The body of birds, that is, the dorsal and the lumbar portion of the spine, upon which the body or trunk may be said to be articulated, has no specific action to perform in what may be termed the working motions. Hence, though it is composed of vertebræ, and by that means less liable to fracture than if it were a single bone of the same substance, the vertebræ admit of little motion, most of them are soldered together, and some of the junctions in time become ossified. It is the same with the sternum or principal bone on the under part. That is very large, and consists of five bones, which are closely united from the first, and ultimately soldered into one. One of these occupies the centre, two the sides anteriorly, and two posteriorly, the latter being forked at their posterior edges, though in some species the terminations of the forks are united by bone. The sternum in birds is a very important bone. One of its uses is to support the muscles which move the wings in flying; another to protect the contents of the body from injury or pressure from beneath, and a third to give support and firmness to them. From the number and importance of these uses, the sternum of birds is of no small value in the distinction of the different tribes; and on that account we shall have to revert to the notice of it in another section.

The furcal bone, or "merry-thought," formed by the union of the clavicles, and attached to the two projecting processes of the coracoid bones, keeps the shoulders apart from each other, and in their proper places during the powerful action of the wings in flight. The more powerful the flight of the bird, the more completely does this bone form an arch, so that it resists that compression which might otherwise take place in the throat and chest. Its form and strength vary much with the habits of the different tribes.

The bones of the pelvis advance considerably forwards; but they are open in the rear for the passage of the eggs. They and the bones of the rump are closely united together. The ribs, too, have very little motion, so that the operation of breathing alters the form and capacity of the body much less than in the mammalia. The greater part of the body may be regarded as a sort of box formed of bones, not breaking by slight pressure (as a box composed of one bone would be apt to do), but still very firm and stiff, stiffer anteriorly in those birds which fly much and powerfully, and more produced, particularly both in the sternum and the ribs, in birds which swim and dive. As a whole, it may be said to admit of no lateral bending; and the little that it admits of in the vertical direction is confined to the lumbar vertebræ.

The bony part of the tail of birds is generally short, the effective tail, as an organ of flight, being composed of feathers; but in all birds which have much motion of the tail, the number of vertebræ in that organ is considerable, though each individually is very short, and the whole tapers to a point.

The wings, or anterior extremities of birds, which correspond in position to the arms of man and the fore legs in the mammalia, are adapted for flight only, or, if they perform any other office, it is merely that of balancing. Their general action in flight has already been partially mentioned; their several parts, as they appear externally, will be mentioned in the next section; and their peculiar forms, as adapted to the different habits of the various tribes and genera, will be found in the accounts of these, under their respective names. We shall here only mention, therefore, that the bones of the moveable part of the wing consist of a humerus, a fore-arm, and a hand; the part answering to the fingers of the latter being very much elongated, with only one finger fully developed, but the rudiments of the other more or less apparent, according to the power of action in the wing. The flying feathers are placed upon these bones, and the thumb generally carries a little plume of stiff but short feathers, which is called the bastard wing, and in some species it is armed with a claw or spine. The head of the humerus is articulated nearly where the scapular bones, which are imbedded in the muscles on the shoulder, the coracoid bones which proceed from the anterior parts of the sternum, and the furcal bone, or united clavicles, which projects as an arch in front of the breast, protecting the vessels of the throat, at the same time that it keeps the heads of the coracoids and scapulars in their proper places, meet each other. The shoulder-joint, or articulation of the humerus, which is the centre of the grand action of the wing, is thus placed on the firmest of all supports—a tripod, which is the only number of supports that will form a sure base upon all kinds of surfaces. In birds of the most powerful wing, these three supports divide the space round the articulation into nearly three equal parts, and they do not differ much in strength; they all "give" a little, so that the joint is not nearly so liable to dislocation as if the point to which it is articulated were fixed; neither is there so much danger of fracture or of concussion to the vital parts by any sudden jerk given violently to the wing.

It is one of the most beautiful parts of the structure of animals, that those organs which have to perform the most violent motions are never directly articulated on an immoveable base, or a base immediately in contact with the spinal column, far less with the bones of the head. There is always the play of a slow-moving joint, or union of some description or other, between the articulation of the moveable bone and that bone which encloses the nervous mass. By this means that mass is made to ride smoothly while the animal leaps, or bounds, or flies, or otherwise acts powerfully and irregularly; just as the springs of a carriage enable those within it to ride smoothly, notwithstanding the jolting of the wheels upon an uneven road.

The scapula, or blade-bone, has less motion in birds than in mammalia, because, with the exception of those mammalia which have flying membranes, the motion of fore-legs is crosswise to that of wings. In the bat tribe there is a slight approximation to this species of insertion of the humerus in the large clavicles and blade-bones; though even in them the adaptation for an organ of flight is much less perfect than in birds. In bears, on the other hand, whose habit is to climb trees and otherwise to hug by the compression of the fore-legs together, the blade-bone is very moveable, and there are no clavicles.

Some of the birds which can fly, often use the half-expanded wings to assist in balancing them when they run; and this habit is most frequent with those that have the legs long. Some of the birds which cannot fly, have rudimental wings, which they appear to use for the same purposes. The only bird which has the wings so perfectly rudimental and concealed within the integuments as not to be of any use in balancing, is the Apteryx (see that article); and it has the legs very short and stout, and, though its habits are not known, it is probably not much of a runner.

Those short-winged birds which dive under water, whether they tread the water itself by means of webbed feet, as is the case with the diving ducks, and divers properly so called, or tread the bottoms of the shallows with feet that have the toes free, as is the case with the dipper, use the wings in the water. But wings are not very efficient instruments of progressive motion either on the ground or in the water, though they are of advantage in balancing on land, and in ascending or descending in the divers. All wings, whether perfect or imperfect, are formed and articulated on the same general plan; and though they admit of a little inclination to the front or the rear, their principal motions are always across the axis of the body.

From what was formerly said of wings acting more efficiently in an atmosphere rather rare than in a denser one, it follows that they must act still less efficiently in water than in the densest atmosphere. Indeed water is so nearly of the same specific gravity with the bird, that an action of the wings analogous to that of flying in the air, could not possibly be performed in the water. Air—the free air of heaven—is therefore the proper element for wings, and their proper function is flying; so that any other which they may perform must be regarded as a departure from the typical character of a bird, of which feathered wings are the grand external characteristic.

And here we may pause to remark on the wisdom of an arrangement which ensures a species of tenantry for the air, as beautiful as that of the most picturesque inhabitants of the earth. Clothed in a plumage no less durable than that of the most favoured of the animal kingdom, and performing, in their aërial flights, a series of gyrations ever varying both in form and character, to say nothing of their changeful and varied colours, which by the motion of the bird are made to rival the glowing tints of "the arch of heaven."

The posterior extremities, or feet, of birds, are their chief organs of progressive motion, and their chief supports when at rest, upon the ground or other solids. But the feet perform more operations than the wings. In some birds they are used for clutching or killing prey; in others for scraping in the ground for food, and also in the digging of burrows and the preparation of other places for the depositing of the eggs; in others, again, they are used as a sort of hands in climbing, in which operation they are in some species assisted by the bill; and in others still they are occasionally used in conveying the food to the mouth, or in holding it while it is preparing for swallowing, by the action of the bill. They are also varied to suit the kinds of surfaces which are frequented by the different tribes; and they serve as stilts for wading, and as paddles or oars for acting in the water. The general characters of the foot and leg of a bird are so well preserved through all their almost innumerable varieties of form, that there is no danger of mistaking them for the feet of any other class. The feet of some of the reptiles resemble them the most; but still the shape, the articulations, and the covering, even in the part of the bird which is not feathered, are all or each sufficient for distinguishing the one from the other.

The feet of birds are the organs of one of their most important motions; and thus they are made one of the grounds of that very imperfect classification which science has been enabled to make of the feathered race. As the bill is a sort of guide to the species of food; and the wings to the kind, style, and partially the purpose of flight; so the feet are a sort of guides to the home and habitation of the bird, and also to the place of its feeding, if its habit be not to feed on the wing; and whether that is its habit or not, can, in some degree, be determined by the characters of the wings and the bill. Birds which habitually feed on the wing have, in general, pointed wings, and can wheel and turn on the tips of them, whatever may be their other characters; and they have generally either a wide gape or a powerful and rapid action of the mandible, so as to catch their prey by snapping.

The leg and foot always consist of three principal pieces, independently of the toes: the femur or the thigh-bone, the tibia or leg-bone, and the tarsus or foot-bone. The tarsus, like the bones of the wings, answering to the palm of the hand, is always very much elongated; and it is popularly called the leg, though in fact it is the foot. Birds, in general, follow the same law as the mammalia in the use of their posterior extremities as organs of walking; they are digitigrade, or walk upon the toes, and not on the tarsus; and those which walk upon the latter have even a more awkward and shambling gait than the mammalia which have that habit; and indeed they can hardly be said to walk at all. The knee joint, or articulation of the tibia with the femur, which bends forward only, appears to be inadequate to the balancing even of a nearly inflexible spine in any but a nearly vertical position. In man we have a flexible spine, balanced with the whole length of the tarsus on the ground, but it is in an erect position; and besides there is the astragalus or heel-bone in man, which not only sustains the balance of the foot, but gives a lever power to the *tendo Achillis*, which, when pulled by the strong muscles to which it is attached, throws the pressure of the body upon the balls of the toes. The human foot is not, however, a fit subject of comparison with the feet either of birds or of the mammalia. See the articles BIMANA and MAN.

Those birds which bring the whole length of the tarsus to the ground when they walk, or attempt to walk, are but few in number; and they are all aquatic birds, the proper functions of whose feet is swimming and not walking. Their legs are articulated far backward, and they have that oblique motion of the joints for throwing the swimming feet at some distance from the body of which some notice will be found in the article BEAVER. They spend most of their time, and find the whole or nearly the whole of their food, in the water; and such of them as have not the power of flight (for some of them are so exclusively aquatic that they can neither fly in the air nor walk on the earth) deposit their eggs near the margin of the water, so that their terrestrial operations are limited to shuffling along a few feet, or sitting erect upon the rocks, in which latter, and even in the former, the tail assists in supporting them, as is the case with beavers when they stand up.

The head of the femur is articulated rather farther forward in walking birds than in the mammalia; and the femur itself is not so free or so much used in the motion of the leg. The tibia, or true leg, is the part usually called the thigh, or in the larger birds, which are brought to table, the drum-stick. In birds which make much use of their feet, the tibia is much loaded with muscles; and it is generally protected by a profusion of soft and downy feathers, especially in those birds which are much exposed to the weather, and use their toes in clutching or killing their prey.

Many of the wading birds, and some of the running ones, have a portion of the under end of the tibia bare of feathers; but the muscles do not descend so low as that part; and it may be considered as a general arrangement in the structure of birds that the muscles are always under a protecting covering of feathers.

The tarsi and toes, and also the naked portions of the tibia, contain few or no muscles, but are made up of bones, tendons, straps of ligaments for keeping the tendons in their places, and the integuments, which are very firm and tough skin, variously covered with scales, sometimes imbricated and sometimes reticulated; and there are often pads on the under part of a consistency not very unlike caoutchouc, or Indian rubber, and nearly as elastic and as difficult to wet as that substance.

The toes on the foot, three before and one behind, may be regarded as the normal number in the order; but they are fewer in some of the running birds, and more numerous in some of the other orders. The toes, however, vary so much in the manner of their articulation, in their size and power, and in their appendages, that they do not admit of general description. The toes are the portion of the foot usually taken as the ground of systematic arrangement; though as the principal muscles which move the toes are not in the toes themselves, or even in the tarsus, the whole leg would be a better indication of the habits of the bird; though, being a more complicated structure, an arrangement founded upon it would make the elements of the system apparently a little more difficult. But the difficulty would be apparent and not real; and it is very probable that, if we included a little more character, and thereby gave a little more meaning, to our larger divisions of the several classes of animals, we would both shorten and smooth the road to that accurate knowledge of the individuals, which is the valuable, and indeed the only valuable, part of the whole. The other method, that which takes but one portion of an organ as the ground of resemblance, is simple only in proportion as it teaches little, and simplest of all when it teaches nothing. See the section on SYSTEMATIC ARRANGEMENT in this article; and also the general article CLASSIFICATION in its place in the alphabet.

In all birds, the bending of the tibial and tarsal joints has the same effect in the contracting of the muscles which close the toes. This may be seen in those birds which draw up one of their feet, either to warm it, or to rest on the other; for the toes of the foot which is drawn up are always clutched together, and to open them out with the foot in that position requires an effort. It even requires an effort in the bird to keep the toes expanded. When it rests its weight on the feet the weight causes the effort; but the toes of a dead bird are always partially closed, which shows that a muscular exertion is necessary for keeping them open when that is not effected by the weight. When the bird is dead, the muscles, which act both ways, are of course equally rigid, and the toes close, to the degree at which the living muscles would balance each other, and the leg be in a state of repose.

This tendency of the foot to close when the leg is bent is effected in a very simple manner: the tendons of the contracting muscles pass over the outsides of the bent joints, and those of the extending ones over the insides; so that, by the bending, the former are pulled much in the same way as if their muscles were contracted and the latter are slackened in the same way as if their muscles were relaxed.

All feet which bear on the ground with jointed toes, and partially even those which have hoofs, possess this property, though few of them possess it in the same perfection as the feet of birds.

And when we consider the difference of habit between clutching, climbing, and perching birds, and quadrupeds which have actions somewhat similar, we can at once see that this property is most necessary in the feet of the birds. Mammalia which clutch prey with their paws have a point of rest for their other feet, either on the body of the prey, or on some other solid substance; and even in those climbing mammalia which are the most dexterous leapers, the spring is taken from the hind feet, and the grand use of the fore ones is to catch hold at the end of the leap. In slower climbers the one set of extremities are always fast while the others are extended; and in the few mammalia (such for instance as the sloths) which may be said to perch, the proper perching apparatus is hooks so formed by the claws and toes that the requisite shape is preserved by stops of bone. Thus, as the flexible spine of the mammalia requires to be borne up by two sets of supports, when it is in a horizontal position, so when they are in action they may be said to have always two points of support upon the ground or other surface which bears them up, a fore and hind one, of the opposite sides, alternately, when they walk; and the two fore and the two hind ones alternately when they bound and leap. The former of these actions is confined almost exclusively to the legs and feet, but in the latter the spine comes more efficiently into play, as may be seen in the leaping of the cat tribe or in the coursing of a greyhound.

Birds deriving no support upon solid surfaces from their anterior extremities, and having no action of the spine to assist them in leaping, and yet having to perch, and not only poise themselves, but find food, construct nests, and perform other operations upon perches far more unstable than any upon which the mammalia have to rest, must be more sure-footed in proportion. The slender sprays of trees, the flexible stalks of herbaceous plants, and all sorts of substances, not only of a yielding nature in themselves, but exposed to the violent action of the winds, by which both perch and percher are rocked at no moderate rate, are all pathways to one race or other of the feathered tribe. Nor, though at first sight such seems to be the case, is that the footing most difficult to be maintained; for, upon a bending twig or stem, the perch and percher soon acquire the same momentum, swing together, and have no more tendency to separate than water has to escape from a glass, when that glass is set in one side of a hoop, and the hoop whirled rapidly round on the opposite point. This concert of motion, as we may call it, is general in mechanics, and the application of it is of great service to all birds which feed or repose on perches of the description alluded to. It is the resistance of the bottom and sides of the glass to the centrifugal force of the water, and the resistance of the hoop to the same force in the glass, which keeps these three together, or in concerted motion; and in like manner when a bird is rocked in the spray, all that it has to do is to resist its own centrifugal force by the clutch of the feet.

But when the bird has to perch on the pinnacles of the rocks, as is the case with the mountain eagles and some of the other mountaineers, and also with several of the more predatory and powerfully-winged sea-birds, it has not the advantage of concerted motion along with its perch, but must either abide at rest, despise the tempest, or drift before its fury. The habitations of those species which sit on the pinnacles of rocks are the very homes of the tempests; for winds war upon rifted shores and among rugged mountains when the expanse of the sea and the plain are still. Not only this, but these birds live much upon the havoc which the tempests produce among other creatures; and thus it becomes necessary that they should be enabled to remain on their watch-towers, and mark its progress. But here, as in all other cases, the purpose of nature is accomplished, and accomplished by apparatus the most effective, and at the same time the most simple.

It is chiefly by the pulling of the tendons which close the toes, by the mere action of bending the joints of the leg, that this firmness on the perch is maintained. Their tendons pull all the phalanges of the toes; and thus the same action, and that not a muscular exertion, which would tire, but a state of greater repose than when the legs are not bent, enables the bird to hold on with the whole foot, and the hold taken by the elastic pads and tubercles is far more firm upon a hard substance than if it were taken by means of claws. The rock perchers also, in general, use their claws in clutching and killing their prey, so that they could not be used in keeping the perch without blunting their points, and thus unfitting them for their proper purposes; neither could a hold merely by means of the claws be kept for any length of time, unless the hold were above the body, and kept by the pressure of that. All perchers by the claws for repose perch with the back undermost, or at least in such a way as that the weight hangs upon the claws as upon hooks, the form of which is maintained either by stops of bone, or by the weight of the dependent body pulling the tendons, and the firmness is given wholly by the latter.

Those provisions for the secure maintenance of their place, in animals, arising from structure merely, and not requiring any muscular exertion, or other effort on their part, which can in any way fatigue them by its continuance, are among the most striking instances of that superiority of design and adaptation of which every thing that nature produces is an example. We know, from our own case, that if even a single muscle of the system, except those which are employed in immediately carrying on the vital functions, be exerted, not one part of the body, far less the whole of it, can be in that state of repose which is necessary for enabling the active system to recover its tone. With us, an easy position on the couch, in the chair, on the grassy sod, or on the bare earth, according to the habit, and the need that there is for rest, is the position for repose; and if we were to attempt to sleep, clinging by the hands, or in any other way in which our mere weight is not the means by which we retain our position, we should assuredly fall. But birds have to repose in all varieties of situation, and their means of keeping their places are increased and varied accordingly.

In their alimentary system birds are variously formed, according to the general nature of their food. If that food is wholly animal, their stomachs are simple and membranous, and their intestinal canals short, and without cæca. If wholly vegetable, the stomach is more complicated: one part, which is styled the craw, and which is little else than an enlargement of the inferior part of the gullet, being a sort of receptacle into which they can take much more food than the bare stomach can at once receive for the purpose of digestion. In this respect it bears some resemblance to the paunch, or first stomach of the ruminant mammalia; but as birds have no chewing apparatus in the mouth, the food taken into the craw does not return to the mouth, but proceeds into the stomach portion by portion, as the progress of digestion requires. The craw of these birds is generally placed in front of the sternal bones, so that it can admit of distension by a large quantity of food without disturbing the other viscera, or requiring any enlargement of the bony cavity of the body to admit of its distension. Even this position of the craw, which at first seems a very simple matter, is attended with considerable advantage to the bird. The habits of birds require that the size of their body should be as small as possible, and that the capacity of it, as determined by the bones of the trunk, should be as uniformly the same as possible. Now, if this craw, which, as a magazine of food, is sometimes empty and sometimes much distended, were lodged within the bones, it would either press in an inconvenient manner upon the other viscera, when full, or it would leave a vacant space in the cavity of the body when empty. Either of these would be attended with inconvenience, as the pressure on the viscera would disturb the functions, and render the bird inactive, and the additional space would require an enlargement in the cross section, and thus cause the bird to oppose more resistance to the air in proportion to its power of flying, and thereby to the same extent diminish that power.

The avoiding of the same inconveniences requires the existence both of the craw and the true digestive stomach as separate organs. Vegetable food contains much less animal nourishment than animal food, and in many birds there has to be as much and as severe labour used in the procuring of it. The waste of substance, and the necessity of food, is in all animals in proportion to their activity; therefore active vegetable-feeding birds must take a proportionably greater quantity of food than animal feeders of the same activity. This is well exemplified in the case of pigeons, and also in that of all the finch tribe which are active birds, and also very vegetable in their feeding.

If this excess of food were taken into the stomach at once, and that stomach lodged within the cavity of the body, the same inconveniences would arise as if the craw were situated there; and the stomach itself, as containing a greater quantity at once, would either require to be more powerful, or it would perform the function of digestion less efficiently. But, with the addition of the craw as a reservoir, the gizzard, or muscular stomach, which may be said to perform the operations of both mastication and digestion, can afford to be smaller; and this, besides making the organ more efficient, with the same exertion of muscular energy, leaves room for the greater length of the intestinal canal, and for the cæcal appendages which are necessary in extracting the chyle from the vegetable aliment.

Thus we see that, in the structure of the alimentary system in these birds, there is the same evidence of wisdom of purpose, and perfection of execution, as in that of their external organs. These advantages are not confined to the mere convenience of that system in which they are found. The advantage goes to all the habits of the bird. In birds, as well as in mammalia, the vegetable feeders are the chief prey of the carnivorous ones, and thus they require to be on the alert, and capable of making their escape at all times when their enemies are abroad. But if they took into the true stomach, and had subjected to the process of digestion at once the great quantity of food which is required for their support, they would, as in the case with birds of prey, be incapable of flight, or, at all events, indisposed to it, after a hearty meal. Their food they must take during the day, and not after dusk, and yet it seems that they require the digestive process to be going on constantly; and thus the moderately-sized gizzard, and the supply in the craw, are remarkably well adapted to their habits; so that, after taking an abundant supply of food, they are nearly as fit for flight as when they are empty.

The carnivorous birds, especially vultures, and other species which feed upon the carcases of the larger animals, when these are killed by other casualties, are remarkable for the opposite structure of the alimentary system, and for indolence after a full meal. Their stomachs are membranous and simple, and their intestines short, and without any cæcal appendages, so that the process of digestion is with them a much more simple matter. But when they have made a hearty meal, the full stomach presses upon and retards the action of the other parts of their viscera, or, at all events, the process of digestion monopolises the whole of their energy; so that, though birds of long and powerful flight when hungry, they are so reluctant to take the wing after feeding, that they may be knocked down with a stick, or taken with the hands, without making much resistance.

Their power of enduring hunger seems to be in proportion to that of taking food directly into the stomach, and converting it into nourishment by a more simple apparatus; and, unless when they are forced from their retreats by hunger, they are far more retired and quiet than the vegetable feeders. The same analogy holds between the carnivorous and the herbivorous mammalia,—the former come abroad only at particular times, the latter are habitually upon their pastures, and their hunger begins when the receiving stomach is empty, or nearly so.

Birds which are exclusively vegetable in their feeding, and those which are exclusively carnivorous, may be regarded as the extremes of the class, in so far as the alimentary system is concerned. The former have that system largest, most complicated, and most constantly in action, and the true stomach always a gizzard. The latter have, in proportion to the general size of their bodies, the alimentary apparatus smallest, and also the most simple, acting readily, but acting, or requiring to act, only at intervals; and they have the stomach always membranous.

Those vegetable feeders that live much on seeds and in temperate climates which is the case with the majority, require an auxiliary to even the muscular action of the most powerful gizzard, in order so to grind and divide the food as that the gastric juice can act upon it. For this purpose they swallow small stones and gravel; and it has been observed that some of the gallinaceous birds were kept in equal condition and in better health upon much less food when they had access to those auxiliaries. It is not improbable that a small quantity of resisting matter may help the digestion of all stomachs; and that it is upon this principle that brown bread is more digestive by the human stomach than bread of the finest flour from which the whole of the husky matter is separated.

Intermediate between those two extreme forms of the digestive system in birds, there are many modifications, adapted to all varieties of food. Some of them have the stomach more membranous toward the one extremity, and more muscular toward the other; in some the character of the stomach is partially changed by long continuance on a different kind of food; and it is by no means improbable that, in some of those species which live in great part upon insects at one season of the year, and chiefly upon vegetable substances at another, the stomach may undergo seasonal changes.

In proportion as any animal, whether bird or not, is more vegetable in its feeding, its abdomen, in a natural and healthy state, is always the more bulky in proportion to the whole body. This is very conspicuous in the mammalia, (in which the size and distinctions are more easily seen,) in which all the grazing tribes are full, and all the carnivorous ones lank in the belly; but it holds also in birds, though in them it is less conspicuous, as the whole body is covered with feathers, and the several parts are not so easily distinguished from each other. If, however, we attend carefully to the outline of their forms, we may, in most cases, discover a greater uniformity of thickness throughout in the vegetable feeders. This appears not only in the larger birds, in which the difference of other habits may be supposed to have some effect, but even in the small birds.

Generally speaking, too, vegetable feeding birds are not so well winged as those which feed upon animal matters. All the gallinaceous birds are heavy, comparatively bad fliers, and take only very low and short flights; while the birds of prey are among the most powerful fliers in the whole class; though even these are perhaps not so constantly on the wing, or so very long flighted, as some of the tribes which feed chiefly upon insects. In accordance with this formation, the vegetable feeders are not so regularly migratory. Some of them, indeed, change their abodes to considerable distances within the same countries; but they do not so frequently cross the seas, or range so far in latitude in their migrations.

The vegetable feeders and the animal feeders, among the mammalia and birds, agree with each other in the feeding in the two races, and differ from each other in the different feeders of the same race, in other respects. The vegetable feeders are, in almost all the genera, more or less gregarious, both in the one class and in the other; and when they migrate, they generally migrate in flocks, often in flocks containing immense numbers. The passenger pigeons of America, and also some of those which migrate seasonally in the longitudes of the east side of New Holland, New Guinea, and the Molucca islands, appear in numbers far exceeding those of any migrant birds of other regions or other species; and some of those which belong to the latter migration are as gay in their plumage as the parrots, or any other of the finest birds of warm climates. The males are also more polygamous among the vegetable feeders; and it is among them chiefly that they fight battles of gallantry, though many of the omnivorous ones agree with them in these, and also in some other of their characters.

That increased energy of character, which more or less affects all birds in the pairing season, appears to affect the different feeders in a different manner. Their breeding plumages are much more gay, as compared with the ordinary dress throughout the year, and the naked skin upon the head blooms into more brilliant hues. The eagles and hawks, which are the most carnivorous of the whole race, show the least change, either in colours or in manner, at that season; but the vultures, in which there is a slight approximation to the gallinaceous character, and a more decided one to the omnivorous, show a little more seasonal change; and, though race after race is constantly breaking in and destroying the regularity of the gradation, there is an increase of change till we come to those families which may be said to bloom and fade yearly, something after the manner of plants.

It is these breakings in of one tribe of birds upon the characters of another, which makes the systematic arrangement of this class of animals so uncertain and difficult; and the more that we study them, nay, the more intimately and accurately that we become acquainted with them, the less hope have we that any future knowledge can remove the difficulties. The four systems of the food, and the three habitats—air, land, and water, present themselves in such varied combinations and proportions, that the conclusion which we might very fairly draw from one character is barred by an opposite one, which follows as naturally from another; so that we cannot have a chapter of the inductive results of our observation of birds without an appendix of exceptions of still greater length.

But, though we must receive it with exceptions and limitations, there is still observable in birds, according as they depart in their general characters from the rapacious ones, an increase of seasonal change, connected with that energy, which is awakened at the pairing time; and though the individual characters of this change vary exceedingly, there are two great and not very badly marked divisions of it, the one taking place in those birds which are more vegetable in their feeding, and the other in those that feed more upon insects. In the former, it displays itself in greater brilliancy of plumage, and more intensity of action generally, especially in the male birds; under the latter it displays itself more in change of place. Not a little of the character of birds, both in themselves, and also as they are by analogy (which they are largely and accurately), indices to the rest of nature, might be worked out upon this principle; but, even though the length of this article did not threaten to exceed all wonted bounds, in treating on the same subject, this is not exactly the place for it. We still want the elements, in the accounts of the modifications of character by the feet and the wings, and also of the bill, as the grand prehensile organ in the feeding system; and therefore we must defer the general conclusions till we come to the articles on Change of Plumage, Migration, and Pairing. We shall therefore only further remark, in passing, that much of the character of the different tribes depends on the varied development of this seasonal energy; and that the character thus produced is much modified, according as the energy is more marked off in the locality which the bird inhabits when it is at first exerted, or prompts it to migration to a distant region.

The systems of circulation and respiration, in birds as in other animals, are closely connected, though not so much so as in the mammalia. The circulation in both is performed by means of a double heart, consisting of two ventricles for propelling the blood, and two auricles for receiving that fluid on its return; and connected with these, as in all animals that have the heart double, there are two sets both of arteries and of veins,—a pulmonary set and a systematic one. The circulation is, as has been hinted already, more rapid in birds than in the mammalia, which agrees with the greater violence and longer continuance of some of their actions. But though these more violent actions,—such as coursing on two feet as fleetly as antelopes do on four and with the aid of the flexible spine and its muscles, as in the ostrich, plunging into the water like the gannet or the cormorant, dashing through that element like the divers, cleaving the air beyond comparison with all terrestrial speed, as in the plovers, the swift, or the pratincole, or breasting the tempest with the majesty of the eagle, require, and are furnished with a supply of blood, proportional to the waste which their great energy must occasion; yet they are by no means so well suited to an equally rapid breathing by means of lungs. But the application of renovating air to the blood must, in all animals, be proportional to the circulation; and, among vertebrated animals, it is only the reptiles and fishes which have the temperature low and the circulation lagging, and which spend much of their time in a state of comparative inaction, that can carry on their systems in a healthy state with only a partial aeration of the blood.

If the subject is considered according to our plans in contriving and executing, there is thus a difficulty to be overcome in the case of the birds, similar to which nothing occurs in that of any of the other vertebrated animals. They stand more in need of the action of the air than any other animals; and their habits are such that they are less able to bear even the same action, by means of the ordinary apparatus of lungs.

Now this is one of those difficulties which human wisdom could never see the means of overcoming, except in the accomplishment of the very object, the means of accomplishing which are the subject of inquiry; and therefore it is wholly above the reach of the human powers, and in itself a perfect demonstration that the works of creation must have originated from One omniscient in knowledge, as well as omnipotent in action. But though in this, as in all other cases, we could never have fathomed the purpose of the Eternal, without the example which he has set, yet the lesson held forth in that example is, when scanned with even a moderate degree of attention (a degree of which any human being is competent), is so plain and simple, that a child may understand it. It is the same with all nature; and if the vain affectation of superior wisdom on the part of those who have attempted to school us in it, had not encumbered and concealed it by the clouds and darkness of words and wayward theories, the learned and the unlearned might read this, the elder and more general volume of "The book of the living God," together, and with nearly the same pleasure and the same profit.

And the means by which the action of the air on the blood of birds is rendered equal to the rapidity in circulation, and consequent necessity of vital repair, in that fluid, without the painful fatigue of ever-panting lungs, is made, like all other contrivances in nature, to answer other important purposes at the same time. The lungs of birds are ample in their dimensions, and have the cells into which air is admitted larger than in the mammalia; and they are kept in their places by being fastened to the bones. Ramifications extend from them in tubes and cells through the whole cavity of the body, into the hollows of the bones, and in short, along the course of every artery which is not immediately imbedded in those muscles, which are in action during the violent exertions of the bird. The blood-vessels in these muscles are fewer than those in the muscles of the mammalia, as any one may infer from the greater rigidity of their texture, and the whiteness of their colour. Thus, there is not a blood-vessel of any considerable size in the whole body of a bird, to the coats of which the air has not access during the greater part of their course; and thus the real action of breathing in birds is not concentrated into one organ, to be toiling and panting there, as it would be in the lungs of the mammalia, but distributed over the whole circulation, and consequently diminished in local intensity, in proportion as it is extended over a greater surface.

This is a subject which it is impossible to bring to the test of numbers, so as to compare accurately the diminution of local action by means of the general access of air to the blood-vessels. There are two difficulties, neither of which can be, from the great nicety of observation which they would require, overcome. In the first place, we know not, and we cannot ascertain, the relative surfaces of the blood-vessels exposed to the air in lungs only, and in the whole system, as in birds; and, in the second place, we know not the difference of action which the air may have on the coat of a very small blood-vessel, such as those in the lungs, and that of a larger one. We do know that the exposed surface of the vessels in the lungs must form but a small portion of that of the whole vessels in the system, because in the freest breathers, that is, what is usually styled the "longest winded" of the mammalia, which have their blood aerated in the lungs only, or chiefly, the portion which passes through these organs at each respiration of the breath, is only a small fraction of the whole. We know also that the coats of the larger blood-vessels must, in order that the vascular system may have equal strength in all its parts, have their coats much thicker and firmer than the smaller ones, though we cannot precisely say in what proportion; neither do we know to what extent the difference of thickness in the coats of the vessels diminishes the action of the air upon the contained fluid. Perhaps the thickness of the coats is directly, and the action of the air inversely, in some such ratio as that of the squares of the diameters of the different vessels; but this is a mere theoretic guess, undemonstrated, and incapable of demonstration.

Analogy shows, however, that the advantages which birds derive from this general admission of air to the blood-vessels is very great. The race-horse is quite fatigued with a few miles at his full speed, and so is the greyhound, while the lion himself is in need of repose after a single leap. But birds can maintain their rapid flight during the livelong day, and for hundreds of miles upon the stretch; and when they do, as is sometimes the case, drop down in agitation or in exhaustion, the former seems generally to be the effect of fear, and the latter of muscular fatigue, for they do not pant as the mammalia do when they have over-exerted themselves.

But the advantage in the aeration of the blood is not the only one which birds derive from this peculiarity of their structure. The same air which exerts its renovating influence upon the blood, supports all the more delicate structures which it reaches and surrounds, as a cushion of the most perfect softness and elasticity; so that, by the most rapid motion, and the most violent twitches which the body receives in the changes and turnings of that motion, there can be no concussion of the parts more immediately necessary for the life of the bird.

We should now proceed to consider the productive system in birds, the progress of the egg, the processes of nidification and incubation, and the attention of the parent birds to their young; but the egg itself can be more advantageously noticed in comparison with the eggs of other animals; and the principles of nest-making require a knowledge of the haunts and habits of birds, as well as of their vital functions. The one part of the subject can, therefore, be better explained in the article Ovipari, and the other in the article Nest. We shall, therefore, here close this section, the various topics involved in which no explanation could exhaust; and of which we take leave with feelings of regret, as one of the most interesting and fascinating with which the student of nature can be occupied.

II. External Parts of a Bird. The subjects to be noticed in this section are much less interesting and instructive than those slightly glanced at in the former one; but as the descriptions of all birds are founded chiefly upon the colours of the external parts, and as these are all that we know about those species which belong to science only as museum specimens, this part of the subject becomes necessary in a general article descriptive of the class. Its minor importance will, however, enable us to treat it more briefly.

The external parts of birds, as they immediately present themselves to the eye, consist of three kinds of surfaces—horn, naked skin, and feathers. The first of these requires little description, being only the bill, the claws, and partially the scaly coverings of the naked parts of the feet and toes, and is most conspicuous on the upper sides of the toes, and the anterior sides of the tarsi. The naked surfaces are also limited in extent, being confined to the head, portions of the neck in some genera, and those unfeathered parts of the feet and toes which are not covered by horny scales. The feathered parts are much more important in the popular description of birds, as it is to their forms and colours that the attention is first attracted.

The horny surface of birds varies in hardness in different species, and may, in general, be said to be firm in its texture in proportion as it is dark in colour. The more powerful birds of prey have the beak and claws black, with a slight bluish tinge; but some even of these have them yellow when in the immature state, whatever may be the colour when they are full grown. This change of colour in horny substances appears to be the effect of atmospheric air and light; and it is not confined to birds, but takes place in the hoofed mammalia, the young of which, in general, have the hoofs yellow, though they turn black after a short time. The forms of the bills and the claws of birds, being closely connected with some of their principal habits, will be noticed in another section of this article.

The naked skin of birds has generally a porous or spongy appearance; and in many species it has a bloom of colour in the living state, which is often very brilliant, and displays an iridescence which is not very easily describable, but which fades the instant that life is extinct. The bills of some birds, such for instance as the toucans, is covered with a membrane, in which there is a similar display of colour, that fades in the same manner; but in most birds these portions of naked membrane with perishable colours are on other parts of the body. When there is a naked membrane reflected on the upper mandible of the bill at its base, that membrane is called a *cere*, from its surface having some resemblance to that of wax. When it extends to, or surrounds the eye, it is called a *lore*, which means an armature, or covering. Sometimes there is only a naked spot or tubercle over the eye; in other cases there is a projection of naked skin on the top of the head, as in the domestic cock, which is called a *comb*, because it is often pectinated, or divided in its margin. Sometimes also there are pendent portions of naked skin hanging from the sides of the under-jaw, or from the cheeks, and these are called *wattles*. In some instances the anterior portion of the throat is entirely covered by tuberculated portions of naked skin; and that is often capable of inflation, as in the case of a male turkey. In other instances, again, the entire neck and greater part of the head are naked, and often beautifully coloured, as is the case in the king vulture. When a large portion of the throat or neck is naked, there is generally some portion of the neck or breast covered with hair, or at least with feathers very much resembling hair in their form; but what connexion there is between the nakedness of one part and this species of covering on an adjoining one has not been ascertained.

When the naked skin on the head, or partially on the neck, covers appendages rather than the natural form of the parts, it is found principally in the male birds; and in the pairing season, these appendages increase in size and heighten in colour, their general colour being red of some shade or other, often with blue reflections; but in many birds they are, at the season alluded to, of the most intense scarlet. The females of the gallinaceous birds, have generally some portions of naked skin on the sides of the head, which bloom and fade with the season, in the same manner as those of the males, though not with equal intensity.

No particular name is given to the naked skin on the feet of birds, unless it covers appendages, or extends farther up than the articulations of the tarsi, which are often styled the knees, but which are in reality the ankle joints of the birds. When there is a portion above these unfeathered, it is called the *garter.* It occurs chiefly in running and wading birds, and sometimes it is differently coloured from the rest of the feet. The appendages to the feet of birds consist of margins, lobes, and webs, which have all reference to water, or to soft and sludgy surfaces; and therefore the description of them falls properly within that of the general account of the feet of birds, as characteristic of their haunts and of one of their principal actions.

With the exceptions above stated, the bodies of birds are covered with feathers. These feathers are of three, or even of four kinds,—down or under-clothing, common clothing, or imbricated feathers, flying feathers, and supplemental or ornamental feathers, of which the uses, in the economy of those birds which possess them, are not very well known.

Before proceeding to consider the situation, structure, and use of the principal feathers upon birds, it may assist those who have not previously studied the subject, to examine the figure in the next column. Feathers vary so much with the habits of birds that it is impossible to select a specimen possessing all the varieties of characters; and therefore we have selected the common magpie, as one which is well marked in its general character, and also easily observed, from being of common occurrence and rather familiar in its habits. It is necessary, however, to notice, that the magpie is a peculiar bird, and that its form necessarily accords with this peculiarity, so that no general conclusion can be drawn from it; but we should have had nearly the same limited representation if we had selected any other specimen. The magpie is alternately a tree and a ground bird; and its structure adapts it for leaping up and down, and making its way among tangled branches, rather than for long flight. For this purpose, the wings are only of moderate length, but they are well adapted for taking the air at all angles, and also for turning. The tail too is much produced, capable of considerable action, and wedge-shaped; the first and second properties being requisite in the frequent ascents and descents of the bird, and the last in avoiding the twigs and other obstacles which the bird could not have so well avoided if the tail had been square at the end.

MAGPIE DISPLAYED, SHOWING THE MORE REMARKABLE PARTS OF A BIRD.—A, the ear coverts. B, the bastard wing. C, the lesser coverts. D, the middle coverts. E, the greater coverts. F, the primary quills. G, the scapulars. H, the secondary quills. I, the nape. K, the under tail coverts (not shown). L, The rump and upper tail coverts.

No particular name is given to the common clothing feathers on the head of a bird, but they are distinguished by the names of the parts on which they are situated—as the front or fore-head, the crown, and the occiput or nape, on the upper part; the cheeks on the sides; and the chin on the under part. There are often, however, supplemental feathers on the head, and these are distinguished as crests, conchæ, or beards, according to their situation. Crests consist of produced feathers on the upper part of the head, sometimes standing over the whole, or a greater or smaller portion of that, and nearly covering the eyes, as in some varieties of poultry; sometimes they are long and pendent from the nape, as in herons, divers, and generally in birds which strike forward with the bill with long and swift motion, in which the crest appears to answer nearly the same purpose as the feathers on a dart or arrow.

The conchæ are formed either round the eyes or the ears, but generally round the former. They are most conspicuous in nocturnal birds, especially in the owls; and they seem to answer some purpose in concentrating toward the eyes the faint light in which those birds habitually seek their food. The tendency to produce enlarged feathers on the sides of the head in some birds of this tribe is so great, that they rise on the sides of the head something in the same manner as the ears of cats; and the species which have feathers standing up in this manner are called "eared owls," or "horned owls;" but the names are not very accurately applied, or at least, they must be understood with some limitations, because the ears or horns are feathers merely, and have no projections answering to them either of the bones or of the flesh of the head. Feathers which form what are called beards, or mustachoes, are dependent from the angles of the gape, or the sides of the lower mandible, and proceed, for a greater or less distance, down the sides of the neck. They are generally of a different colour from the neighbouring parts, and remarkably soft and silky in their texture. Some birds have feathers similarly produced, and resembling these in their texture, upon the breast, the shoulders, or other parts of the neck, or adjoining it.

The only general groupes of separate feathers on the heads of birds, which get a distinct name, are those which are over the openings of the ears. They are called the *ear-coverts*, and the name "covert" is in general given to all those feathers, upon whatever part of the bird they are situated, which are not merely clothing feathers, and at the same time neither feathers for flight, nor supplemental or ornamental ones. Thus the word "covert" becomes a general one in describing the plumage of birds, and coverts are styled *upper* or *under*, according as they are on the upper or under sides of those members which they cover. Those of the ears are peculiar as covering, with more produced and downy plumage than that on the surrounding parts, the openings of these organs; and though their use is not very well known, they probably answer the purpose of external conchæ to the ears, and at the same time protect those delicate organs from the action of the air when the birds are in rapid flight.

The feathers on the neck and body of birds are also named from the places upon which they are situated. The neck is described as the throat, sides, and back. The distinctive parts of the body are more numerous; and they are often spoken of, generally, as the upper part and the under part. The entire upper part of a bird includes all that part of its surface which is seen when the head, the wings, and the tail are stretched out, and the eye of the observer placed opposite to the middle of the back. The under part, in like manner, means all that which is seen when the bird is stretched out in a similar manner, and the eye of the observer against the middle of the belly, or rather the posterior edge of the breast bone. But as these general significations of the terms include the wings and the tail, as well as the body of the bird, and as those organs require separate description, the upper and under parts are generally understood in a more limited sense, as not including these parts. Thus when it is said that the upper part, or the under part of a bird is of any particular colour, it is not meant to be asserted that the corresponding side, either of the wings or of the tail, is of that colour.

The upper parts to which names are given, are the setting of the neck, which is often marked by differently coloured feathers, or produced ones which form a mantle on the shoulders; the scapulars, or feathered parts over the blade bones, the middle of the back, and the rump or part of the back next the tail, which is often differently coloured from the rest. Upon all these, the feathers, excepting those birds which have supplemental ones, are smooth and close, and so beautifully imbricated, or placed over each other like tiles, that they form a very close and smooth surface, which is perfectly water-proof in some birds, and not very easily wetted in any.

The manner in which these and all the other clothing feathers are applied to each other, and also adapted to the shape of the bird, is well worthy of study. Generally speaking, they are placed alternately, or one over two, that is, with its shaft in the opening between them; but they cannot be said to form regular rows taken in any direction, and they vary considerably both in shape and in size.

They are all however placed in such a manner as that the action of the wind from before tends to smooth them down, and from behind to raise their points, though differently in different birds, and even on different parts of the same bird. The shoulders, and the turns or front edges of the wings, are the places on which the beautiful application of the feathers is most striking, as they are not only the most difficult to fit from their greater curvature, but the ones which are the most exposed during flight. The feathers on these parts are so placed, that let the wind take them as it may, it can hardly raise or ruffle them; and the strength and curvature of the shafts, and the extent and texture of the webs, are all equally worthy of observation.

The general texture of the surface of the upper feathers, is in most cases more glossy than that of the under ones; and in most birds it has more or less of metallic lustre, and generally, though not always, its colours are deeper.

The structure of the clothing feathers of birds might be almost made a means of classification, as it varies both with climate and with habit. These feathers upon birds of prey are firm and decided, so that each individual feather may be traced; they are less so in omnivorous birds, less so again in those which feed chiefly upon insects or vegetable matter, and the least so in birds which are the most exclusively aquatic in their habits. Birds of hot climates have also the feathers more decided in the upper part, than those of nearly similar habits which reside in cold countries:—indeed the study of the structure, texture, and gloss of the general plumage would, though somewhat more circuitously, lead as certainly to a knowledge of the characters of birds, as that of the more active parts of their bodies.

The feathers on the under parts are distinguished as those on the breast, the flanks, the centre of the belly, the thighs, and the vent. But some of these names must be understood with limitations. Thus what are usually called the thighs are in reality the legs of the bird, the thigh bones being to a considerable extent imbedded in the muscles, and capable of but little motion, except in those species which have great action in their feet. That which is called the belly of a bird also requires explanation; for it does not, even in any of the species, answer to the soft abdomen to which that name is given in the mammalia; and in swimming birds the sternum and ribs extend so far backward as that a portion at the vent only, of a size sufficient to allow the expulsion of the eggs, is unprotected by bones.

The feathers of the under part are, generally speaking, smaller in size, and softer and more downy in their texture than those on the upper part. The differences of character indicated by them are not so great or at all events not so striking as those indicated by the upper part. In general, however, there is the same gradations from the more perfect air birds to the more perfect swimmers, the last of which, especially those which inhabit the colder seas and do not migrate far toward the equator in winter, abound in down of the finest description. This down consists partly of a second feather produced at the end of the barrel or tubular part of the principal one, and partly of a separate clothing, each particle of which has its own insertion in the skin, and which has no distinct shafts, or any of the common characters of feathers. This down, whether produced on the feather or on the skin, is always frizzly or flocculent, as well as soft. It thus has no general direction, like the feathers, but stands every way; and thus is very elastic as well as warm and light.

The different apportionment of this downy part of their clothing to the several climates and elements in which birds move, as well as to their habits, is very remarkable; and many of the swimming birds can remain for days in water very little above freezing, and yet sustain no inconvenience from the action either of the cold or of the water.

The feathers of birds are in themselves, to a considerable extent, water-proof, and all birds are more or less furnished with glands near the base of the tail which secrete an oily liquid. This liquid the birds can reach and extract with their bill and apply it to the feathers, by drawing these between the mandibles. This operation forms part of the process of *preening* or trimming the feathers, in which birds occupy a portion of their time. They do this for three purposes—to strain the water from such feathers as get wet, to smooth the webs of such as get ruffled, and to apply the oily secretion as occasion may require; and they also make use of the bill in removing those decayed feathers which become incumbrances instead of being useful to the birds in their motions. The structure and economy of feathers, with the changes which they undergo from age, season, or climate, are, however, much too extensive for being explained in a general sketch; and therefore we must refer to the word Feather for the structure, and to the word Plumage for the economy and changes, confining the remainder of this section to the enumeration of the acting feathers and their auxiliaries in the wings and the tails of birds.

But as introductory to the notice of these, it may not be improper to remark that, generally speaking, the nearer that the clothing feathers of birds approximate to the form of flying feathers, the latter are the more firm and perfect in their structure; and that this holds not only in different species of birds, but in the plumage of the same species during its progress to maturity. There is even a gradation from the ordinary clothing feathers to the flying ones through the medium of the coverts.

In the wings, the bones, the humerus, the fore-arm, the wrist, and the hand, are free. They, and the muscles on them, are clothed to some extent with feathers similar to those on the body, and partaking of the character of upper feathers above the turn, and under feathers below it, passing imperceptibly into each other on the turn itself. To these succeed the several coverts, of which there are generally three rows, more or less distinct, and more or less produced, according to the species, but generally increasing in length and strength as they approach the quills. These are called the lesser, the middle, and the greater coverts, of the particular quills, or portion of the wing to which they are applied; and there are similar coverts on the under sides of the wings, only these are weaker, smaller and more soft and downy in their texture,—the whole under side of the wing being so formed as to take the greatest possible hold on the air, while the upper side is formed for rising through the air with the least possible resistance.

The quills, or real feathers of flight in the wings, are distinguished as primaries, secondaries, and tertiaries, according to the place of the wing to which they are attached. The primaries are attached to the hand and wrist, forming the extremity of the wing; and they are, generally speaking, the longest and the most powerfully supported by coverts. The secondaries, which are shorter, are chiefly inserted on the bones of the fore-arm; and the tertiaries on the humerus. In some birds the tertiaries are the shortest quills in the wings; but in others, and these are generally birds which have the habit of running swiftly, with the wings partially extended, they are so much longer than the secondaries that the bird has the appearance of double wings, one set near the body and a longer set farther off. The quills are usually distinguished by numbers, as the first, second, and so on, counted from the extremity of the wing.

The tails of birds, like the wings, consist of produced feathers and coverts for their support, though the feathers of flight in the tails do not get the name of quills.

Both the wings and the tails of birds vary much in form, in magnitude, and in power of action; and though they are both concerned in the flight of the bird, and partially also in its motions on land or on the water, they do not vary according to the same law, and therefore they do not indicate the same habit. Still, however, as they are both concerned in the flight, or other motion of the bird, they must, in all their apparent discrepancies, be the best adapted to each other.

In those land birds which have not the power of flight, such as the ostrich, the emu, the apteryx, and a few others, none of the feathers have much approximation to the character of flying feathers, properly so called: they more resemble a peculiar species of down, but still it is feathered down, and the different portions are more minutely feathered in their ramifications than even those of flying birds; so that all the produced feathers upon these species are calculated for taking a powerful hold on the air; and the hold so taken no doubt helps to support the birds as they walk along. This use of these produced feathers is rendered more probable by their being more conspicuous in proportion as the bird is longer on the legs and otherwise better fitted for swift motion. The emu is not so swift footed as the ostrich, and the feathers upon it are all more nearly of the same length and form. Judging from its structure, for of its habits we know nothing, the apteryx is but a slow moving bird, and the feathers upon it are all pendent and flexible, resembling thatch as much as they do ordinary feathers.

The supplemental or ornamental feathers, of which the uses are not well known, appear on various parts of the body. They are generally confined to the male birds, or at least most conspicuous in them; and in some instances, as in that of the ruff, they make their appearance only during the breeding season. Birds which are subject to additional plumage, or even to rich additional colours in their feathers, during the breeding season, are generally, if not invariably, birds of warm temperament, and excited to contests of gallantry with each other, and other displays of more than ordinary courage, at that season. The affection appears to be one of the whole body, though the effects which it produces are differently localised in different species. Sometimes the additional feathers are on the neck, sometimes in the crest, sometimes in the scapulars and feathers of the back, and very generally in the tail.

The use of these feathers in the economy of the birds is not known; unless it be that the production of them (for feathers appear to be one of the most elaborate of nature's productions), exhausts the surplus of that energy which, from its very violence, might otherwise be injurious to them at those times when they do not require to exert it immediately for those purposes which, physiologically considered, it is intended to answer.

This is an exceedingly curious part of nature; but it is as obscure as it is curious. In all the living and growing races, there is a bloom or evolution of richer and more intense colour than that which accompanies ordinary growth, attendant upon the process of production. This is less conspicuous in the animal kingdom than in the vegetable; and in both, those species in which the process is otherwise secret or obscure, partake little or nothing in this rich display; but it is to the nuptial dresses of plants and of birds that the gay season of the year owes the most of its beauty; and nature, true to her general law, lavishes the richest of her ornaments upon the most essential of her operations—upon that operation by which alone she maintains all the races of her children, and triumphs over time itself.

As the uses of those supplemental feathers, whether seasonal or permanent, are not known, they cannot be used for any purpose more general than that of being specific or trivial characters of the races in which they appear. We must therefore refer the further consideration of them to the particular articles descriptive of these.

III. Skeleton of Birds.

As it is not the province of natural history, especially of that popular form of it to which this work is restricted, to enter into the details of anatomy, any farther than is necessary to obtain a general notion of the way in which the motions of animals are performed, the present section will be very short. We have already alluded to some of those peculiarities in the bones of birds, which enable them to perform their chief aërial motions; and our main object in again reverting to this part of the subject is to place before the reader a sketch of the bones of what may be considered as the model or utmost perfection of a bird, before proceeding to point out how the classification of birds is founded upon one or more of their three grand actions, as these are dependent upon, or arise out of their varied organisations.

This sketch represents the bones of the Jer Falcon (*Falco Icelandicus; Hierofalco*, of Cuvier), which is the boldest, the most perfectly winged, and, in proportion to its weight, the strongest both for action and endurance of all the feathered tribes. Dwelling in the wilds of nature, subjected to violent winds, to heavy snows, and to long-continued rains, and compelled often to endure long periods of abstinence in those parts of the world where there is not a tree, and hardly even a bush, for the shelter of a bird, and requiring at other times to range for several hundred miles before it can procure a meal, either for itself or for its young; the jer falcon, estimating according to the average powers and experiences of animals, may be said to have the hardest lot in the whole kingdom. But even upon this, the grand extreme, as it were, of his works, the Creator has not left himself without a witness; for if the task which the jer falcon is called upon to perform in nature is harder than that of most other birds, the preparation of this falcon for the performance of it is greater in fully the same proportion.

Jer Falcon.

The sketch which we have given of this bird, which is, now at least that falconry is not the fashion, rather rare in substance, in skin, or in skeleton, is taken from a very fine specimen in the possession of Mr. Yarrell, which that gentleman very obligingly lent us for the purpose. It was originally obtained from Iceland; and we believe in part at least cleaned and prepared by marine insects on the Iceland shores; and these creatures are far from the worst preparers of the skeletons of larger animals, when the object is to have them perfectly clean and at the same time quite entire.

It is impossible to do justice to so complete a piece of natural mechanism in a sketch, and it would be no easy task even for the most elaborate engraving; but the general arrangement of the bones, and their remarkable compactness and adaptation to the powerful actions of the wings, the feet and the bill, can be easily seen. Of these motions and their organs, as diversified in different tribes, we shall have occasion to speak afterwards; but we may here notice that the jer falcon possesses all the three in the highest perfection; and that as, although it is a day preyer, it must often prey in lowering and cloudy weather, its power of vision must be strong in proportion. It must also, adapted as its plumage is to the violence of storms, have some very acute means of general perception, otherwise it could not return to the islands which it inhabits, after its long excursions over the northern ocean.

The most remarkable general property of this skeleton is its compactness, and the equal perfection with which, as an artist would say, all its points are made out. None of the bones are very long ; and those of the legs, as the bird is not much in the habit of walking, are rather short; but they are firm and well proportioned, and the processes toward their extremities, whether for giving firmness to the joint, insertion to the muscles, or lever power to the tendons, are very conspicuous.

The general form of the spine, as it has already been hinted at, can be seen in this example. The vertebræ of the neck all admit of ready motion ; and the position of repose, or that in which all the bones bear equally upon each other, is a curve.

All the vertebræ of the back, at least as far as the posterior edge of the sternum on the other side, are soldered together, and afford a firm base for the blade bones, which are considerably produced, and lie nearly parallel to the mesial line of the spine. The coracoid bones are strong, and enlarged at their extremities where they meet the anterior edge of the sternum, though they are more flattened there, so as to agree in thickness with that bone. The furcal bone is also a perfect circle, and placed with its flat side in the direction of the strain, so that it resists the separating or bringing together of the shoulder joints, the grand centres of motion for the wings, in the most powerful manner that could be obtained from the same quantity of bone. This bone, it will be perceived too, forms a large opening, in which the neck can play freely, without the least pressure upon any of the important vessels which it contains.

All the bones of the wings are well formed, and the fingers, though only one of them is perfect, can be distinctly traced. The humerus is the longest and also the strongest and heaviest bone in the wing ; and the lengths of the others diminish in the proportion of their other dimensions ; so that though when the wing is moved, the different parts move with velocities proportional to their distances from the centre of action, yet the effect of the entire wing is very uniform, and the bird, when in powerful action, may be said to fly with the whole of it, that is, to strike the air with nearly equal effect with the whole of its under surface. The stiffness of the intermediate joints in such a wing, the perfect freedom of the shoulder joints, and the remarkably steady base which from their size, form, and place, the scapular, the coracoid, and the furcal bone, give to the centre of action, render the flight of the bird exceedingly smooth ; and, though it is heavy for its bulk and even for the length of its wings, the jer falcon never appears in the least to labour on the wing. Birds more loosely boned, in any of the respects that have been mentioned are incapable of this perfect steadiness and beauty of flight. The short winged ones of them flutter, as if they had not wing enough, and the long winged ones have their bodies tossed upward by the down stroke of the wings, and downward by the up stroke, as if their wings were too much for their management. This falcon, however, which has to range over somewhat bare and very stormy pastures, has its wings and its body adapted to each other with the utmost perfection, so that it can rush onward in any line of direction that it pleases, without the least deviation ; therefore it flies from point to point by the shortest line possible ; and thus while it is the perfect model of power in flight, it is at the same time the perfect model of economy.

The lumbar portion of the jer falcon's spine admits of a little bending downwards, so that the articulations of the femoral bones, or those joints which answer to the hip joints in the mammalia, can be lowered a little. The bones of the tail are also more numerous and better " made out" than in most birds. This arrangement of the posterior portion of the sternum, enables the falcon to perform more effectively its double action in the air, as by this bending, the foot, with which it strikes its prey, can act so far below the plane of the wings as not to interfere with their motion of flight. Not only this, but it also affords a support to the tarsus, upon the joint of which the whole force of the stroke would otherwise be thrown as a cross-strain ; and, though that joint is a firm one, yet it is contrary to the general law of nature's mechanics, to subject even the firmest joint to the greatest strain which it has to bear in the least favourable position. Indeed, there is seldom any joint subjected alone to a very great strain, in the natural action of animals. As there is but one life in the animal structure, so there is always concerted action when that life is strongly excited, be the object of the excitement or the organisation which it more immediately sets at work, what they may. There is some part upon which, in case of partial failure, the acting part can fall back for support if not for assistance ; and the very fact that organs which have to perform violent motion, are connected with several centres, and those centres all susceptible of yielding to some extent or other, shows that the animal is organised for a concert of the parts in its action.

There is much firmness in the foot and leg of the falcon, and the position in which the foot is carried when hawking, stiffens the hind toe by pulling the tendon, and that without any muscular exertion, to the very angle at which the claw gives the stroke with the greatest effect. It is an oblique thrust, neither directly against the end of the last phalanx of the bone, nor across it, but in a tangent to the curvature of the claw at its point; and any one upon examining the foot of a falcon, will find that this is the very direction in which a shock can come so as to jar or strain the least possible, and at the same time to divide the pressure most equally among all the joints of the member which acts. If the stroke were given directly in the line of the axis of the toe and claw, the crush or jar would be the greatest possible ; and any one who unwittingly strikes the point of the stiffly extended finger against an obstacle can tell how much more painful it is than if the yielding finger struck the same obstacle with double the force. There is another very appropriate illustration : by holding the joints of the legs and feet easy, one can drop upon the feet from a considerable height, not only without risk, but with little pain or shock at the moment ; whereas if one were to drop even two or three feet with all the joints of the legs and feet kept purposely extended and rigid, the pain from the jarring would be considerable, and a tumble would be the probable, and broken bones or dislocated joints, the possible, and indeed the very likely consequences. Thus we see that in nature's mechanics, the contrivances by which purposes are accomplished, are not only the best adapted for those purposes, but they are applied for the accomplishment of them in the best manner, both for success in the end and for safety to the instrument.

This principle is one of the most difficult to carry into complete, or even tolerable effect, in the whole compass of human mechanics; but it is one which nature invariably displays in all her structures, and in all the varieties of their working. This must, however, in the case of animals, and especially in that of predatory animals, be considered true only as affects the animal to which the structure belongs: for as the prey and the preyer are part of the general system of nature, and as such made for each other, the perfection of the system requires that the prey should be taken as much at a disadvantage to itself as there is advantage on the part of the preyer.

And this is well exemplified in all birds which strike, or otherwise capture their prey on the wing, and more especially in the jer-falcon, which may be said to perform that operation in most magnificent style, at least in so far as the slaughter of one bird by another can be considered magnificent. The jer-falcon, at forward flight, and without the excitement produced by the joint effects of hunger and the sight of that which can appease it, can cleave the air at the rate of at least one hundred miles in the hour; but when she works herself to the top of her bent, and then rushes forward in the tempest of her impetuosity, her motion is double, triple, nay, probably more than five, or even ten times that rate; so that if she could hold on with the same speed, she would keep pace with the motion of the earth on its axis, even at the equator, where it is about a thousand miles an hour, and outstrip it by much in her own northern latitudes.

Hard as are the bones, and tough as are the tendons and ligaments in the foot of the jer-falcon, they could not hold directly against so terrible a rush as this; and were she to strike against a solid and fixed substance, she would be dashed to pieces by her own velocity—would perish through the very excess of her own strength.

But this violent motion of the falcon, the circumstances under which it is exerted, and the organisation by means of which it is performed, are all admirably adapted to each other. The stroke of the falcon, unlike the spring of the beasts of prey, or even the stoop of the eagle, and the other predatory birds which kill their prey upon the ground, does not, in itself, arrest the violence of her motion; for when she misses, if she hawks at flocking birds, as she often does, she dashes onwards, and strikes again; whereas the lion and the tiger must pause and crouch before they can take a second spring, and the eagle must regain her height before she make a second stoop. Thus the prey of these animals, if not captured at the first attempt, has a chance of escape much greater than the prey of the jer-falcon.

When we consider the circumstances under which this gallant bird strikes, and the force of the stroke, which is sufficient to fracture a wing, sever a head, or crush the chest and burst open the body of a bird, we can easily see that the great velocity of the rush is necessary for effecting the natural purpose of the bird; and that, though the jer-falcon would probably dash herself to pieces where she to exert all her energy in preying anywhere else than in the free air, yet she is exactly the bird, above all others, for that element. Her prey is of course escaping from her with its best wing, though the agitation produced by such a follower must of course render that wing a little tremulous; but still the motion of the prey must be deducted from that of the falcon, in order to get the true impetus with which the latter strikes. Besides this, the bird has no resistance but that of the all-elastic atmosphere, and the inertia arising from its weight diminished by its motion; and therefore a stroke given with moderate velocity would have very little effect upon it. But the speed of the falcon over the speed of the prey furnishes the power; and the instrument, as already mentioned, sustains no injury on account of its position, and of the communication, and consequent extinction of the shock upon it; first, in the elastic part of the falcon upon which it bears for support; and, secondly, in the air, against which the entire body of the falcon would recoil if necessary, as the smaller hawks may be seen to do when they are flown at too heavy game.

Far from the least remarkable part of the skeleton of this model of a flyer is the sternum. It will be observed, on looking back to the sketch, that the forks in the posterior portions of that bone are not only united by bony continuations, but that only a small aperture is left in the place of each. The keel, or central ridge of the sternum, is also remarkably elevated, and much produced at its anterior extremity, so that its outline forms a complete arch. We shall afterwards have to compare the *sterna* of different genera with each other, and with their several habits, as among the means of forming an arrangement of the class, approaching at least to a natural one. But as in that we must have some model from which to start (the means of proceeding then being comparison, and comparison not being an instrument of knowledge, unless one of the subjects is known), and as the sternum of the jer falcon is the one best adapted both for exceedingly rapid and for long-continued flight, it is about the best model that we can select. From the shape of this bone, as well as from the general arrangement of the skeleton, we can see that, though the legs are rather strong in their bones, and the muscles by which they are moved are rather powerful, yet that the great strength of the bird is thrown into the anterior part of the body. Here it is not a little remarkable that this form of the body of a bird, while it admits of the best organisation for flight, is also the best one for being propelled through the air, or through any other fluid, be the propelling force what it may. When it is desirable to have a very fast-sailing ship, which shall at the same time make the closest course, or the least lee-way, and therefore get through the water with the least strain from the action of the wind, the shape which answers best for the hull of such a ship is not unlike that of the jer-falcon—full at the bows, and narrowed away at the stern, so as to make the least wake or turbulence in the water behind her. This coincidence of the shape of birds which impel themselves through the air by the energy of their own muscles, with that of ships which are impelled through the water by the action of the wind on their sails, is not a little remarkable; and it is one of those cases which shows that there is a lesson for our instruction, and an example for our imitation, so far as we can imitate, in all the operations of nature.

Before taking leave of this branch of the subject we may further remark, that there are three muscles on each side of the keel of the sternum, in all flying birds; and that the principal action of the wing in flight is produced by those muscles. There is an advantage in this arrangement; and so also is there an advantage in that arrangement in the legs of birds, by which the muscles of these are placed near the body, and the tarsi and part of the tibiæ formed chiefly of bones, tendons, and ligaments. By the arrangement in the wings, the wing itself is rendered lighter than if muscles had been distributed over its whole length, to any greater extent than is necessary for stretching and bending the local joints. Not only this, but the circulation of blood necessary for the support of much muscular energy, and the supply of the waste which that would occasion, could not be carried on without an extraordinary propelling power, in organs which move so rapidly as the extremities of the wings. Here, again, we may perceive a remarkable coincidence of advantages. That structure of the wing which adapts it best for being an organ of support and progressive motion jointly in the air, is also the one which renders it the most easily moveable and the most easily nourished, so that the labour, whether mechanical in the muscles, or physiological in the energy of life by which the muscles are worked, is always the least possible in proportion to the motion produced; and thus while every bird has enough and to spare of energy for the average performance of those functions required for its place in nature, it is at the same time an instance of the most perfect economy in the whole of its furnishings and arrangements.

Of the three muscles on each side of the sternum, by far the largest one is that which depresses the wing. It is called the great pectoral muscle; and, in birds of powerful flight, those two muscles are heavier, or contain more substance than all the other muscles in the body. The second muscles raise the wings, and prevent them from turning on edge, which neither of the other muscles could do without impeding the freedom of their proper motion in working the wing upwards and downwards at right angles to the axis of the body. There is, however, a slight oblique motion in the elbow joint of the wing, by means of which this third or central muscle causes it to strike partially forwards, at the same time that the great pectoral muscle makes it strike downwards.

Such are some of the motions of the more efficient wings of birds, and such some of the instruments by which they are performed; but from the jer falcon, in which they are the most perfectly developed and the most in accordance with the whole skeleton and other structure,—and therefore form, along with the most predatory claws and beak, and the digestive organs the best adapted for subsistence upon recent flesh, the most direct means of arriving at the habit and character—there is a gradual decline of the efficiency of the wings, as compared with the other active structures, until we come to the ostrich, which has only a sort of rudimental flaps to steady it as it runs, the penguin, whose rudimental wings seem to answer only the same purpose in swimming, or the apteryx, whose wings are covered by the skin, thatched by the feathers, and seem to answer no purpose whatever. But though there is this gradation, and though in as far as the wings, and all those parts of the skeleton, and the muscles which are connected with the wings, are concerned, we can trace it with comparatively little difficulty, yet it is so far from taking the habit of the bird along with it in any other respect than that of mere flight, that one pair of wings carry us to the sea, a similar pair to the forest or the plain, and a pair still similar to the cliff of the mountain. Nor are the purposes for which the wings carry the birds, and also us in the study of them, less varied than the places,—wings very similar to each other, act to capture warm-blooded animals, insects, fishes, berries, seeds, and so endless a variety of substances, that we are compelled to examine the other characters of the bird before we can arrive at any certain conclusion respecting the office which it performs in nature, or the use to which it may be applied in art. We are not, however, to attempt making a classification of birds, but to explain the principles of one which is already made; and therefore the shortest as well as the simplest course would be, first, to mention the classification, and then to point out those peculiarities in the three grand actions of birds, and their requisite organisations, upon which that classification is founded.

IV. Classification of birds.—In this we shall, as already said, adopt chiefly the arrangement of Cuvier, not that it is perfect, or even free from objection in all its parts, but because the well-earned celebrity of its author has given it a stability in the general opinion of mankind, the overturning of which would require much knowledge and more hardihood; and be, till more knowledge is obtained, after all a work of supererogation, except in some of the details.

Cuvier divides the whole class into five orders,—Birds of prey (Accipitres); sparrow-like, or hopping birds (Passeres); climbing birds (Scansores); poultry birds (Gallinidæ); running and wading birds (Grallidæ); and web-footed birds (Palmipedes). This certainly has the advantage of that simplicity of which it partakes in common with other *artificial* systems of the works of nature, that the first step in the knowledge of it is very easily taken. But it has, at the same time, all the counterbalancing disadvantages. It does not simplify the knowledge of birds; it is only simple because it conveys very little knowledge. When we come to grapple with the real knowledge, we must go to more minute divisions, and encounter much more labour; but even thus much is a beginning, and may prove an incentive to some, though it may also lead others to be content with the shadow without the substance, as has been remarkably the case with the Linnæan artificial system of Botany.

The characters of these orders, as well as of the tribes or families into which they are divided, and the genera and species of which they are made up, will be found under their respective names in the order of the alphabet, and therefore we need not here enter into the particulars. But, as we cannot show the connexion which there is between the three great systems, to which the bills, the wings, and the feet, are, as it were, the keys, without some notice of the general characters on which the orders are founded, or at least their fitness for being such a foundation, we must devote a few words to each.

Accipitres. This order is the most natural in the system, and it is so, because it is founded not upon a single character, but upon the general habit of the birds, in the formation of which all their leading organisations bear a part. The distinctions of the two primary subdivisions of diurnal, and nocturnal or crepuscular feeders, are distinct, so that the one cannot, in any species, be mistaken for the other; and though, especially in the diurnal division, there is a very considerable gradation in all the leading characters, so that those at the one extremity differ much from those at the other, yet there is enough of general resemblance preserved, in the beak, the feet, the wings, and even the plumage, to distinguish them from the birds of every other order.

Passeres. This is a much more numerous order than the birds of prey, and by no means so natural. This might be expected from its extent, and also from the name, which being that of one genus, or species of bird, that of the sparrow, can have little meaning as descriptive of an order.

The five sub-orders or tribes, into which it is divided, improve it a little, but still they are far from perfect, as they bring together in the system birds whose structures and habits are very different from each other. These five orders are, *Dentirostres* (toothed bills), which are, generally speaking, feeders upon insects or mollusca, though some of them occasionally kill birds; *Fissirostres* (open bills), in which the mandibles do not shut close for their whole length, which are chiefly insect-feeders, and catch their prey by hawking on the wing; *Conirostres* (conical bills), which have the bill more or less enlarged at the base, and tapering to the point, which are more miscellaneous in their feeding, but differing so much in their characters and habits, that no one can be selected properly descriptive of the whole tribe; *Tenuirostres* (slender bills), which feed much on larvæ, and other small animals in the soft state, but catch them in such different situations and ways, that they can hardly be said to have one very striking character in common; and *Syndactyles* (united toes), which agree in that structure of the feet, and in several characters, though they differ in others.

That the last of these tribes or subdivisions of the order is founded upon the structure of the feet, and all the others upon that of the bills, is of itself sufficient to show that they cannot be very accurately descriptive of the birds. *Dentirostres* is far from accurate, because the birds have a notch in the bill rather than a tooth. The falcons are the true dentirostres, the tooth in the bill being one of their leading characters, and they are the most typical birds in the order accipitres. Besides, these birds are not the only ones which have a notch in the bill, for some of the divers, and other fishing birds, that have not the tomia of the bill serrated, for the prehension of their slippery prey, have it notched towards the tip. This subdivision of the order contains birds so different, both in appearance and in habit, that it does not admit of much useful general description; because the characters applicable to one part of it could not be applied to other parts without so much modification as would render them almost entirely new.

The *Fissirostres*, or open bills, are much better. They are but few, and though some of them are nocturnal, and others diurnal, yet they agree tolerably well in their general habits. Their bills are all very broad at the base; they are very wide in the gape; and they do not close in the length of the tomia, so as to cut or bruise hard substances. The whole division are consequently insect-feeders, and feeders on the wing, as this form of bill is not adapted for picking food out of crevices, or even off the ground.

The *Conirostres*, though not quite so vague as Dentirostres, are still by no means well or generally described by the name, as any one will perceive upon finding that it includes the lark, the raven, and the bird of paradise, three genera which are unlike each other in appearance, character, haunt, and manners. The name is not indeed accurately descriptive of the bill, as it appears generally in birds of the division. No doubt the bill is, generally speaking, enlarged at the base, and tapering toward the tip, straight, or free from any notch in the tomia, more firm in its general texture, and especially in its cutting edges, than the notched bills of the first division; but it is conical only in a few genera, and most conspicuously so in the grosbeaks and finches. In other genera it is of a great variety of shapes, sometimes angular, sometimes arched in the culmen, sometimes coulter-shaped, and, in fact, of so many different forms, that it cannot with propriety be described by any one general epithet, for the more accurately which that epithet were descriptive of the bill of one genus, it would be the less descriptive of that of others.

There is, however, a shadowy sort of general resemblance in texture and function among those bills, though it is not very easy to find an appropriate name for it. The texture, at least at the cutting edges, is always firm; these, in general, close for the whole of their length, and thus they are capable of bruising hard substances, such as seeds with tough coats, and also for digging or boring into the ground in quest of earth insects, or of albuminous roots. Sometimes, as in the case of the crossbills, the bills of those birds have a very peculiar structure and action; and, generally speaking, the muscles which move the bill are more powerful, and consequently the head is more enlarged than in the species which feed more exclusively upon insects.

The birds of this division certainly range awkwardly together, whatever name they may be called by; and yet it is not very easy to separate them into groups more numerous than families or genera, in a manner that would be much less exceptionable.

The species which may be considered as forming the one extreme of the division are birds of powerful form and firm plumage. Many of them are voracious, and somewhat gross in their feeding. They eat all manner of carrion and garbage, have no great objection to kill any animal which they can master, especially if they find it in a sick or weakly condition. Some of them occasionally hawk after small birds on the wing, but that is not a general habit with them; they proceed by stealthiness and craft rather than by daring, as the accipitres do, and in general attack only that which they can take at a disadvantage. They are also great plunderers of the nests of other birds.

The species which may be regarded as forming the opposite extreme of the division are birds of very different characters and habits. They are of small size, not much disposed to attack other birds for the purpose of preying upon them, and, generally speaking, vegetable feeders, though most of them add worms and the larvæ of insects at the time when they have their young.

These two have been named from the general nature of their feeding—the first, *Omnivora*, or general feeders; and the second, *Granivora*, or feeders upon grains, or vegetable seeds. These names are not, in themselves, very precise, as Omnivora is rather too general a name, and other birds are scarcely less omnivorous than them, as, for instance, poultry are very miscellaneous feeders. Granivora is quite as vague, as pigeons, and some other birds, feed as much on the seeds of vegetables as the birds of this division.

Still, as applied to the extremes of the division, these names, with some explanation, would not be undescriptive. But it would not be easy to make a perfect separation of the two, for their characters pass so gradually into each other, that there are many genera of which it would be no easy matter to decide whether they are more omnivorous or more granivorous; and thus their place in the one group or the other would be much more a matter of fancy than a matter of science.

This blending of characters on the confines of the different divisions, in what manner soever those divisions are made, is, in addition to the confusion produced by the three principal means of classification, one of the great difficulties in the proper arrangement of birds. If the comparison may be allowed, birds are like the tints of the rainbow; we can call these red in one part, yellow in a second, green in a third, and so on; but no art can fix a line any where in the bow which can so divide colour from colour, as to enable one to say, "all on this side is yellow, and all on the other side is red." Even the colour which we can name the most readily is of no measurable breadth as one uniform tint; for the moment that we, for instance, lose the red on the one side of the yellow we begin to find the green on the other; and therefore, however small a portion of the breadth we take, we always find that, as compared with the whole, it displays more than one tint.

It is very much the same with birds; and birds, like rainbows, are children of the sun, more affected by that luminary than any other vertebrated animals, and partaking more of those radiant hues which the pencil of the sun alone can limn. We never can draw a definite line between order and order, or group and group; and as little can we find even a single genus which has no conformation or habit in common with another. When we put the rest of the rainbow out of consideration, we can give a name to the tint of any particular part; and, in like manner, when we take a single species of bird, and examine it without reference to the rest of the class, we can describe all its appearances and habits, so far as they are known to us, in a manner perfectly satisfactory. We can thus study birds, and know them, and learn from them, with perfect ease and certainty; but we cannot classify them.

The great locomotive powers of birds are among the chief causes of this. What with their ordinary journeys, and what with their seasonal migratory ones, they are here, there, and everywhere. Sea or land, mountain or plain, waste or cultivated field, we find them there as inhabitants or as passengers; and there is not a spot of land or spot of water but may become the inn of a wayfaring bird. Their clothing adapts them well to the weather; and it is necessary that they should not be very particular in their food, for they are exposed to many changes of it, and must frequently take what they can find without any choice. It is for this reason that classifications founded on the shape of the bill fail so much in other respects; and this is peculiarly the case with the dentirostres and conirostres of Cuvier's order *Passeres*, whose bills are very differently formed in the different genera.

The *Tenuirostres*, or slender-bills, form a much more natural division, though they too vary considerably in the different genera, both in the kind of their food and in the places and manner of finding it. Their bills in general accord with the name in being slender; but the smallness of their diameter is no indication of weakness. On the other hand, they are very firm in their texture; and though, from their form, they are not so well adapted for breaking hard substances between the mandibles as the larger hard bills of the former division, they can reach their food in places which are not accessible to these. Many of them are bark birds, which run in all directions upon the boles and larger branches of trees, and extract the insects or larvæ which are lodged in the crevices. Some of them run upon walls and rocks, and catch spiders in the same manner; while some again hover over the nectaries of flowers, from which they extract honey or small insects. They are an interesting race, from the agility of their motions, often for the brilliancy of their colours, frequently for their great power of wing as compared with their size, and not unfrequently for their extreme littleness. The humming-birds, which make the air under the action of the equatorial sun so gay with gleamy tints as if all the gems and the finest metals were flying about, belong to this division; and some of them, while to appearance not bigger than humble-bees, have the sternum and all the apparatus of flight nearly as well developed and as perfect as in the jer falcon.

But though this division is a very natural one, it is doubtful whether the bill is the best foundation for their natural distinction from other birds, as it is neither their most constant nor their most conspicuous character. The bill is always slender at the tip, and it cannot be said in any instance to be thick in proportion to its length, but it is often a large bill for the size of the bird, and it varies considerably in shape. Thus in the nuthatch the bill is straight, very strong for its thickness, being fortified with angular ridges on the culmen and at the edges of the mandibles; and thus it is capable of digging into the bark of trees, or hewing open the shells of nuts. It is partially a vegetable and partially an insect feeder. The rest of the family or division have the bill of weaker structure, generally larger, more slender, and not so straight; and some of the humming-birds have the tip of it so formed as to answer as a sucker. Thus, though the bills of all may without impropriety be said to be slender, yet slenderness is not a character of them, neither have they any one remarkable character which is common to the whole.

The feet form a better, or, at all events, a more constant character. These are all of the kind of double climbing or perching feet, of which some account will be found in the article Anisodactyli; and the using of these as characteristic of the division, rather than the mere slenderness of the bill, which, as has been said, is not a very constant character, is attended with some other advantages. It leads more naturally not only to the following and last division of this order, but to the order which Cuvier has placed next in succession, and which, if we take the general habits of the birds in both, has really more of what is called natural affinity to this division than it has to the one which Cuvier interpolates between them.

The *Syndactyli* form the only division of the order *Passeres*, which Cuvier classes from the structure of the toes; but if the leading character is, as it unquestionably ought to be, taken from the most efficient part of the organisation, then this is the very last class of birds which should have been characterised by the feet. All the division are energetic and active birds; but their feet are not only the least efficient parts of their own organisation, but they are among the least efficient for any active purpose, that are to be found in the whole class. There are birds which are worse walkers, though these are but lame at that kind of motion, and not much in the habit of using it; but then in most, if not all, other birds, which have the feet badly adapted for walking, they are on that account better adapted for some other purpose. They are climbing or swimming feet in proportion as they are ill adapted for walking; and even in the case of the swifts, (though the common swift has got the name of apes, or "footless,") the foot, short and weak as it is, is well adapted for taking hold on an upright wall, or the face of a rock; and the toes and claws have the form which is the very best adapted for these purposes. But though the feet of the birds of this division are, of course, as well adapted to the purposes which they are intended to answer, as the feet of any other birds, yet those purposes are not very important, nor very constantly required in the general economy of the birds. Such of those birds as nestle in holes in the earth, which is a habit with many of them, use their feet adroitly in the digging of those holes; and they can also perch upon bushes or trees; but they generally feed upon the wing, and never use the feet for any purposes, save those of digging and repose. Some notice of the structure of these feet will be found in the article Bee-eater.

The birds of this division have some resemblance to each other besides the mere shape of the feet; although none of the names by which they have, either in whole or in part, been called as a group, is very applicable. Those which have been styled *alcyonidæ*, after the kingfisher, have neither the form nor the habits of that genus, as it lives in great part upon small fishes, while those other genera which are classed with it live much upon insects. The hornbills, or rhinoceros birds, which, along with the same description of feet, have many of the habits of omnivorous birds, could not be brought within any group, the character of which were to be taken from the bill. Indeed the bringing together of the birds which are included in this division, appears to be rather in order to prevent them standing alone, than because of any well marked general affinity between them.

Cuvier's third order Scansores, or climbers, though named from the habit, is in reality, like the last division of the second order, founded upon the structure of the feet, and therefore the name of Zygodactyli, or "yoke-toes," which has also been given to them, is fully the more accurate of the two. A style of motion, or any other habit, taken singly, is rather a loose ground of classification. It is so with climbing in the case of birds of this order. It is not climbing generally, but climbing in a particular way, which is descriptive of them; and then that does not apply to them all. They are not the only climbers among birds; for the nut hatches, and especially the creepers, which are, in the same system, classed with the slender-bills, and others of the anisodactylic birds, are much more adroit and graceful climbers than these. Birds of this order are all, almost without exception, tree or forest birds: the greater number of them are inhabitants of the rich forests of tropical countries; and these are generally gay in their plumage. Indeed, the woodpecker and wryneck of our own country are showy birds; and perhaps the one of most sober plumage, though peculiar from its habits, and interesting from the time of the year at which its note is heard, is the common cuckoo.

The feet of these birds are grasping rather than climbing feet. The exterior front toe is reversed, so that the toes act two against two, which is the reason why the birds are called zygodactylic, or yoke-toed. In some of the species the feet are used in the same manner as the grasping feet or hands of the tree mammalia; and as some of these climbing mammalia use the prehensile tail as a fifth hand, some of the climbing birds use the bill or beak as a third one. Those which have that habit, have the upper mandible hooked at the tip; and the acting parts of both mandibles are short, but very strong, and act with much force like nutcrackers. The muscles which move these powerful mandibles, give considerable enlargement to the sides of the head. Those which have this habit are mostly vegetable feeders, and live among the twigs, nestling in the holes of old trees.

Taking the whole together, they are not a very natural order, even in the use of that part of their organisation after which they are named;—for whether, with Cuvier, we call them "climbers," after the habit, which is not general, or with others "yoke-toed," after the structure, which is general, though much modified in the different genera, their feeding, the structure of their bills, and many of their modes of life differ greatly from each other.

In their feeding several of the genera of this order bear a considerable resemblance to the Gallinidæ, or poultry birds, at least to those species of them which are natives of the forests of warm countries; and there are two genera, if not more, natives of Africa, which appear, as it is usually expressed, to "connect" the two, that is, which partake of the characters and display the habits of both. These are the genus *Corythaix* and the genus *Musophaga*, the former inhabiting southern Africa and the latter the more tropical parts of that continent. They have partially the bills and wings of the poultry tribes, though from the forks in the sternum being less deep, and that bone in consequence stiffer, they are birds of more continued flight. Their chief relation to the climbing birds consists in the structure of the feet, which have not, however, the toes acting so generally two against two, as in the birds which properly belong to the order, though the exterior so readily admits of a reversed position. They are tree birds nestling in holes; and the one which is known in southern Africa is chiefly a vegetable feeder, feeding upon wild fruits. It is a bird of beautiful plumage, bright green, with some of the quills crimson, and an elegant crest on the head. It has sometimes been classed with the cuckoos, apparently from the structure of the feet; but there appear to be but slight grounds for warranting such a conclusion.

Great allowances must be made for mistakes and errors in the classification, and even in much of the description, of the birds which Cuvier has brought together in this order. With many of them we are abundantly familiar, but there are many others which inhabit only the depths of the tangled and almost impenetrable forests; and the manners of these are of course as little known as their haunts.

Cuvier's fourth order, the gallinaceous or poultry birds (GALLINÆ, or rather GALLINIDÆ, for the other genera have of course only resemblances to the common domestic cock (*gallus*), and are not identified with it), form in many respects a natural order; because though there are great differences of appearance and habit, and still greater difference of climate and haunt,—some, as the ptarmigan, dwelling only on the mountain tops in cold countries, and others, as the peacock and the jungle fowl, dwelling only in the wooded parts of tropical climates,—yet there is a general character which runs through the whole. They are not birds of powerful wing; and though many of them perch in trees, few or none of them find their food there. They are ground birds; and only cull the seeds of those herbaceous plants which they can reach when standing, and gather such other seeds, insects, worms, and various succulent or farinaceous vegetable substances, or often animal ones (for some of the genera are not very particular in that respect) as they find on the surface, but scrape up the rubbish with their feet, in search of such substances suited to their taste, as may be found under it. The march of the males is stately, and they are often very gay with ornamental plumage peculiar to their sex. They are all, however, heavy and laborious fliers; and make but little use of their wings, except when alarmed, or in reaching those perches upon which they pass the night secure from the attacks of foxes and other predatory mammalia which hunt during the night but do not climb.

The flight of the gallinidæ is so peculiar, that it might be taken as their descriptive character, with fully as much propriety as any other action is of a division of birds; and certainly with more than climbing can be as characteristic of the last order. The domestic cock, for instance, is quite a soldier in his wars; and like a *gallant* soldier (and he himself is the type of pugnacious gallantry as well as the original of the name) he fights for the honour of the victory, and not, like a mercenary, for pay and "provend." When he leads forth the dames of his seraglio to a public breakfast in the newly-expelled litter of the stable, his strut is quite Oriental, and might of itself lead one to the knowledge of his native clime; but when he attempts flight, there is a sad falling off; the bravery of the soldier and the strut of the bashaw are no more, and the lord of the dunghill vexes the air with encumbering wing, and flies less gracefully than a bat or a beetle.

This laborious and painful flight, for it is certainly laborious to the birds themselves, as they can continue it only for a short distance, and if it is not painful to them, it is painful to look at, is common to the whole order properly so called; and on this account Cuvier appears to have departed from his usual attention to structure as forming the basis of classification, in uniting the pigeons with this order. The pigeons are birds of powerful wing, and have as much command of the air as the true gallinidæ have little; and besides, the habits of the races are in almost every respect different from each other. Pigeons are monogamous, and though they breed often, each brood consists usually of only a single pair: the gallinidæ are in general, though not in all the species, polygamous, breeding once, or at most twice in the year, and their broods are numerous. Pigeons are, in many of the species at least, migratory, and they both migrate and associate in numerous, and, in some cases, in countless flocks: the gallinidæ are never migrants, and those species which are mountaineers, would rather perish in their alpine habitations than descend to any great distance on the plains; and when they associate with each other, it is at particular seasons rather than habitually, and in families, or at most in packs of a few families, and not in large flocks. Their daily range is indeed so limited, and they use the wing so little in seeking their food, that a very large flock of them could not subsist in the same locality.

Pheasants, though they have the same style of flight as the rest, are certainly not the worst fliers; and yet there is a very striking difference between the common pheasant and the common pigeon in point of capability of endurance in the same locality. Where pheasants are kept in numbers, a preserve is made for them, which is understood to afford them not only shelter, but the greater part of their food. Common pigeon-house pigeons seldom have any pasture preserved for them, and cultivators drive them off from their crops. The native habitations of vast numbers of the parent stock, too, are often in rocks or places comparatively barren, where they must range to great distances for their food—for pigeons require proportionally more food than the gallinidæ, and, indeed, than most other birds.

Now if pheasants and pigeons *naturally* belonged to the same order of birds, we might surely, under these circumstances, expect that the pigeons should suffer most from casualties. If not, there could be but small propriety in uniting the two families of birds into one order; for if there is nothing more of similarity in the several members of the order than that structure of organ, or habit, or whatever else it may be upon which the order is founded, then truly the formation of the order is a very idle matter on the part of him who establishes it, and a very deceptive matter to those who seek for information from it. The name of the order, or other group, should, no doubt, be founded upon one of the most striking coincidences in the genera that compose it; but if there are not other coincidences behind to which that one is the key, then any attempt to get information from the system will be somewhat like an attempt to get a knowledge of Macedonia from Fluellin's comparison between it and Monmouth:—"There's a river at Monmouth, and I'll pe pound there's a river at Macedonia; and they call it Wye at Monmouth, and it is out of my prains what they call it at Macedonia; but it is as like as my fingers to my fingers, and there's sawmons in them both." This, though not brought out with the same graphic exposure of its absurdity, is very often the kind of analogy which the systematists in natural history propound for the edification of mankind; and even the acute mind of Cuvier, which was less frequently bewildered than that of most naturalists, must have been lost in the fog when he united the pigeons with the gallinidæ.

To those who already know the characters and habits of birds, or any other animals, it is of little consequence in what juxtaposition the several kinds of them are presented; but those who have the knowledge to acquire, and resort to the system for aid in the acquiring of it, of necessity conclude that there is some general correspondence in the nature of those which are united in the same order, or other division; and if, as in the case of poultry and pigeons, there is really no such correspondence, they either waste their time in vain search after that which is not to be found, or they turn from the system (and, in part, from the subject) with disappointment, as promising that which it cannot perform.

The feet of poultry and of pigeons are both adapted for walking on the ground, and those of some species of both are adapted for perching: their bills, too, are both adapted for ground feeding, though not exactly for the same kind of surfaces or of substances; but when thus much has been stated, the parallel is nearly at an end. Thus far may be seen at first sight of the two; and when we come to study them more intimately, there is nothing, even of inference and analogy, in the general history of the one, that can lead us to the general history of the other.

The different casualties of the pheasant preserve and the pigeon-house show that, physiologically considered, the two races have little in common; that—independently of difference of power and style of flight, feeding, incubation, nesting and breeding, texture and flavour of flesh, and all other particulars—there is a difference in the whole nature of the birds, as they stand related to the course of natural events. The pigeons have, as has been stated, only a lodging in the pigeon-house, while the pheasants have both cover and food in their preserve—that is, not merely shelter while they are at rest, and accommodation for their nests, but food, and protection from the weather while they are gathering it. But under all the apparent differences of accommodation, the pigeons thrive best. As their numbers increase they extend the range of their feeding excursions; and though on these they have to use the wing much, and often to contend with the severity of the weather, they do not appear subject to any casualty of nature, but to thrive as well and be as healthy when they range over many miles as when they are kept at home and fed by the hand. The pheasants, on the other hand, cannot endure even their natural powers to increase beyond a certain limit; for (as was not many years ago proved at Wanstead, in Essex) if they are allowed, even in the most favourable preserve, to increase beyond a certain limit, *epizooty* falls on them, and they die by the score, not of hunger or any other perceptible cause, for they die in good condition, and the mortality continues till their numbers are reduced considerably below what would be left by a judicious sportsman.

Our native gallinidæ have not, perhaps, been so carefully studied; but there are well authenticated instances in which excessive preservation has been followed by, if it has not actually produced, epizooty, both in the mountaineers and the inhabitants of the plains. If such were the case only with pheasants, their foreign origin, and the many mild climates of which they are natives, might be alleged as the cause; but as the ptarmigan is the highest dweller of all our native birds, and the grouse live in more bleak places than the pigeon, and as they are subject to the casualty from which pigeons are exempted, we must conclude that the whole of the gallinaceous tribes, of which these are the most hardy, are physiologically different from the pigeons, and tempered to the elements in a very different degree. Taken alone, this would be a good argument against uniting the two in the same order; but when taken along with the structural, and even the textural differences of the birds, and the differences of all their actions and habits, it becomes irresistibly conclusive; and gallinidæ and columbadæ should unquestionably form separate orders in any system pretending to be natural.

If this is done, each of the orders becomes well-defined as well as natural; and they do not even clash or get confounded with each other on their confines, as is the case with many of the other orders. The structure, the action, the habits, and the general character, as inferred from the whole, are all so constant in each, and so different in the two, that if we know one genus well, we never can be at a loss with any other in the order; neither can we, in any instance, confound the two.

The fluttering and apparently painful flight of the gallinaceous birds may excuse a few sentences of explanation, as it is one of their most general and most striking differences from most other winged birds, and as the explanatory notice of it will throw some further light upon the structure of the organs of flight. This becomes the more justifiable, because the more necessary and useful, when we consider that the superiority of the flesh of the gallinidæ to that of all other birds, as human food, if not dependent upon, is at least intimately connected with their imperfect power of flight.

When we speak of the flesh of any animal as an article of food, it is always the muscular part of the animal which is chiefly understood. We cannot exactly estimate the power of muscles upon common mechanical principles, because the energy of life in the animal to which they belong is always an element, and one which we can subject to no calculation. But the quantity and texture of the muscle are also elements; and though we cannot say that the power of action varies exactly as any one of them, or as both jointly, yet it does increase with their increase and diminish with their diminution. Now, air birds, whose action is chiefly performed by the wing, have almost the whole muscular structure of their bodies concentrated upon that; and if they have to remain long in the air, and contend with the wind there, the structure of the muscles is proportionally rigid, and they are, of course, difficult of mastication and digestion. In these cases, extra dressing, whether by the action of the dry fire or by boiling, does not cure the evil; for though these muscles become more easily divided in proportion as they are more dressed, they become at the same time, and perhaps in a greater proportion, more dry and tasteless, and less digestive and nourishing. A dinner of the pectoral muscles of well-seasoned eagles, or the larger hawks, would be serious labour for the jaws of even the most willing masticator; and bating the bitter taste, a rook of five broods would make almost as tough a meal as oakum or old junk. These qualities decrease as the birds make less use of their wings; and in those birds which are not allowed to fly at all, while fattening for the table, the muscle is more juicy and tender than in any others. But that preparation may be overdone, by the bird having less exercise than accords with a healthy state of its system, and then what is gained in tenderness and even mass of flesh, is more than lost in flavour and wholesomeness. If the inactivity is unnatural and the food abundant, the tendency is an over-production of fat; and the fat of birds is the least wholesome of all fat. It consists chiefly of *elain*, and not of crystallisable fat, and as such it very readily passes into an oil, difficult of digestion and very much disposed to become rancid. A barn-door fowl, which roams freely as it lists, enjoying plenty and variety of food, and clapping its wings and flying a little if so inclined, is, in point of flavour and wholesomeness, worth all the penned birds that ever were "prepared for the market." This is, as nearly as can perhaps be obtained in Britain, the natural state of the bird; and though there is no doubt something of the influence of name in the matter, the fact of their living and feeding in a state of nature is one grand cause of the preference given to the wild gallinidæ. But the flesh of these also is tougher and more dry in proportion as they are more in the habit of using the wing; and therefore if they cannot be dressed before they stiffen at all, they require to be kept till incipient putrefaction makes them tender; and when they are very high, the organs of taste and smell sometimes have disputes about their real worth.

Thus, the qualities which the flesh of the gallinidæ derives from their small tendency to flight, renders them more immediately valuable to man than any other birds; and the very same circumstances, taken in conjunction with their other habits, render them among the most easily obtained. They are also among the most prolific, and instead of vanishing before the progress of culture, as is the case with many other birds, they increase in proportion as man cultivates the ground. The partridge comes where man ploughs, and in proportion as he plants, pheasants increase in numbers.

The chief use of the wings of the gallinidæ, besides enabling those which perch during the night to reach their perches, appears to be safety against quadruped foes. Their fluttering gets them, perhaps, sooner above the reach of these than if they had a more steady and forward style of flight. From birds of prey they may be said, one and all, to be incapable of escaping on the wing; their safety from these consists in crouching among the clods or lurking among the herbage; and their general colours are such that they are not easily distinguishable from these. Their wings are short, broad, and concave, and they are also looser in the plumage of their under sides than the wings of almost any other birds. All these qualities make them take a great hold on the air, which assists them in "working upwards," though it renders even that direction of flight more laborious. They can thus reach the height of escape from a ground preyer, or that of perching, upon a more perpendicular line, or with less forward motion than birds of more powerful wing. The same form of wings enables them to drop down more readily than almost any other birds, except those which, like the sky-larks, drop from a great height, and acquire an impetus from the descent. This power of quick descent is as advantageous to them as that of speedily rising, for they drop so quickly into their cover that one can hardly point to the precise spot, and the difficulty of so doing is increased by the wheeling motions which they have when in the air, and also by their running in a different direction from that in which they were flying, before they squat, or otherwise pause, for the purpose of hiding themselves.

Thus their apparently clumsy and ungainly wings are as well adapted to their peculiar habits and haunts as the finest and firmest wings that cleave the air. It is also worthy of notice that, as their power is not concentrated in the wings, but diffused over the body, all the parts of which have more or less of motion in their several actions of walking, running, crouching, standing up for observation, and others, the whole body comes more into action, and labours more during their flight, than in the more elegant fliers.

This is an instance of a very curious habit of the bodies of animals, which is so general that man himself is not exempted from it. It is this: if any one system of the body, be that system what it may, whether external or internal, is to work in its most graceful and efficient and least laborious manner, it must work alone, and the rest of the body must be trimmed to its accommodation, and not in a state of excitement or action. This is a proof that the principle of animal life in the individual is one, in the same manner as the intellectual principle in man is one. If the breathing, or the circulation, or the digestion, labours violently, the external organs become unfit for motion; and if the whole body is excited, no one organ of it can perform its function so well as if the rest of the body were tranquil. In man, this is called self-possession, coolness, or firmness, and every one knows its value; in other animals it arises from a different cause, but its effect is nearly similar.

We find the difference between the wholly excited and acting body, and the acting of one part only, with the others trimmed or borne in accordance with its action, well exemplified in the spring of the lion or the tiger, and the stroke of the falcon. In the beast, the impetus is given with the whole body; in the bird it is given with the wings only. Thus it is momentary and exhausting in the former, but in the latter it may be continuous, with comparatively little abatement of energy.

The flight of the gallinidæ may be regarded as only a sort of semiflight. It is performed with the whole body, and partakes of the exhausting character of every motion so performed; and the faster that these birds attempt to fly, they can fly for the shorter time: they never fly fast but when they are excited, and they very frequently scream as well as flutter, showing thereby that they are in a state of unnatural excitement—that such flight is not their natural habit.

And when we examine their structure, we find that the whole body must act when they fly. The deep forks or clefts in the sides of the sternum, render that bone flexible; the form of the furcal bone, which is that of the letter Y more than that of an arch, and with the branches not placed with that side to the strain with which they would be stiffest; and the looseness of the blade-bone; all conspire to render the socket of the humerus unsteady and capable of play in all directions. The whole side of the animal thus works in lessening the effect of the wing-stroke, and at the same time fatigues the bird more than would be done by a firm wing. The muscles are also, as has been noticed, of less firm and enduring texture, in proportion to their bulk. Thus the gallinaceous bird is, by its structure, kept to its element as an inhabitant of the earth, and rendered incapable of soaring with the air-birds, to share either the grandeur of their flight, or the dangers to which they are exposed on the wing.

But while the loose and fluttering wings of these birds keep them to their own element and place in the world, they are not less adapted to their habits and necessities there, than the swiftest and most enduring wings are to their different element. We have already mentioned how well they are suited for escaping the foe or gaining the perch; and the looseness of the scapular socket is not the least beautiful part of their adaptation. The haunts of the birds are among shrubs, and bushes, and tall herbage, and they have often to use their wings and get quickly above their ground enemies from among these. They have also to close their wings among interruptions, and with as little rustling of the wing or that which disturbs it, as possible. The broad wing and the loose and moveable nature of its articulation, answer another purpose in the economy of these birds, which though not so immediately important to the individual, is equally so to the race: the females gather their young under their wings in the early stages of their existence. This protection of nature appears to be necessary, as the young of these birds are but lightly covered with down, as there is no formal nest for them, and as they are, even in the perching species, unable to perch till they are fledged. They have, however, more use of their legs, more general activity, and are better fitted for finding their own food when they have the skill, than the young of any of the preceding orders.

This state of the young when produced, corroborated as it is by their general structure and habits, very clearly points out the place of the gallinaceous birds in a natural system of arrangement. If the birds of most powerful wing, and of which the air is the principle element—the races which most perfectly answer the definition of the term bird, in being most exclusively dependent on their wings,—are to be placed foremost in the system, as they unquestionably ought to be; and if the gradation is to be regular from them to the races which are wholly dependent on the earth, and can neither fly nor swim, and proceed from them to those which are wholly dependent on the water; then, unquestionably, the proper place of the gallinidæ is immediately before these ground birds, which have less power of flight than they, and after the pigeons.

This mode of arrangement, as we shall attempt to prove in a short induction from the particulars, after we have given an outline of the remainder of these, is borne out by a regular gradation in all the leading habits of the several races from the time that they leave the shell till they become parents, and display those instincts which complete their mature character in the way in which they provide for, or otherwise treat their young. There are apparent anomalies in such an arrangement, because at some parts of it there seem blanks, where the characters of the one division do not meet those of the next one so as to preserve the continuity; and there seem at other places to be redundances, where two races, different in some of their characters and habits, have others so much in common or so equally, that it is not very easy to say which ought, in strict propriety, to be placed first. In some instances, these wants and redundances, these breaks and doubles in the chain, so to speak, exist only in our partial view of the matter. But when we consider that birds, in one or another of their varied tribes, inhabit the whole land and sea, and that the characters of these are, in some places, uniform over a considerable range, and in others constantly varying; that some are exuberantly productive, and others bordering upon sterility; we may easily see that the birds must crowd both in species and in numbers to the places of abundant and varied production, and be fewer and more uniform where food is scanty and nearly all of the same description. The natural series of birds is thus not one which can proceed by uniformly equal distances between race and race, but by distances varying with the haunt, and the varying abundance of the food for them, whether local or seasonal.

Cuvier's fifth order, which is a very numerous one, and includes birds very varied in their appearances and habits, is that to which he gives the name of Echassiers, or, "stilt birds,"—birds, generally speaking, with long legs, all capable of walking, and many of them fleet in that motion, but varying much in their powers of flight, and also in the shape of their bills, according to the nature of their food, and the places in which they seek it. They are otherwise styled *Oiseaux de rivage*, birds of the water's edge, bank birds, shore birds, *grallæ* or waders, and *grallatores*, or *grallideæ*, birds resembling wading birds. They are also sometimes divided into two orders or sub-orders, *Cursores* or runners, and *Grallidæ* or waders. But no name, whether founded on one haunt, habit, or peculiarity of structure, as all of those are, will suit the whole, neither can any general definition or description be so framed as to be explanatory of the whole.

There are few or none of the orders already mentioned, which do not reach the water's edge in some of their genera; and even the most aquatic of the sea-birds are reared on the shores, and compelled to seek the shelter and safety of these when the ocean is in its fury. Some of the eagles fish; some of the omnivorous birds seek their food within flood-mark when the tide ebbs; the swallow tribe skim the surfaces of pools; almost all the *syndactyli* live in holes in the banks, and the king-fisher is named from the manner in which it finds its food; even the common pigeons are found wild in sea-beaten cliffs; and one species at least of gallinaceous bird, has the feet partially webbed, and frequents marshy places. When therefore we speak of a "bank bird," our expression is exceedingly vague, unless we go on to explain at length how it is employed on the bank, and that explanation would give us the information as well without the name as with it. This is therefore a portion of the class, and it is a large and important portion, which is not clearly set forth in the system.

The distinctions of runners (*Cursores*), and waders (*Grallidæ*), are applicable and definite enough, as expressive of the extremes of the order; but as walking and wading are motions of the same kind and performed with the same organs, only with a difference of the element, and a difference of the organs to adapt them to these. But they interfere on the confines; and there are some, indeed many, of the species which perform their ground motions so equally on the land and in the water, that they cannot with propriety be considered either as walkers or as waders. If, however, we separate those species which have no aquatic habit, but are found upon dry places only, and they are habitually found upon pastures more arid than any other ground birds, and consider them as Cursores (for they are all swift of foot, and the majority of them are incapable of flight), making them a distinct order; and then include all the others in another order Grallidæ, or birds which can and occasionally do wade, we shall perhaps come as near to accuracy as is possible without a much greater, and indeed an inconvenient number of primary divisions.

Cuvier divides the order into five principal groups or families, to which he has to append some genera which do not conveniently come within any of the groups.

The first group, *Brevipennes* (short-wings), consists of the ostriches and other land birds which cannot fly; but the name is not very accurate: and the group to be natural and preserve the gradation should include some birds which can fly, such as the bustards, which form the connecting link between the gallinidæ and the ostriches.

The second group, *Pressirostres*, includes those birds which have the bill hard and compressed laterally; and which are long on the legs, and have the hind toe wanting or merely rudimental. Some of them are bank birds, but none of them wade deeply in the water; and their proper character is that of running birds. In a natural arrangement, some of them should precede and some follow the ostriches.

The third group, *Cultrirostres* (knife-shaped, or ploughshare-shaped bills), is pretty natural, though the epithet does not express the shape of the bills of many of them. They are, in general, long-flighted birds, ranging far and wide, especially in those countries which are subject to alternate drought and inundation. Many of them are true waders, and perhaps the most typical birds of all the grallideæ.

The fourth group, *Longirostres* (long-bills), is also tolerably natural, though the single epithet "long" is hardly sufficiently expressive of bills of so many different shapes and textures, as are possessed by these birds. Some genera of this group have so much the habits of the former, that there is a very natural transition from the one to the other; but very many of them are marsh birds, seeking their food in boggy earth, sludge and ooze; and these in general have the bill flexible, and provided with nerves and vessels, so that it is a more sentient organ than the horny bills. As these find their food more by the touch of the bill than by sight, they are often nocturnal or twilight feeders, and remain in the cover of the tall aquatics or marsh plants during the day. On this account they are often really resident in places from which they are supposed to migrate.

The fifth and last group, *Macrodactyles* (large-toes), differ more in their characters in proportion to the number of the genera. They are, as it were, on the confine of the order, and begin to partake something of the swimming character. This is the case with the *coots*, which have the feet lobed, and so articulated that they are not very efficient for walking. There are others, again, which, though they are not found in arid places, can hardly be said to be aquatic in any of their habits, or even to resort to the margin of the waters, of which the common corn-crake is a familiar instance. These, and some others, have considerably more affinity with the gallinidæ than many of the other genera, and even groups, which are interpolated between them in the system. The pratincoles, flamingoes, and some other genera which Cuvier appends to this group, without meaning it to be understood that they naturally belong to it, are also of a mixed character. The pratincoles have at least some of the characters of those insectivorous birds which have syndactylic feet, and also some of those of the gallinidæ; and it does not appear that, though they frequent the margins or surfaces of the waters, they are in any respect wading birds. It is also not very easy to assign the proper place of the flamingoes in any system which pretends to be quite natural.

We must not, however, either wonder, or be perplexed in our inquiries, at these apparent anomalies. It has been hinted, that the rich places of nature are those at which birds appear to interfere with, or, if the expression may be allowed, to *overlap* each other, agreeing in some of their characters, and differing in others; and as the margins of the waters are the richest places, and the places which are most permanently rich in the food of birds, it is natural to expect that upon these there should be the greatest interference of race with race, and consequently the greatest difficulty in so separating them from each other, as to give distinctness to their systematic arrangement.

Palmipedes, or webbed-footed birds, form Cuvier's last order of this class; and in so far as that they can launch themselves upon the waters, and be in their element there, they are a natural order. But they are not the only birds which can swim, for some of those of the former order can swim readily, and others can do it occasionally, although their feet are not webbed, but have only partial membranes, more or less produced, attached to their toes.

If we were to take a regular gradation in the birds of this order from those which have the feet the least adapted for acting upon the water, to those which have them the most so, we should begin with those which have the toes only lobed and margined, and proceed to those which have all the four toes united by one membrane or web. But the other active systems of the birds interfere with this arrangement, and their varying powers of flight interfere with the classification which otherwise might be founded on the structure of the feet, and render it imperfect.

Aquatic birds have wings of very varied structure. Some have about the longest and most powerful ones of all the feathered tribes; some have them short and round, and some are almost wingless, though there is no sea-bird so completely so as the apteryx. Their wings are also used for very varied purposes. Some use them habitually in feeding; some in ranging the surface of the ocean; and some chiefly for migration from place to place, as changes of season and of food may require.

Their bills vary nearly as much in structure. Some have the form of spears for transfixing fishes, upon which the birds dash from a considerable height; some are toothed in the tomia, for catching the finny prey as they drive through the waters; some are fitted for cutting and tearing the carcasses of the larger sea animals, which are often floating dead on the surface; some are adapted for collecting oil on the surface of the waters; and some for dabbling in the mud on the shallows.

Organs so differently formed, and applied to so many purposes in so many ways, render the division of aquatic birds into natural groups no easy matter, though some of the groups are as distinct and well defined as any of those of the land birds. Cuvier arranges them into four tribes.

The first of these consists of *Divers* (*Brachyptera*, or "short wings"), which have some affinity with the shortest winged and most aquatic of the bank birds, and they run on, becoming more and more birds of the water, and less birds of the air or the land, till those species are arrived at which can neither fly nor walk. The show of resemblance may be said to run to a termination in this group; for, as the last ones can only swim and dive, and there are no other birds which can do either in greater perfection, there is no point of general character upon which any others can be connected with them. The popular name is also not quite precise, because, though they are probably the only birds which drive through the water, they are not the only divers.

The second group, Longipennes (long-winged birds), agree well with the name in that part of their organisation to which it applies. They are the birds which career over the surface of the ocean, and make the shores lively with the motion of their wings, and clamorous with the sound of their voices. Their food and their manner of obtaining it differ so much, however, that they do not admit of any general description.

The third group, Totipalmæ, or birds with the feet "entirely webbed;" that is, having the hind toe considerably produced and included in the membranous web, as well as the other three toes. These birds are much longer winged than those of the preceding group, and they are good swimmers, and some of them at least can dive; but the peculiar structure of their feet, and the use which they make of these in walking up to the surface of the water after they have plunged into it from a considerable height, render them very distinct from the other sea birds.

The fourth and last group into which Cuvier arranges these birds, Lamellirostres, or flat-billed birds, comprehending ducks, geese, swans, and allied genera. There are considerable differences of haunt and habit among them; but still they are distinct, and well-marked as a group. But it is doubtful whether they should occupy the place which Cuvier assigns them, as they more resemble the divers in all their general characters than they do the birds of the two intermediate groups.

Such is a short outline of the systematic arrangement of birds, as proposed by the most scientific general systematist of modern times. Many parts of it are imperfect, and some are obviously faulty; but the imperfections are much more easily felt than amended, and the faults much more easily seen than corrected. These imperfections and faults are also of the less importance, inasmuch as it is in the individual genera, or, at all events, in groups much smaller than most of those which have been mentioned, that the real history of birds must be studied. We shall now, in three successive sections, shortly examine and compare the bills, the feet, and the wings of birds, as the foundations of their leading characters.

V. Comparative forms of the bills of birds. The armature of the jaws of birds, which answers the same purpose in their economy which the lips and teeth do in that of mammalia, always consists of two mandibles, one placed over the other, and opening and shutting chiefly by the motion of the lower one. This organ is sometimes called a *bill*, and sometimes a *beak*, but the distinction of these names is not very clear. Bill is, however, the more general of the two, in the usage; for all beaks may be called bills, but all bills cannot be called beaks. According to the popular understanding, which, rather than any etymological definition, is the rule in popular language, the mandibles of a bird, in order to entitle them to the name "beak," require the three attributes of firmness of texture, power, which requires considerable depth and breadth in proportion to the length, and curvature downwards, with pointedness at the tip of the upper mandible, and projection of it over the under one; but the precise degree in which these are required, as well as their relative proportions to each other, is indeterminate. Those to which the term beak is more generally applied are the mandibles of birds of prey, and those of the parrot tribe, and some other vegetable or omnivorous feeders which use this organ in breaking hard substances, or in assisting in the operation of climbing.

All beaks, whether used for one purpose or for another, have a considerable resemblance to each other, not only in the shape but in the mode of using. They are always cutting or bruising instruments, the effect of which is produced by pressing the one against the other, and not by striking with the point or darting, as is the mode of action in many bills. The form of the tomia or cutting edges, are therefore the leading distinctions of different beaks, and the indexes to the different characters of the owners in so far as these depend upon those instruments; though there are also some corresponding differences in the shape and strength. In the tomia of beaks there is a slight resemblance to the teeth of animals, as indicating the nature of their food. Those which are carnivorous have the tomia irregular in their outlines, approaching in form to something like a tooth; and those which are more exclusively vegetable feeders, have the lines of the tomia less broken, and the acting surfaces adapted simply for breaking or bruising rather than for tearing asunder. Some of the latter are, however, more strongly formed than any of the former; because the shells of some fruits upon which certain species at times feed, require more force to break them, than is required to tear the average consistency of the flesh of animals, even in the most recent state. But the bills of the most vegetable feeders have little or no lateral motion by which they can prepare the food for the stomach by grinding; and that appears to be the chief reason why birds of this description always have muscular gizzards, strong in proportion as their food is more difficult of division.

These characters of the tomia belong to bills as well as to beaks, though bills have in many instances additional characters, such as being serrated, sometimes with little teeth reflected backwards along the whole line of their margins, and at other times with small transverse channels, or furrows, along a certain breadth at the margin. The first of these descriptions belongs principally to birds which dart upon fishes, or other slippery prey; and the latter to those which dabble in the sludge, and, as it were, sift the water and mud from their food by means of the channels. The former are generally hard in their consistency, so that they may penetrate and retain their hold like barbs; the latter are more frequently soft and flexible, and there is reason to believe that they are endowed with sensation, by means of which they can distinguish the food from other substances, and thus retain the one and reject the other.

Bills are, however, of so many forms, and so different in the texture of their substance, that no general definition can be made descriptive of them. If omnivorous, they are generally stout, sharp at the tip, and with ridges on the culmen, or centre of the upper mandible, and also often at the tomia of both; and these ridges, which render the bill much stronger and stiffer than if the same quantity of horny matter were equally distributed over the entire surface, often give a quadrangular form to the section of the bill. Bills which dig into the bark or wood of trees, into hard ground, or into other substances which offer considerable resistance, are also provided with ridges. This is the case with even those very small bills which pick minute insects and larvæ from the crevices of bark, and thus such bills are often much stronger than others, which, having a larger diameter, look more formidable. All bills, too, which are used in striking or thrusting with the point, are fortified by ridges, and such bills never have so much curvature in their general shape, as that the line joining the tip and the centre of the base falls anywhere without, or even near the surface of the bill. If they act both by thrusting and by cutting between the edges, the ridge of both mandibles is usually a little arched, the arch in that part being the form which, with an equal quantity of matter, enables the mandibles to compress any substance between them with the greatest force. But if the thrust be the only powerful action of the bill, the ridges of the mandibles are generally concave, with the curvature increasing towards the base of the bill, something in the same manner as that of the bole of a tree increases near the surface of the ground. This is the outline of greatest stability, and as such it is adapted for lighthouses and other structures which are much exposed to strains from the action of the wind or the waves. In those bills, this enlargement toward the base, over which the tip is generally situated in a perpendicular line, causes the bill to strike with more precision, and also with much less jarring of the cartilaginous substance by which it is united to the bones of the head than if it had any other form. Thus we see that in those organs of birds which have not generally any sensibility or proper motions of their own, the same mechanical perfection is displayed as in the more sentient or more active parts.

We need hardly say that the bill or beak is adapted to the general structure of the bird, because all the parts of every organised body, be the organisation what it may, are always the best adapted to each other, and to the whole; but there are certain other parts of the structure with which the bill has a more immediate agreement If the bill has to tug and wrench in tearing asunder the food of the bird, the neck has always great strength and great power of lateral motion united. If the bill has to strike forwards, the neck admits of less lateral motion; but it moves the head in the direction of the stroke with great celerity. Thus the blows of the woodpecker are given in such rapid succession that the motion of the bill can hardly be seen, or the strokes counted; and though the neck and bill of the heron tribe appear unwieldy, they strike out with amazing rapidity.

The adaptation of the bill to the other acting parts of birds depends, however, in no small degree upon their habits; for, after all, it is to the habit that the whole parts of the bird are adapted. Thus, though the taking of the same food, generally speaking, requires a bill of the same structure in its working parts, yet as that bill is brought within reach of the food in different ways, and by means of different organs, it must be so modified as to accord with these.

If the principal action of the bill consists in detaching the food or breaking it, it is always short, or only of moderate length, and stout in proportion to its length; if the bill is used in hewing or digging for the food, it is longer, straight, and hard and pointed at the tip; if it bores into sludge, it is still longer, straight, broader at the tip, and generally sentient, so as to discover eatable substances by touch; and if the bird feeds in the free air, or on the clear surface of the ground, the bill is, in general, of moderate length. But all birds which capture living food, either in the water, or concealed among herbage, by a sudden thrust of the bill, have it long.

There are other purposes to be answered by the form of the bill besides the mere capture of the food, and adaptation to the place where it is, and the manner of getting at it. It is a general law in the economy of animals, that they shall be safe while they are feeding, at least from dangers connected with the food itself, or the place where it is.

Now, besides being pruners and weeders to the vegetable kingdom, and a sort of general scavengers for removing the waste of all nature, birds appear specially appointed for keeping within proper bounds the numbers of fishes, mollusca, insects, and reptiles. The power of production in all of these is very great; and, with the exception of the fishes, which settle matters by eating each other (often their own species), this productiveness is far above the average support, or even the room which there is for them in nature. The tadpoles which appear in one brook would, were they all to live and breed, speedily cover a county with frogs; the caterpillars on one branch would, if so breeding, soon clear a forest; and the snails would speedily multiply till not a green leaf were to be found. The ophidian and saurian reptiles are, in many of their species, co-operators with the birds; but they frequent the places where the food of birds is abundant, and they are not fitted for long migrations. The motions of molluscous animals are proverbially slow; and though many of the insect tribes are clever on the feet, the wing, or both, they are not capable of long journeys. Locusts and some other tribes do migrate; but no insects can continue long on the wing. They want the feathers, the characteristic organs of long flight; and though their muscles act to very considerable advantage, they must move their wings so incessantly that they are soon worn out, and fall to the earth.

There is here a very beautiful chain of adaptations, which is worthy of study in itself, besides being intimately connected with the general economy and structure of birds. All these natural trimmers of the exuberance and removers of the waste of growing nature are wanted up to the full amount of their powers. But they are so wanted only for a season; and though that season varies in length in different latitudes and climates, there is not a spot on earth where it could be perennial, or even of one whole year's unbroken duration, unless the laws of the whole system, that is, the qualities of the several parts of which it is made up, were totally changed. The vegetables could not bring all their "briards" and buds to maturity, nor would the earth supply sowing ground for all their seeds; and the creatures, of whatever kind, which keep down the superabundance of these, would, in like manner, speedily overstock the room that there is for them. But still they must all have that elasticity by means of which they can instantly adapt themselves to the changes of the system. The earth consists of a definite quantity of matter, occupying a definite space; and to that quantity and that space all the productions of the earth must be capable of accommodating themselves, otherwise the system would be imperfect.

The earth itself is, perhaps, at once the best index to the system of the earth's productions, and the best illustration of the mode in which that system works. It careers round the sun, altering its distance from that luminary, and the rate of its motion, every moment, and differently affected as its own attendant moon, or any other body in the solar system, is differently situated with respect to it. But though *altered* it is not *disturbed;* the balance is never deranged, and we are so far from feeling the inequalities of its motions, that it is only after the most profound investigation that we become aware of their taking place. The law which God has given it is a perfect law; and no case can arise to which it does not apply with the same ease and perfection. If the motion requires to be accelerated or retarded, in order to keep up the perfect balance, the very necessity for the change is, in itself, the cause of that change; and, be the aberration ever so much, there is always a principle inseparably connected with it, which, in due time, produces a return.

Just so with the growing and living productions of nature; if the general circumstances are such as to harmonise with an increase, there is no waiting for that increase as man must wait in his workings, and no toil as he must toil to bring it about. The necessity and the supply come so simultaneously, that the one cannot be called the cause and the other the effect. They at once prove their origin from the same cause; and that that cause is no part of the system of nature, although intimately familiar with it all in extent and in duration.

The preservation of the whole system of nature requires that, at certain pauses, and those not very wide of each other, the races which, among their other uses, put the birds in motion, must be as "the dry bones in the valley of death;" but the Author of nature has so ordered that, when their activity becomes necessary, there is "a spirit" breathed by them into the system, which can, unseen, and in an instant, pass over them and recal them to life and activity. Thus the cold winter of the polar climes, and the withering drought of the equator, are alike necessary for preserving the energy and the beauty of the world.

All preyers, and birds in an especial manner, as being the most discursive rangers, are highly valuable. They give play to the energy of life generally in that which they individually destroy; and but for them the earth would become rank and foul with the carcasses of those tribes which must perish and be renewed in the different seasons.

In the performance of these labours, many species of birds have to prey upon animals, the immediate contact of which with the body of the bird would be attended with fatal consequences; and in other cases the prey is in places which the bird cannot, with safety, approach too closely. The parts of birds which are naked of feathers, whether they are covered with horn or with skin, contain few muscles or blood-vessels, so that they are not easily wounded or otherwise injured in such a manner as to affect the general economy and action of the bird. This is the more necessary on account of some of the creatures upon which the birds feed being capable of inflicting poisoned wounds, all of which would be painful in the fleshy parts of the bird, and some of them very speedily fatal. It does not appear that the animal poisons, known by the general name of venom, are deadly, or even in the least injurious, if they are not taken into the circulating blood. Whether they must be so taken by direct introduction into a blood-vessel, in order to produce their fatal effects, or whether the poison may be carried into the circulation by the lymphatics, which pour what they collect into the veins through the thoracic duct, is not clearly ascertained; but as the effect of those poisons always shows itself locally, near the place of the wound, before it injures the system generally, it is probable that a direct mixture of the venomous fluid with the blood is necessary, in order that it may produce its destructive effects; and this is rendered the more probable from the fact that the same fluid may be taken into the stomach without the smallest injury, by animals to which it would prove fatal in a very short time if taken into the blood.

Many birds feed upon creatures provided with poisoning apparatus,—as the bee-eaters and other species feed upon many insects that have poisoned stings; and various species of birds feed upon serpents which have poison fangs. Now, all those birds are so constructed, that those parts of their bodies which could be seriously injured by the sting or the fangs, are kept out of the way. If, like the bee-eaters, they capture stinging insects on the wing, the bill is long, and the tongue either short or indurated, so that no part of them which comes in contact with the insect, is liable to be hurt by its puncture or its venom. In those species which eat poisonous snakes, the bill is long, and the tarsi also, so that all those parts of the bird which are vulnerable by the reptile, are elevated above its reach after it is once pressed to the earth by the feet, when it is not at once killed by the stroke of these on the head, which is a very common habit with birds in the case of such prey. If food which is thus dangerous is taken by the bird on the wing, as is the case with wasps and other venomous insects, the bill is long, and the tongue either short, or callous towards the tip, so as not to be very liable to injury, if the snap of the bill, which however is seldom the case, should fail in despatching the insect.

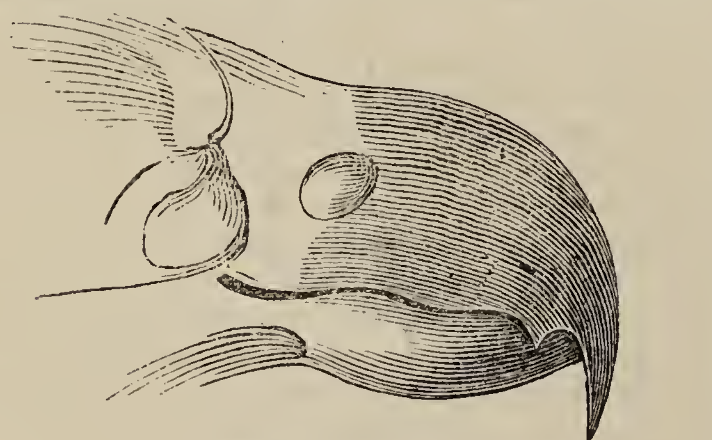
If the food is in itself harmless, and not liable to escape rapidly, so as to require a quick dart of the bill, that organ is short, and any inconvenience which may arise from the distance at which it is below the level of the body, or from the difficulty of the surface on which it is found, is usually got the better of by the length and flexibility of the neck; but as a long and flexible neck is neither so steady nor so quick in its motions as a shorter one, the bill and neck are seldom both long unless in those species which take their food from the water, by darting rapidly on it by an aim taken when the eye and head are above the surface. Birds of this structure usually find their food on the margin of the water, or in the shallows; and there is hardly any instance of a bird which feeds on the wing, having both a long bill and a long neck.

The same observation applies to birds which seek their food while launched on the waters. Swans, geese, and those ducks which never get wholly below the surface, though they get with the head perpendicularly under them, and hang, as it were, upon the water by means of the feet, have the neck, and generally also the bill, much longer than the divers which plunge wholly under water; and the legs of the latter are articulated more in the rear, which makes them more efficient organs of motion through the water; but the birds could not recover their horizontal position on the surface, by means of them, so easily as those swimmers which have not the habit of diving. Those ducks which do not dive, turn on the articulations of the legs, and bring their heads to the surface with very little progressive motion; whereas the divers rise head foremost, and always at some distance from the place at which they plunge. The common duck gets the head down chiefly by the action of the neck; the plunger by a swing upon the webs of the feet, the whole length of the body acting as a lever. The diver, too, can make the body follow the bill, as guided by the eye when under water; and the bill is compressed, or at all events narrowed and rounded at the tip, so as to make it readily available in that action; whereas the bill of the dabbler, which does not dive, is probably available only in the sludge, and incapable of capturing prey that can move swiftly. Dabbling ducks rarely capture even the fry of fishes, in those shallows which they frequent; but these are the principal food of many of the divers.

The bills of birds are, however, so much in harmony with the other parts of their organisation, that it is impossible by any description, however lengthened, to give a clear and satisfactory notion of them, even in their leading function of feeding instruments. They have, in many species, other offices to perform; and though these are subordinate to the alimentary function, as the functions of the mouths of all animals are, yet the bill must necessarily vary with every natural operation to which it is applied.

The secondary functions of bills are chiefly preening the feathers, climbing, constructing nests, and defensive or offensive operations not connected with feeding. These functions are performed with so apparently equal ease by bills of so different forms, that it is not easy to say which answers the best; and then the comparative merits of bills, as working tools, can hardly be so generalised as to convey any information useful to the student of ornithology. We shall therefore proceed to give some instances of bills belonging to well-known or well-marked species, as illustrative of the several orders.

Bills of the Accipitres.—The annexed figure of the bill of the jer falcon may be regarded as the most



Jer Falcon.

perfect type of those of diurnal preyers upon the wing. It is short, compressed, and so formed on the culmen that it is perhaps stronger in proportion to its size and quantity of matter, than the bill of any other bird. The tooth is prominent, the notch well defined, and the tomia curved in the greater part of their outline. The form of the tip of the lower mandible is peculiar, acting with a sort of sliding motion against the hook of the upper one; and this sliding motion is in part communicated to the tooth and notch, and to all the irregularities in the lines of the tomia. The action of the mandibles is, in consequence of this form, compounded of the direct cut of a chisel and the drawn cut of a knife. We shall find the same sort of action, partially at least, in some of those sea birds which live much upon floating carcasses, though in these it is a simple slide at the tip, without any notch or tooth.

This is not so much a killing beak, as a tearing one; and it answers in the economy of the bird, to the tearing grinders in carnivorous mammalia, the claws performing the operation of killing in the falcons, just as the canine teeth do in those. It is not suited for thrusting or striking; and therefore it is not so formidable as a weapon as some of the straight bills; but it takes a very firm hold; and there is no soft part of an animal which it will not divide with the greatest ease. It is also well formed for pulling feathers; and by means of it the falcon can deplume her game, as neatly, and with as little injury to the flesh, as the most expert poulterer. It can also cut open the birds, divide the tendons and ligaments, and when scarcity of prey renders economy necessary, it can separate all the joints, and leave not an atom of eatable matter on the bones.

In proportion as the different species of falcons and hawks have the bill approaching to this typical one, they are preyers on the wing, and consequently preyers upon birds, killing their own game, and eating it in the recent state. In proportion, too, as they have this structure of the beak more perfect, they fly at "higher game," or birds of more powerful wing. The plumage of these is more firmly set, and the tendons and even the muscles are much tougher than in birds of lower flight; and besides, the low-flying hawks, harriers, and buzzards, strike prey upon the ground; and prey upon small mammalia, or occasionally take a mess of carrion or garbage.

It is thus not without some shadow of reason that the high flying falcons were called "noble," and the low-flying ones "ignoble;" for there is a sublimity in their style of hawking, as compared with that of the others. They are the genuine birds of prey; for though they descend to the earth to strip and eat their game, their preying is, in a state of nature, confined to the air, the appropriate region of birds.

The peregrine falcon is probably next to the jer; but the gradation in the beak is not very strongly marked among the high-flyers; for the smaller ones, such as the merlin and the sparrow-hawk, have it very beautifully formed, better adapted certainly for dividing and tearing flesh than any instrument of human contrivance.

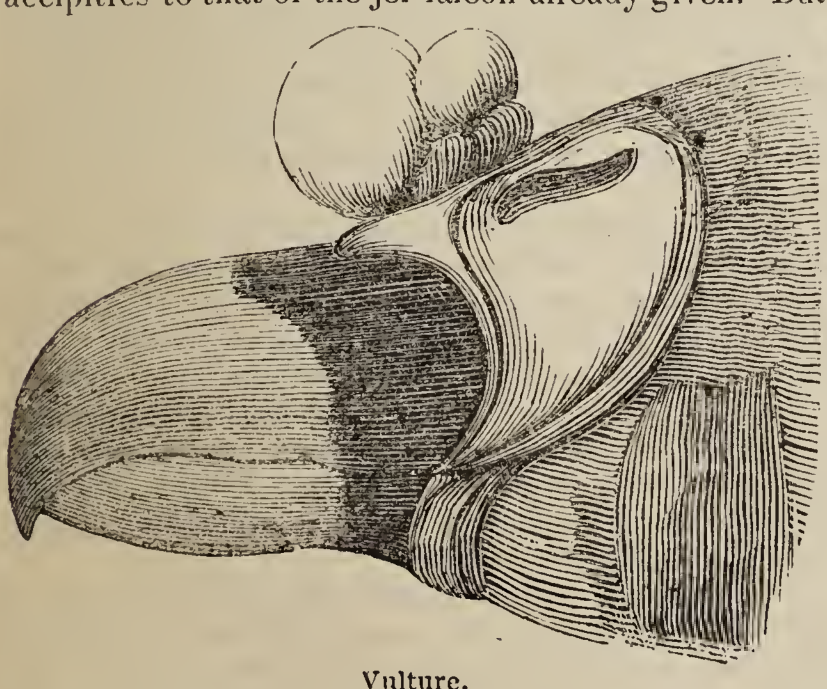
Through the low flighted hawks there is a gradual departure from the model of the jer falcon, till we come to the beak of the kite, which combines some of the characters of the falcons with some of those of the owls. And the feeding of the kite is of the same mixed character. It captures birds when it dares and can; but it does so chiefly on the ground, adds mice and reptiles to its mess; and although a bird of fine wing, and one of the most airy hoverers of the race, there is no dash or dignity about it.

In the eagles we have a further modification of the bill. It has no decided tooth in any of them, neither is it so strongly formed in proportion to its size as in the high-flying falcons, even in the most powerful of the race; and in the fishers, the outlines of the tomia are nearly even. New characters present themselves in this division of the order; they do not contend with their prey in the air and on the wing, and they feed more upon mammalia than the hawks, though they also make great havoc among the larger ground birds. We shall, however, be better able to understand those differences when we come to consider the feet and wings.

The beaks of the vultures are much feebler than those of any of the species already noticed. Instead of the arched outline, which, though it gets flattened in the others from the falcon downwards, is nearly an unbroken curve from the tip of the beak to the posterior part of the skull, the vultures have a depression at the base of the bill, and another in the middle in some of the species. The bill is also much longer and also wider in proportion to its height, and the cutting edges of the tomia are in all the species nearly, and in some of them completely plain; and it is without the sliding action at the points of the mandibles. Thus it can grasp a larger portion of substance than the beak of the falcon; but it can separate that only by simple pressure of the mandibles against each other; and, independently of its being without the sliding or tearing motions, the mandibles are neither so stiff for pressure nor moved by such powerful muscles as those of the other diurnal birds of prey.

From their mode of feeding, and the substances on which they feed, vultures do not gain from the velocity of the points of their long mandibles that which they lose in power from the diminished strength. In birds, and in animals generally which snap, the velocity makes up for the loss of power; and though the greyhound cannot hold fast like the bull-dog, his momentary bite is sharper. It is the same with many of the long-billed birds; but the vultures are gnawers and not snappers; and they are not so able to divide recent flesh as the other diurnal accipitres. Therefore, their chief food is carrion, or the bodies of animals which have become tender by the progress of putrefaction.

The annexed sketch of the beak of the vulture may be regarded as the opposite extreme in the diurnal accipitres to that of the jer falcon already given. But



Vulture.

the vultures do not lead by a natural gradation from the more typical diurnal preyers to the nocturnal ones. They point to another portion, or rather to two other portions of the class. In the forms of their bills they have some approximation both to certain species of the gallinaceous birds, and to certain tribes of that division of Cuvier's great order, Passeres, which, for want of a better name, we shall call omnivorous; and it is not a little remarkable that, like the gallinaceous birds, they have naked skin upon the head and neck, and that skin *blooms* in the season as in these.

The nocturnal birds of prey have the bill more slender than the day-feeders, generally much hooked from the base, compressed, sharp at the tips of both mandibles, smooth in the outlines of the tomia, and without tooth or notch. It takes up the connexion with the bills of the diurnal feeders rather from one of the characters of that of the kites, than from those of the vultures, which, in their general structure, may be considered as the lowest in the diurnal division; and this might be expected, as the nocturnal feeders—the owls—are not feeders on carrion, but in general kill their own game, chiefly mice, and other small mammalia, which have been mentioned as forming, in part, the food of the kites.

But, though such is the general food of the majority of the owls, and though they have the habit of wounding and disabling such prey by the snap of the bill, as well as by the clutch of the talons, there are some of the more powerful species which have different habits, and the bill differently formed, to agree with those habits. These are chiefly inhabitants of the north, and in certain states of the weather they come abroad in the dim twilight sort of day, which, at some seasons and in some states of the weather, obtains in those dreary and inhospitable climes. Mammalia are the general prey of those more powerful owls upon such occasions; but it is said that they also attack and despatch birds, especially when these are exhausted and overcome by the violence of the weather. They have been described as giving chace on the wing, but it has not been said that they kill prey in the air; and indeed, the muffled feathers and soft flight of owls do not fit them very well for such an office. They are popularly called "eagle owls;" and if there is any propriety in the name, they should kill their prey on the ground, though they may seek for and in so far follow it in the air.

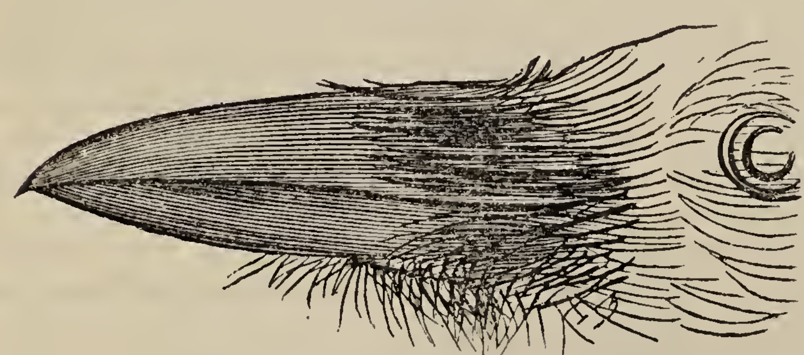
In proportion as the birds of this order depart from the type of the jer falcon, they seem to be incapable of depluming their prey, or depriving it of its indigestible covering, or taking the flesh from the bones. In proportion as they are thus incapacitated, they take the indigestible parts of the food into the stomach. But these do not pass the pylorus into the intestinal canal. They remain in the stomach till all the parts fit for the nourishment of the birds are separated, and then they are discharged by the mouth in sapless balls, called "castings," or quids. The species which have this habit cannot, of course, feed upon animals of any considerable size—not larger than they can swallow, because they cannot masticate; and though an owl can separate the viscera of its prey, it is not capable of disjointing the bones even of a mouse.

We have entered somewhat more into details respecting the bills of this order of birds than we shall be able to do with those of the remaining orders; but they are not only well marked in their structure and habits, they are also in no small degree the typical members from which a general notion of the class can be best formed.

Omnivorous bills.—In the order of Cuvier's classification, an outline of which has been given in a former section, the bills of the *dentirostres* should follow those of the birds of prey; but though these have generally a notch in the upper mandible, and often in the under one, none of them has the bill suited for tearing the recent flesh of warm-blooded animals, as in the falcons, and their claws are so formed as to be organs of motion and support, and not killing instruments. Their general habit, if birds which are so diversified in their appearances, powers, haunts, and manners, can be said to have a general habit, is that of feeding upon insects and their larvæ, in what may be called the "free state;" that is, when they are so situated as the birds have not to hawk for them on the wing, or to dig them out of the earth, the bark of trees, or other places of concealment.

The bills, in order to accord with that general habit, do not require the firm texture and powerful action of those of the accipitres. As many of them have to seize their prey quickly, as they often catch it while it is on the wing, though they do not fly after it, rapidity of motion, both in darting at the food, and in opening and shutting, with firmness and sharpness at the tip, are the requisites of such a bill; and lightness in its general structure is essential to the quick motion. Hence, these bills are, in very many of the species, so thin and weak that they are not able to break the coat of a vegetable seed between the edges of the tomia, and their owners are called *soft-billed* birds. If an arrangement were to be attempted from the bill, as adapted to a certain species of food, the insectivorous birds would have to be taken from several orders, because the feet and wings vary with the manner in which the birds get at their food.

The *omnivorous* bills, and even many of those of the birds that live much upon seeds,—the *conirostres* of Cuvier, have considerably more resemblance to those of birds of prey than the dentirostres. They vary much, as might be supposed in birds which inhabit so many places; but perhaps the most typical of the whole, and the one which takes up the connexions most closely and naturally from the vultures, is the bill of the raven, a resemblance to which may again be traced through many genera.



Raven.

This structure of bill is intermediate between those of the vultures which feed principally upon carrion, and the woodpeckers and analogous races which obtain their food (chiefly insects and larvæ) by digging or thrusting into cracks in the bark of trees, and fissures of rocks. It is inclining to straight, and can inflict a severe wound by thrusting; it is ridged and arched in the culmen, and firm in the tomia, so that it can cut by the pressure of the mandibles; it is a little hooked at the tip, and waved in the tomia, so that it can keep a firm hold, while the owner tugs and tears by the motions of the neck; and as it is long, the snap of the point is very sharp from the rapidity of the motion. It is, in short, a very serviceable bill—a bill of all work, as it were; and when properly examined, it is found to answer well with the omnivorous habit of the owner.

And the raven, though not very numerous in any place, and though dwelling in solitude, pairing for life, and not being very prolific (as is the case with most birds of prey), is one of the most generally distributed of birds. Almost every other species has some country which it can claim to a very considerable extent as its own; and even though it is migrant, and passes the different seasons in places some thousands of miles asunder, it returns with the season, not only to the same latitude, and to the same land, but often to the very same spot. The raven is no migrant, except in shifting a little with the seasons as the supply of food varies, but never quitting the same district; and yet there is no country in which the raven is not found native. The margin of the desert, of the jungle, or of the forest, in the hottest climates,—the heights of alternate cliff and copse in temperate climates, or the rocks and heaths, and even the lichen-clad margins of the inhabited earth near the poles, are all equally the abodes of the raven; and let the sun blaze, the wind blow, the rain pelt, or the snow drive, with ever so much intensity, his dusky wing or firmly set foot is in its element, and the wreck of the rest of nature is with him the season of plenty.

The raven is thus an exceedingly typical bird; and from the numerous and varied habits, and structures in accordance with those habits, which are combined in him, he is what may be called a sort of central type, in which the characters of many other races may be found, though rudimental, or at least partially concealing each other. Those characters are also chiefly combined in the bill of the raven; though in his feet he approaches the vultures, and in his wings partially the low-flying hawks.

In tracing the gradation from the raven through the analogous races, we find that the bill gets less and less powerful in those characters in which it most resembles those of the vultures, namely, its adaptation for tugging and tearing the flesh of animals from the bones. But the raven is also a preyer. He rarely, though sometimes, hawks on the wing, and when he does so, he strikes with the bill, not with the claws; but he preys much on the ground, on young birds, the smaller mammalia, and even the larger ones when disease or casualty brings them within his reach.

Of the others, the carrion crow most resembles the raven; but its bill is neither so formidable as an instrument of slaughter, nor so capable of tearing the flesh of recent prey. The culmen of the upper mandible is not so much arched, nor the tip so much hooked, and consequently the bill can neither cut so well nor hold so firmly. This bird accordingly eats large animals, chiefly in the state of carrion; and finds much of his food in the eggs and callow young of the ground gallinidæ.

The other crows, on to the rook, have the bill more and more approximating to straightness; and in that bird we have certainly an approximation to the ground birds which feed upon seeds; and different as they are in their appearance, and many of their habits, there is a correspondence in nature between the rook and the skylark, which brings them to the same field for their food.

The bill of the raven and crow, is continued through the magpies, the rollers, and several other birds, which differ more and more in the other parts of their structure and in their habits, till we come to those races which are more and more tree birds, and when they become chiefly so, have a considerable part of their character in the feet.

There is still another division that may be traced from the crow tribe, and the portion of the character of the bill which they carry along from the raven, is that of snapping with the mandibles. We find this rudimentally in the jackdaw, a little more developed in the chough, and so on till we come to those birds which catch insects upon the wing ; and here again we find a subdivision : one race having the toes united, and terminating in the bee-eaters, and other tribes with bills very long, sharp at the points, slightly arched, not very heavy, but beautifully formed for possessing the maximum of effective strength and ready motion. The other subdivision leads to the swallow tribe, in which the bill is not so much an instrument of death as of capture ; and they, as well as the former subdivision, are dependent on the air for the chief part of their food ; and, as might naturally be supposed, have their proper characteristic in the organs of flight.

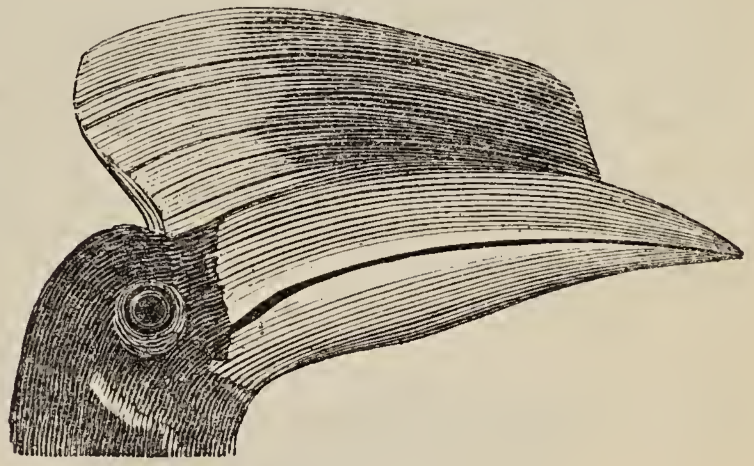
To trace out these connections with all that minuteness which they would require, in order to see clearly the resemblances and differences of birds, as depending on the nature of their food and their organisation for capturing it, would far exceed the limits to which this sketch is restricted. But the hints which have been thrown out may serve to call the attention of observant readers to this very instructive part of the subject ; and if such shall be the case, the object of what has been said will be, in a great measure, accomplished ; and that object, if we are to allow that the great business of human life, is pleasurable enjoyment—is one of far greater importance than those who have not reflected on it are aware of. Birds are always about us, in a state of nature, go almost where we will ; and the greater part of them, instead of seeking safety by escape from our view, as is the case with all those animals which cannot fly, and which are not too formidable or too repulsive to prejudice for our remaining to examine them, seek it by rising and spreading themselves out, as it were, for our examination in the free atmosphere. Hence, when we are abroad, be it for pleasure, for health, or for business (and the journeying time is, in so far as the last of these at least is concerned, so much time lost), the birds are an ever-open book, in which every one may read as he walks or rides ; and thus turn to a means of acquiring the most useful knowledge those hours which to them who have not this habit are not only utterly lost, but which are even painful in the passing.

There is in this last circumstance, and it is one the pain of which is felt by every one who is not absolutely seared to indifference, a most useful lesson. If we throw idly away those portions of time which we cannot employ in our ordinary business, they fail not in galling us for the neglect, and if we persevere in the idle habit till it ceases to be galling, the mind is thereby so unnerved and broken down that, if we do not seek ruinous escape in dissipation, we become unfit for those very avocations, our eagerness for success in which is the cause why we neglect that nature which should afford employment to our minds in the necessary pauses.

It is worthy of remark and remembrance that, in all those revivals in which nations have come back from a state of listlessness and decline to vigorous action and improvement, the study of natural history has always formed an early and a prominent part ; and that, in all the fallings-off, that study has been among the first to be neglected. As it is with nations, so it must be with individuals ; for the one is merely the sum of the other, and the sum can be nothing but equal to the individual parts of which it is made up, either in quality or in quantity. But to return to our more immediate subject.

Many of the foreign species of omnivorous birds differ greatly in their bills, as well as in their general appearance, from those which are met with in the British islands. The most remarkable of these are chiefly inhabitants of warm countries ; and the hornbills (*Buceros*) and birds of Paradise (*Paradisea*) may perhaps be regarded as the two extremes, at least in peculiarity of structure.

The following figure of the bill of one of the hornbills of India and the Oriental Isles, will give some notion of the form of this singular organ.



Hornbill.

The bills of the other species differ from that of this one chiefly in the form of the horny enlargement on the base of the upper mandible ; but as that is not developed, or at least does not attain its full size till the birds arrive at maturity, which takes three or four years ; and as it is not nearly as much developed in the females as in the males, it is subject to so many variations in the same species, that it can hardly be depended on as a character. From the figure it will be seen that the true bill of these birds has not the robust thrusting form of the bill of the raven, but more resembles that of the chough ; and notwithstanding its formidable outline it is feebler than even that.

The basal enlargement is cellular, and all parts of the bill are comparatively weak. The mandibles are also more or less notched or serrated along the whole of their cutting edges. This bill, if we except the horny enlargement, the use of which in the economy of the bird is not known, approaches to those of the toucans and other enlarged billed climbing birds of the tropical forests, only in these the upper mandible is much more enlarged, instead of having the enlargement in an appendage. Leaving the appendage out of consideration, the bills which those of these birds resemble most nearly are those of the aracari, only it will be seen on referring to the figure that the aracari has the better formed bill of the two.

Still, however, there is so much resemblance between them as to lead to a presumed correspondence in the habits of the birds, though their feet indicate a different haunt. Both genera eat carrion, eggs, insects, and occasionally vegetable substances; and both are rather indolent and lurking birds in their general habit. The toes of the aracari are yoked, so that it is a branch bird, inhabiting living trees, among which it jerks about something in the manner of the jay. The hornbills have the toes free, like the rest of the omnivorous birds; and though most of them can perch readily and firmly, they prefer perching on dead branches to those which are covered with foliage. When on the ground they do not walk, but hop as magpies do.

A bill of this form cannot be efficient against any very powerful animal, because its great size and length, and light structure, render it impossible to close the mandibles with much force, though the bill may snap at small objects with much less labour on the part of the bird than if it had been of stronger texture. These birds connect the omnivorous races pretty closely with the insect feeders; for though they all eat carrion when it can be procured, the various insects which breed in and consume rotten wood in the tropical forests appear to form the chief subsistence of those hornbills which are more exclusively forest birds; while those which feed more on the ground pick up ground beetles, which are also numerous in those localities. The serrated margins and snapping motion of those large but lightly formed bills are sufficient so to crush an insect as that it can be advantageously taken into the stomach; and when they have recourse to carrion they seem to be equally attracted by the putrefying animal matter, and the larvæ with which it is inhabited.

The other extreme, birds of Paradise and analogous genera, as may be seen by the figure, have bills smaller and firmer, and approximating more to those

Paradise Pie.

of the gallinidæ; and though they are understood to feed less exclusively on the ground than any species of that order, yet their food bears no inconsiderable resemblance; and it is not unworthy of remark, that the native localities of the more remarkable of the perching gallinidæ and the birds of Paradise border with each other in their native localities, as the peacock in India, the Argus pheasant in Sumatra and Java, and the birds of Paradise in the isles immediately to the south and east.

To explain, or even to enumerate, all the varieties in the bills of those omnivorous tribes, and the differences of food and haunt which those indicate, would be incompatible with the nature of a general sketch; but the subject once entered on, is one of very easy study; and there is scarcely any tribe, at least of land birds, traces of resemblance to which may not be found in one species or other of the omnivorous race. Still, however, there is a definite character in the bills of the whole, and that of the raven is not completely lost even in the hornbill or the bird of Paradise.

The whole race are also what is usually termed "foul feeders." Their voices are harsh, but, generally speaking, they are capable of being taught to articulate. They are also familiar birds, and not difficult to be tamed, partly, perhaps, from their indolent habits, and partly from their voracity. Generally speaking, they are prying and hopping creatures; and when they seize living prey, they jump at and stab, or snap it with the bill. Altogether, they are a serviceable race, and their labours tend much to preserve vegetation both in field and in forest in places where they are numerous.

Bills of the Conirostres.—These form the first natural division which we can trace from the omnivorous bill of the raven, upon that part of its compound character which relates to the action of the mandibles against each other by pressure in the simple division of hard substances. Bills of this description are without any notch or tooth; and they are always of firm texture, on which account the small birds that have them are often styled *hard-billed* birds, in contradistinction from the insect feeders, which have the bill with a tooth or notch, but of comparatively slender structure.

Birds having bills of this description vary much in their structure and habits; but generally speaking, they may be considered as more peculiarly birds of temperate and even cold climates. This is what might be expected. In tropical countries, the vegetation of trees may be said to be constant, and the ground vegetation is in a great measure propagated by bulbs, or, at all events, the seeds of herbaceous plants do not strew the ground there either so numerously, or for such a length of time, as they do in regions where the winter is more decided. There is thus not much food for, at least the ground species of the Conirostres, in tropical climates, and where they are found, they are not so migratory in their habits as the soft-billed birds. In such climates as that of England, their grand feeding time is in winter, because the fields are covered with seeds, which are softened and sweetened by the action of the weather, but have not begun to sprout; and perhaps there is no race of wild animals so serviceable to cultivation in such climates as these birds. They come in vast crowds, and clear the stubble field of the seeds of weeds, which, if they were to spring up, as of course they would do, if not gathered by the birds, would completely choke the crops in the following season.

The bills of all these birds are thick and strong, enlarged at the base, sharp at the tip, and the mandibles are often fortified by a margin, which, acting upon the tough rinds of seeds, bursts them, and extracts the farinaceous part, which is much more readily and effectually done by the flat grinding margins of the bill than it would be by sharp edges. The different effect of these two kinds of form in effecting this purpose may be perceived by any one who tries to crack a nut with a pair of scissors, and another with a pair of nut-crackers of the same lever-power.

The birds which have those bills do not feed exclusively, or at all times, upon seeds. Indeed, it will readily be understood, that at those very times when these birds stand most in need of food, that is, while they are preparing their nests and rearing their broods, the supply of seeds for them is very limited compared with what it is in winter. The groundsels, and various other wild plants, keep flowering and producing seeds with little interruption all the year round; but the supply from these, even where farming is conducted in the most slovenly manner, would not support the tenth of those flocks which feed on the fields in winter. Accordingly, though there are a few tribes which eat the seeds of those plants, these form but a small portion of the whole, and there are very few genera which are not, to some extent or other, animal in their feeding during the nesting time. It is worthy of observation, too, that at that season they disperse over the breadth of the country, so that more than the pair, or the family, when these grow up, are seldom seen together, or in anywise associated, even though the same species should collect in thousands during winter. This is a wise provision in nature; for the birds crowd to the fields at the very time when their presence there is most useful; and again, when their individual labours are more immediately required in reducing the numbers of insects and worms, they are distributed over the country.

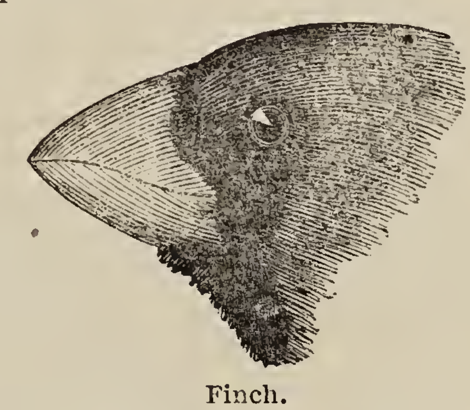
The bills of those birds are familiarly exemplified in that of the common house sparrow, which may be considered as about the average. As is the case in the birds of prey, the smallest bills in this order or division are often the most efficient. The tits are perhaps those which, among our native birds, connect the conirostres most immediately with the feeders on tree insects, or rather, perhaps, with the omnivorous tribes, and they are equally remarkable for the smallness and the efficiency of their bills. The bottle tit (*Parus longicaudatus*) has the bill so very short, that it barely appears beyond the produced feathers at the base; yet this minute bill is one of the most active, hardy, and efficient little instruments in the whole animal economy. It can bite sharply and hold firmly, and there are few birds which construct more elaborately beautiful nests. Though on a very small scale, the bill of this interesting little bird is a perfect model, the maximum of usefulness with the minimum of matter. The bills of the other species of the genus are all finely formed, though none of them are quite equal to this one.

The bills of this genus partake a little of the characters of those of some of Cuvier's *tenuirostres*, though they are capable of performing more severe labour than most of these. They do not break the hard crusts of seeds by squeezing them between the mandibles, but rather hew them asunder by strokes of the bill, and in the same way they dig into the folds of buds and the crevices of bark for the larvæ and the eggs of insects; nor have they any aversion to carrion when it comes in their way.

The bearded reed bird, which has generally been described as one of the genus *P. arus*, has the bill intermediate between those of that genus and the finches and linnets. It is stout in proportion to its size, but it is slightly curved in the upper mandible, and thus it is a bruising bill rather than a thrusting one. The habits of the bird correspond. It lives in reeds over the marshes, the seeds of which are not so hard in the coats as the seeds of plants on dry ground.

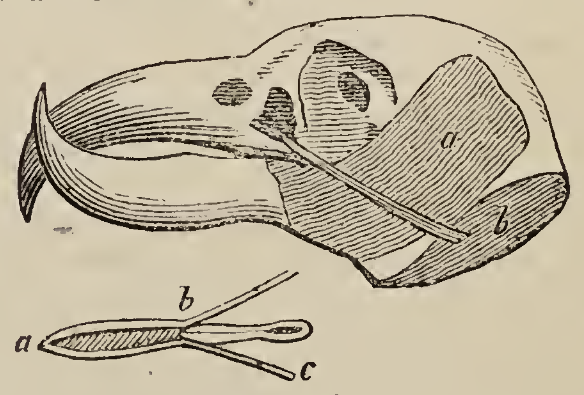
The larks may be regarded as more directly connecting the conical-billed birds with the insectivorous ones; and they have so many points of resemblance to the pipits, which are insectivorous, that these used to be included in the same genus. The buntings stand in nearly the same relation to the larks that the bearded reed bird does to the tits, one of them at least is a reed bird, and they are all more vegetable in their feeding than the larks.

The finches and linnets have the bill the most perfectly conical; and they are thus the most typical birds of the order. They are vegetable, or nearly so, in their feeding, at all seasons. Extending over a great range in latitude, and inhabiting places very different in their vegetation, from the dense forest to the bushless waste, they feed very indiscriminately on the seeds of trees and herbaceous plants, and often the thick tunics of wintering buds. Their bills are simply bruising bills, though they vary in form, size, and strength, according to the food of the birds. In general, however, the mandibles are of equal length, and very sharp at the tips. The following is the general type.



Finch.

The crossbills form a very curious exception to the bills of this order of birds, as will be seen in the following figure of the common crossbill (*Loxia curvirostra*), which is of the natural size, and taken from a dissection by Mr. Yarrel, to whom we are indebted for the original and the best account of this curious organ, and the mode of its action.



Crossbill.

Figure 1, is a profile of the bill, with the skull and the principal muscles. The one marked *a*, and situated in the posterior part of the skull, is articulated behind the centre of motion in the articulation of the jaw; and the one marked *b*, extends before it as far forward as the gape; but these are assisted by other muscles.

Figure 2 is an outline of the tongue, which is as curious as the other parts of this feeding apparatus.

It will be seen that both mandibles have a double curvature; the upper one is curved downwards and the lower one upwards, and the one curves to the right and the other to the left, so that the points cross each other; and Mr. Yarrel found them to be about three-eighths of an inch apart when the bill was closed at the basal part. In the figure the upper mandible curves to the right and the under one to the left; but that arrangement is reversed in many of the specimens. The side to which the mandibles turn is thus not a specific character of the bird.

The upper mandible is united to the frontal bone of the skull by plates of bone which are a little flexible, so that that mandible has a little lateral motion. This agrees with that very general law in the animal economy, in virtue of which every part which is subject to violent motion or pressure is always so formed as to give a little, by which means a sudden strain upon the moving part is not so forcibly propagated to the rest of the body; but beyond this limited motion, the base of the upper mandible is very strongly supported. The lower jaw, the sides of which are deep and strong, and the coronoid process near the middle of their length, is so much elevated as to give them all the stiffness of triangles, is articulated by concave sockets upon spherical processes on the *os quadratum*, and thus they admit of lateral and oblique as well as vertical motion in that mandible. The pterygoid processes of the upper jaw are very long, and the pterygoid muscles correspondingly large; and when the jaws are fully closed, that is, when the coronoid process on each side is brought into contact with the pterygoid on the same, the mandibles are crossed to the full extent. The muscles of that side of the head to which the lower mandible curves, are larger than those of the other side, so that their action has a tendency to draw the mandible toward that side; but as the closing muscles, which have their insertion before the centre of motion, pull the mandible to that side, the opening ones, which are inserted behind that centre, pull it to the other; and thus the parts come in contact when the bill is opened. The action of the bill thus resembles that of a wedge, by the mandibles sliding upon each other, and thrusting the points asunder at once with great force and great firmness.

Before stating how this bill is used, we must advert to the tongue, which is an important part of the whole organ. Fig. 2, on the cut is an outline of the upper side. A portion of the tip from *a* to *b* is in the form of a scoop, raised at the sides, and thin and rounded at the extremity. This scoop is composed of horn, supported by a particular bone, which is articulated to the os hyoides or common bone of the tongue *c c*, at the point *b*; and one set of muscles bind the joint at *b*, and thereby depress the point of the scoop, and draw it backwards; while another extend the joint, and project and elevate the scoop. The tongue has thus what may be called a sort of elbow joint, and the scoop performs the office of a sort of l and in picking up those substances to which access is procured by the oblique motion of the mandibles. The bill thus performs the functions of two bills; and one of them could not performed by a bill of any other construction.

The way in which the points of the mandibles move, draws them into any substance of which they can take hold. If that substance is of a texture not to be cut by the points, they split it open by their wedge-like action; and if it is a softer substance, they at the same time cut it in the cross direction. Whatever may be the depth of the opening, the eye also sees to the bottom of it, and the scoop of the tongue can reach it. The upper mandible is the part of the bill at rest, and therefore to whichever side it bends, the head is bent to the other, and the eye on it commands all the space, which the point of the under mandible pushes open, from the contact to the greatest extent in crossing.

Crossbills are found chiefly in the extensive pine forests of the northern latitudes, where they live upon the seeds of those trees. These seeds are contained under tough woody scales, which continue pretty close for some time after the seeds are ripe; and the chief labour of the bird is to raise these scales by the oblique motions of the bill, till the seeds can be scooped out by means of the tongue; and they do this, or even split a piece of dry wood into strips, with great rapidity. Sometimes, from causes not very well understood, as they are not regular migrants, they leave their native forests in considerable numbers, and do no small damage to orchards of apples by splitting the pulp in pieces to get at the pips.

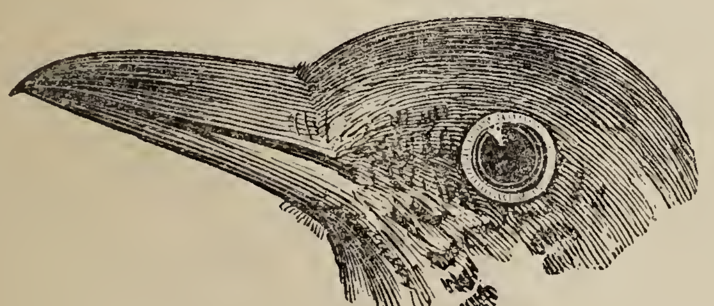
The strong muscles on the sides of the head give them something of the air of parrots; and though they are not climbers as these are, they resemble the parrot tribe a little in their plumage. One species (*Loxia pytiopsittacus*) is popularly termed the parrot crossbill. Indeed, though their habitations are in the opposite extremes of climate, and the parrots get at their food by climbing, and prepare it by cracking the rind or shell with the mandibles, while the crossbills get at theirs by flight, and raise the scales without separating the cone from the tree, yet the two families have many points of resemblance.

Insectivorous bills or *Dentirostres.* The insectivorous birds, when properly restricted, consist of those genera only which have the common normal feet with three toes before and one behind, all articulated on the same level, and thus have their more peculiar characters in the bills, or the bills and the wings. They are inhabitants of woods, copses, and bushes, those being the places where insects are most abundant, though some of them inhabit the margins of waters, and nestle in holes of rocks, or under stones. They all take their food either standing on the ground or perching on the sprays, or they dart upon it by short jerks from the ground or the perch. Their bills are accordingly all snapping bills, generally light in their structure, having the upper mandible rather longer than the under one, and notched near the tip, but not so sharp pointed or so firm in the tomia generally as the bills of vegetable feeders. The point of the bill is the prehensile part of it; and the culmen of the upper mandible is usually a little arched to support that part. In those genera which are characterised by superior boldness the bill is compressed, and the upper mandible hooked at the tip, while in the feebler ones it is rather depressed, and the tip straighter.

The shrikes, a figure of the bill of one of which is annexed, are the most daring birds of this division, and the ones which connect it most obviously with the predatory or omnivorous birds; but the resemblances are much slighter than those which can be traced between order and order in other parts of the system. The larger beetles form the principal food of the shrikes; and as many of those in the larvæ state, and some of them when perfect, are destructive to vegetation, shrikes are useful birds to the cultivator, while, as they do not eat vegetables, they do him no harm. The shrikes are, however, chiefly woodland or hedge birds, and leave the open fields for the pasture of rooks. They do not inhabit the very cold countries, as their staple food is not so abundant in these. Many of the beetles on which they feed have the elytra or wing-cases very hard, almost proof against the action of the bill, notwithstanding its strength and its notches. In these cases, the birds are understood to stick their prey upon thorns, and divide and eat it at their leisure by the strokes of the bill. It is also said that in this way they bait the hedges for the purpose of capturing the feebler insectivorous birds; but though they do sometimes kill birds by pinching their necks between the mandibles as they do beetles, these and some other habits which are attributed to them would require to be well authenticated. The bill of the shrikes can both strike and squeeze more powerfully than that of most of the division; but still it is properly an insectivorous bill.

Shrike.

The next gradation of this character of bill is in the thrush tribe, which have the middle and outer toes united, so as to form a firmer walking foot than that of the shrikes; and they are accordingly more of ground feeders. They partake more of the vegetable feeding character; inhabit colder climates, and live upon berries in the severe weather; but mollusca and worms form the principal part of their summer food. But whether animal or vegetable, these birds prefer soft food—mollusca to worms, and viscid pulpy berries to farinaceous ones or seeds. Their flesh is in consequence more sweet and juicy than that of many birds; and these qualities are increased by the small tendency they have to flight, unless when, as is the case with those that summer in the more inhospitable climates, they are obliged to migrate.



Missel Thrush.

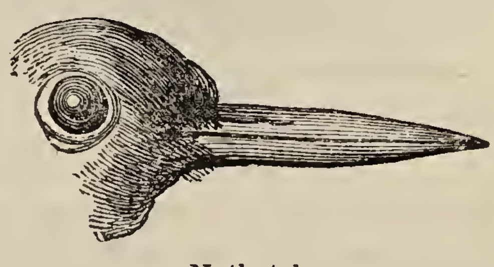
In accordance with these habits, the tomia of their bills are sharp cutting edges, as the hardest labour they have to perform in feeding is breaking the shells of snails, which they do by hewing them to pieces with the point of the bill. The preceding is the general figure of these bills.

The ant-catchers, dippers, menura, manakins, todies, fly-hunters, fly-catchers, and a number of other races, chiefly inhabiting the warmer parts of the world where insects are most abundant, follow these, varying in their bills with the nature of their principal food, and in their other organisations with their haunts and action; but all agreeing in the general structure of the bill as insectivorous, and generally having it of such consistency as that it can bruise or divide a hard crusted insect. The greater part of them also agree in residing where food is more permanently to be found, and consequently not being so much given to distant migration as many of the insectivorous races which remain yet to be noticed.

To these again succeed the chats, wagtails, chanters, warblers, and analogous genera, having the bill generally feebler, feeding on larvæ and soft insects, generally sweet singers, much affected by the vernal season, and migrating to warm climates in the winter. In them the notch in the bill is not quite so conspicuous; and in the wrens, especially the crested wrens, it approaches in some of its characters to the bills of the *Tenuirostres* of Cuvier; and in the pipits to that of the larks, though the insectivorous character is not lost even in them.

Common Wren. Robin.

Bills of the Tenuirostres. These are chiefly, though not all, insect feeders, and have their bills slender and without any notch at the tip; but they differ considerably in form with the places where the food is obtained, and in consistency with the nature of the food itself. They are bark birds, wall birds, or rock birds, yet some of them range the air for their food, and others seek it in the nectaries of flowers. The feet rather than the bill form their distinguishing character. The nuthatch, which is a



Nuthatch.

climber, has the bill straight, angular, and very strong, and it feeds much upon nuts, the shells of which it punches open with considerable activity. The tree creepers which also run on the boles of trees, and dig in the crevices of the bark for insects, have the bill of moderate length and angular, but a little curved. The wall creepers have it very long and slender, and angular only at the base. The nectar suckers have the bill weak and very slender at the tip, and the tongue extensile, tubular as a sucker, and cleft at the tip. The humming-birds have the bill in general long, and the tip of the tongue formed as a sucker; but the bill is in some of the species straight, and in others crooked. The hoopoe has the bill very long and slightly arched, and feeds on tadpoles and other produce of marshy grounds. But the bills of these birds are so unlike in their forms, and differ so much in the uses to which they are applied, that none of them can be taken as any thing approaching to an average of the whole; and indeed the character of the anisodactylic feet is not much more perfect, for in some, as in the nuthatch and creeper, it is a most efficient climbing foot, yet in others it resembles more the common foot of many of the insectivorous birds.

Bills of the Fissirostres. As all these birds use the bill, and the bill only, in the capture of their prey, and as they catch it on the wing, the bill affords a very good general character. They are all feeders upon insects, and generally capture them by speed of flight. They fly at smaller game, and capture it only with the bill; but they admit of a division into diurnal and nocturnal, something resembling that of the birds of prey. The diurnal ones are the swifts and swallows, the former the longest flighted of birds and the most unwearied on the wing. The latter soft and loose feathered, and rather clumsy in their flight, as is the case with the owls. This subdivision contains the goat-suckers and the *Podargi*, some species of which bear a resemblance to some of the owls, and have stronger bills than the rest of the family.

The bill in all of them is remarkable for the wideness of its gape, and the breadth of the mandibles at their bases; and it is sometimes provided with a viscid secretion to which the insects adhere, and at others with mustaches, in which they are caught, or at least prevented from escaping out of the mouth.

The bill of the common goat-sucker is probably the most typical of the whole, at least it is more exclusively used in preying; as the bird not only feeds in the twilight, but flies with the eyes in such a position as that they can be of little or no use.

Goat-sucker.

Bills of the Syndactyli.—The bills of the syndactylous birds also differ considerably in their forms, because the food differs in kind; and there is no doubt that it was on account of this difference of the food that Cuvier named this division after the structure of the feet, and not that of the bills, for the kind of food is the principal ground of his arrangement. But in the case of birds the kind of food is not so descriptive of the whole character as in the mammalia, because the form of the bill depends also upon the manner in which the food is arrived at.

In the birds which should properly belong to this division, the prey is arrived at on the wings, though Cuvier, from having taken the united toes as the general character, has included in it the hornbills, which, in some of the species at least, are as truly omnivorous as the crows, feeding on carrion, and of course feeding on the ground, not on the wing.

Leaving these out, there remain four genera, all of which have the bill long, and catch their prey by the snap, or quick compression of the mandibles against each other. The bee-eaters (*merops*) have the bill rather long, tapering to the point, slightly curved in its whole length, and sharp in the cutting edges. That of the motmots (*prionites*), which, in some respects, answer in America to the bee-eaters of the eastern continent, is much stouter, having a considerable resemblance to the bill of hornbills, though without the enlargement at the base of the upper mandible, by which the bills of that genus are distinguished. The bill of the motmot is serrated in both mandibles, and the tongue is barbed or feathered like that of the toucans. Indeed, it should seem that this genus, as well as the former, ought to be included among the omnivorous birds, notwithstanding the syndactylic feet; the feet of birds in this division come so little into play in those which really belong to it, that they are hardly of sufficient importance for being made the ground of classification. Besides, these birds kill other little birds, either by gnawing them between the serrated edges of the mandibles, or beating them against the ground. They are indeed chiefly ground birds, bad fliers, and though in great part living upon insects, they catch them upon the ground; and almost the only habits which they have in common with the typical birds of the order, are living solitary, and nestling in holes of the ground.

The kingfishers have the bill robust, quadrangular, and straight; and though it is a fishing spear rather than an insectivorous bill, it agrees with that of the bee-eaters in being used on the wing. The following figure of that of the common kingfisher of Europe will give some idea of its general form.

Kingfisher.

The remaining genera of this division, none of which are European birds, have the bill bearing a considerable resemblance to that of the kingfisher, which may be considered as the most characteristic bill.

Bills of the Scansores. These, the climbing, or *Zygodactylic* birds, have no general character in the bill which can be applied to the whole, though in the smaller grades into which the order may be divided, the bill is sufficiently characteristic of the food and manner of feeding.

The whole order are forest birds; and, with the exception of the woodpeckers, some of which inhabit the cold or the medium climates, they are all tropical birds, or birds of the warm countries; of those wild forests which have been sown by the hand of nature, and in which every tree is the very best adapted to the spot on which it grows. Every animal of these teeming climes is also produced under circumstances the most favourable to its development and subsistence; and the energies of life of all kinds, obeying that grand stimulus of material life, the sun, is in the very maximum of activity. Man is the only creature that languishes, or appears to be out of his element, not merely in his mental powers, but in his physical structure. This by the way is a proof, among many others, which the study of nature in all its varieties affords, of the existence of a spirit in man—an immaterial principle, and consequently one over which material death and dissolution have no power. For if he were wholly material, and obedient only to those physical laws to which the whole of material nature is subjected, he needs must be in the state of greatest development in those places where natural action is the most intense. It is no argument to allege that these ardent climates are not so well suited to the human constitution as those which are more temperate; for though this may be true of a native of Europe visiting those countries, it is not true of their native population. Nor can it be said that, physically, man is better adapted to the colder climates than to the warmer, but rather the reverse. Man has naturally no furry coat like the polar mammalia, nor downy feathers like the polar birds; and his only natural clothing is a sort of thatch to the head, as if more immediately to protect that portion of his fabric from the action of the vertical sun. Therefore, in as far as man can be said to be physically adapted to one climate more than another, the adaptation is to the warm rather than to the cold. But we find that the more energetic and valuable part of his character is less developed in those places where nature also is most energetic, and where he, if he were merely the produce of material nature, should, according to all the evidence that we have, be most energetic also.

But though here, as in all cases, man must be put aside as being *over* the system, not *of* it, the rest of the system in these beaming and blooming lands works vigorously and, at the same time, beautifully in concert. The birds may, in all countries, be regarded as the keys to natural history; because in consequence of their aerial nature, and their capacity of better accommodating themselves to such food as they may find when they are very hungry, they can so speedily adjust themselves to changes of season, that the adjustment is made before we are aware of the necessity for making it, as the bird is to us the harbinger of that very change in nature, of which its change of place or of action is the consequence.

There are no places to which the native birds are better keys than the tropical forests. The great majority of them—all this order, with the very few exceptions which have been noticed, are forest birds, either on the trees, or passing from tree to tree, or if they feed on the ground in the open places, not ranging on foot, as the ground birds of our latitudes do, but finding a full meal at the places where they alight.

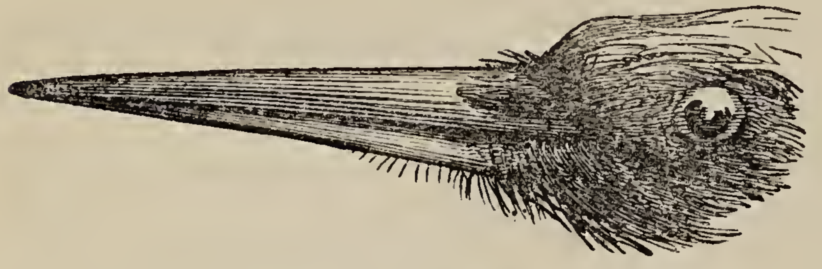
The vegetation of every region determines the character of all its living inhabitants, and though the birds, as the most sensitive to change, are the keys or indices, the vegetable tribes are the foundation of the whole, which support many of the animals immediately, and the rest indirectly through the medium of each other. There are few small farinaceous seeds in those forests; and the leaves of the trees are not so succulent and so well adapted for the food of insects as the deciduous leaves of the mean latitudes. Their average production is perhaps not so great as that of our forest trees, during the short period that they are in activity; but in all tropical countries the season of growth is double, and in many it is of more frequent occurrence, and where there is humidity enough the growth is constant. The leaves are required for shade; and as natural circumstances always produce that very organisation or structure which suits them best, the shading leaf is firm in its structure, and not liable to be gnawed and eaten like the more tender ones.

Woody substance is that which has the tendency to accumulate to excess in those forests; and, therefore, the great body of the insects there attack the wood of the trees. As these insects have much labour to perform in clearing the forests of their lumber, they exist in proportionate numbers, generally social, and in bands which no man can count. These crowd all parts of the trees, and indeed many of the spaces between them; but they are on the boles and branches, and in the decaying wood, rather than on the leaves. The winged ones, too, crowd over the trees and the flowers of those climbing plants, with which the boles are intwined and the branches interlaced. These are, however, more seasonal than the races which inhabit the trees, or rear themselves huts and towns on the ground; and therefore they do not form so large a portion of the food of the more typical scandent birds. The bee-eaters, the cuckoos, some resident and others migrant, and the warblers, and other soft-billed birds which are driven from the temperate climates as the winter sets in, are the chief consumers of this more temporary produce of the tropical forests.

The same absence of farinaceous seeds which prevents the number of ground-feeding birds from being so great in these places, also prevents the smaller seed-eating mammalia. The small mammalia there gnaw bark, and roots, and bulbs and fallen fruits. The number of insect eating reptiles is also very great. All these contribute to the food of the omnivorous races of those climbing birds; but though some of these eat eggs often and birds sometimes, the destruction of bird by bird is not so great in those forests as on the more bleak and barren portions of the earth. There is no scope there for the rush of a falcon, or the stoop of an eagle; and in the depths of the forest, the birds stand more in danger of preyers that commonly crawl, than in those which have wings or even feet. The snakes are the greatest enemies both of the birds and their eggs. Vultures are found in the openings of such forests, for places where there is so much production, and by consequence so much waste of life, require a great deal of scavengership; and where the forest "crops out," towards the mountain, there are also hawks and eagles; but in the depth of the shade, bird is in a great measure at peace with bird. Accordingly though there are some very curiously formed bills among them, there are none that can be considered as of a very murderous character, for the most formidable ones belong to those which feed on vegetable substances; and the owners are so completely tree birds that the bill is a climbing instrument, by the hooked upper mandible of which they can, if necessary, hang a considerable time without sustaining any injury.

The bills, though not admitting of typical example or description, as appropriate to the whole order, may yet be conveniently explained in groups.

The first group includes the bills of the jacamars, the woodpeckers, and the wrynecks. The bill in all these is straight, fitted for digging into the bark of trees, and extracting insects and larvæ; and though some of the birds are of considerable size, and the insects on which they feed remarkably small, yet they pick them up with wonderful celerity. The following figure will show the general character of the bill.



Green Woodpecker.

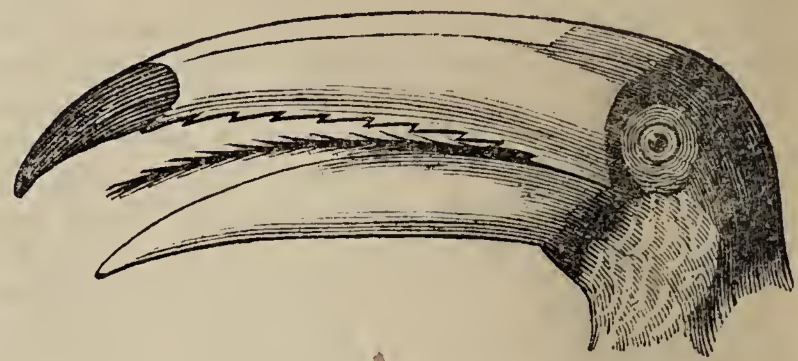
The woodpeckers have the stoutest bill and the best fitted for hewing into timber. The wrynecks as frequently pick up saw-flies and other small winged insects, which alight on the bark for the purpose of depositing their eggs; and the extent and freedom of motion in the neck are both very remarkable. The American jacamars, though they do not peck, have the bill resembling that of the common kingfisher; but their congeners of the East have it more slender, and a little arched, inclining to the form of that of the bee-eaters, and they are not so much in the habit of climbing as the others.

The cuckoos have the bill of moderate length, but differing in form and structure in the different genera of which the group is made up, as these differ considerably in their feeding and other habits. They do not dig in the bark for insects; and they inhabit the copses and open forests rather than those which are deep and tangled.

Between the cuckoos and the toucans there occur several genera with bills very much diversified in shape, and with the owners of course as miscellaneous in their feeding. In general, however, they are insectivorous, or add to these small earth animals, and sometimes the mere succulent vegetable substances. The keel-bill is named from the strong projecting ridge or keel on the culmen of the upper mandible, as one of the best known and most remarkable of these, remarkable alike for the universality of its agreement with its own species, and with all other creatures, excepting those that serve it for food, and for the miscellaneous nature of its feeding. It alights on the backs of domestic animals, and clears their coats of insects.

Of all this order, however, and indeed of all birds, with the exception perhaps of the hornbills, this instrument is most singularly formed in the toucans. There are two genera; toucans proper (*Rhamphastos*), and aracari (*Pteroglossus*), of which the systematic names are not very descriptive, as each has the character expressed by both. Each is *rhamphastos*, large bill, or, colloquially, "beaky;" and each is *pteroglossus*, winged-tongue, or feather-tongue; but the toucans have the bill largest, always exceeding the section of the head, and sometimes as large as the whole body, while the bill of the aracari is not thicker than the head. The following sketch will show the general form of the bill of the toucan.

The general substance of this vast bill is cellular, with the partitions of the cells so very thin that, large as it is, it is very light. In the living state the covering membrane is very finely coloured with prismatic reflections, but these soon fade after death. The rudely serrated edges are a little firmer than the other parts, but still they could not injure any but a very soft animal.



Toucan.

The tongue is stiff and cartilaginous toward the point, and for some distance pectinated on each side with stiff cartilaginous fibres, which give it something the appearance of a feather.

From its structure we may readily conclude that a bill of this description can be little more than a prehensile instrument, unfit for breaking a hard substance, or cutting a tough one. It seems, indeed, to be a sort of mortar, in which soft substances are in so far pounded by the action of the curious tongue, as that they can be swallowed. Insects, probably the naked and the more tender shelled mollusca, and the eggs and callow young of little birds, are the food of these birds; in search of which they hop about the trees, and though their wings are rather short, they fly tolerably well. The two genera are not very different in their food, or in their other habits; but besides the difference in the size of the bills, there is a remarkable difference in colour, which runs through all the species. The prevailing character of the true toucans is black, relieved with brighter tints on the throat, breast, and rump; that of the aracari is generally green, relieved on the same parts with red or yellow.

Though they belong to different orders as well as to different parts of the world, there are some resemblances between the hornbills and the toucans; and the one family of birds perform in the one continent nearly the same office which the others perform in the other. We have a similar instance, with something approaching to the same difference of character, in the *merops* of the eastern continent, and the *prionites* of the western. Indeed, in all cases in which the birds, or other animals of tropical America and the tropical parts of Asia and Africa can come into comparison, we find that those of the former part of the world indicate forests more close and tangled but less abundant in fruits than those of the latter.

Of all the climbing or zygodactylic birds, the parrot tribe, in their several divisions of maccaws, parrots, paroquets, and cockatoos, are the most typical, the most exclusively inhabitants of trees, and the least frequently found upon the ground. The species are very numerous, and the individuals are, in such places as are very favourable to their habits, in incredible flocks. They are all vegetable chiefly in their feeding, but some subsist more on the kernels of those forest trees which have hard membranous or shelly coverings, and others subsist on the pulp of fruits, rejecting the kernels or pips. But whatever may be the nature of their food, there is a general character of the bill which runs through the whole tribe; and, though those which feed more upon pulpy fruits have the bill more enlarged in its cross dimensions than the others, yet the figure of one bill is a very good index to the whole—better than in any other tribe of birds at once so numerous and so varied.

This tribe are more peculiarly characteristic of the tropical forests than any other of the feathered races; because, though they are often found flying over the open places between clump and clump of the forests, and shifting from place to place as they exhaust the supply of food, they are more in the trees, and, feeling the perfection of their climbing powers, are less apt to take wing on being observed, than any race which inhabits the same places. They are constantly in motion, except when they seek their repose, which is usually in the islets of rivers, or other places which are not easily accessible, and they resort there in numbers; and when they are in motion they are abundantly clamorous. Their natural voices are harsh, but they are easily taught to whistle, to articulate, and to imitate very varied sounds.

It is not owing to the form of the bill or the tongue that parrots or any other birds articulate, because their organ of voice is at the lower or pulmonary end of the windpipe, and not at the larynx or upper end. But their powers of articulation are sometimes really wonderful: the coincidences between the questions put to them and the answers which they return, must in all cases be regarded as purely accidental; and they claim their appearance of understanding, just as the predictions of pretended seers do their supposed knowledge of the future, from the fact that the ninety nine cases in which there is no coincidence are forgotten, while the one case out of the hundred in which the answer agrees with the question is remembered and repeated.

The disposition which these birds have to imitate sounds, not only different from their own hoarse cries in their native forests, but from any which they can hear there, are, however, indications of a very curious instinct, but of one which, as is the case with all instincts, it is vain to hope for an explanation upon the principles of reason.

The leading uses of the parrot's bill are, breaking hard vegetable substances, and climbing. A pair of nutcrackers is the nearest comparison to it in artificial instruments, but the bill is beyond all comparison the more universal and effective. This bill does not snap or acquire any force of momentum before it comes in contact with the substance to be acted on. It works wholly by pressure; but the pressure is accompanied by a sliding motion, which differs with the degree of exertion. The lower mandible is raised by very powerful muscles, and it is at the same time pushed a little forwards; the upper mandible has much less motion than the lower, but still it has more than in most birds; and when the bill is exerted with great force, it has a motion downwards and backwards at the same time. The substance acted on is thus wrenched round at the same time that it is pressed by the cutting edges of the mandibles; and every one who has attended to the subject, knows how very much a cutting operation is strengthened by accompanying it with a wrenching one.

The muscles which move the mandibles are very powerful, and give that peculiar fulness which appears in all the cheeks of the tribe; and the motion of the upper mandible, limited as it is in space, brings the whole of them into action. It is these compound motions of the working parts of animals, which enable them to act with so much less exertion than our mechanical contrivances; and taking time and effect both into the estimate, there is no tool by means of which the shell of a hard nut could be broken, without the expending of far more than double the power which is expended by a parrot. The tongue is of considerable use in guiding the substance to the most effective part of the mandibles; and even the motions of the neck are of service in breaking detached substances, as well as in detaching fast ones.

Very hard substances are broken between the point of the under mandible and the hook of the upper one, the lower side of which is slightly hollowed and roughened like a mill-stone by means of angular furrows, with their apices directed towards the tip.

The bills of the falcon, the crossbill, and the parrot, may be reckoned the three most powerful bills in the action of the mandibles that occur in the whole class, and as their action is wholly structural, not deriving any assistance from momentum, they may be reckoned the three most perfect species of mechanism—the first, for tearing; the second, for wrenching open; and the third, for breaking and bruising; and all of them are so formed as to have compound motions.

There are several tolerably distinct forms of bill in this very numerous and abundant family. The parroquets, which fly much from branch to branch in search of their food, have the bill smaller than the others, not exceeding one-third the length of the head, and not very broad; but it is very firm in its texture, and perhaps proportionably the most powerful of any. The parrots, properly so called, which are the most scandent, have it half the length of the head, and very thick and strong. The cockatoos, which inhabit more marshy places, and live upon softer food than the others, have the bill feebler. The maccaws, which use the wing more than any of the others, and find much of their food on the tops of forest trees, have the bill large, as long as the head, and very sharp. When birds feed wholly or partially on the wing, the bill is generally larger in proportion as the food is smaller. The ground parrots, which are better walkers than the rest, have the bill large, but the food appears to be, in part at least, taken by the tongue,

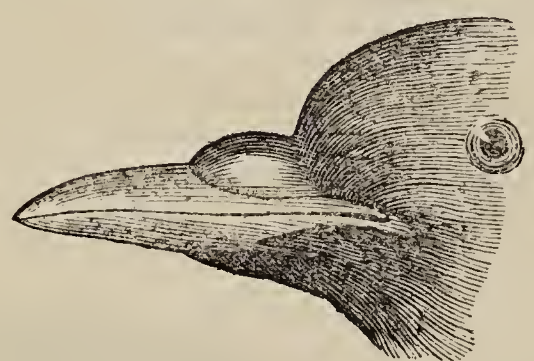
Cockatoo.

which is more slender than that of the others, but capable of being protruded, and armed at the tip with a horny portion cleft in two. The above figure will show the general form of the bill.

Bills of the Columbadæ.—We have already mentioned some of the reasons why the dove or pigeon family should be separated from the poultry; but as they are chiefly ground feeders, and as some of both perch on trees, and others sit or squat on the ground or on rocks, we may expect some correspondence in the form of their bills. The pigeons are, however, more vegetable in their feeding; and though they are by no means elaborate nest-builders, some of them at least do much more in that way than the gallinaceous birds.

There are three forms of bill among the pigeons, each corresponding to a difference of habit; but they differ so little from the bill of the common pigeon, and that is so well known, that we need not describe them at length, or illustrate them by examples. They are all simple feeding bills.

The tree pigeons, which are chiefly inhabitants of the warmer parts of the eastern hemisphere, and live upon the seeds of trees, which they gather on the trees themselves, and migrate from region to region after their food, have the bill strong, considerably arched, compressed and very sharp at the tip. In some it bears a resemblance to the bills of the smaller hawks, only it has no tooth, but in its use it approaches more nearly to the bills of the parroquets. The common pigeons have the bill more slender than the tree ones, and flexible for some part of its length, and they have their characters the more decided the more exclusively that they are found on the ground. The long-legged pigeons of the oriental isles, which are large and heavy birds, and more exclusively confined to the ground than any of the others, have the bill still more slender in proportion to their size; and in some of their habits, as well as some of their characters (such as having naked skin on the head), they resemble the gallinidæ. Both agree in having the nostrils pierced in a membrane at the base of the bill, and protected only by a cartilaginous scale, and not by hairs or feathers.



Pigeon.

Bills of the gallinaceous birds. The gallinaceous birds are all ground feeders, though they vary a little in the nature of their food, and the places where they find it. The whole of the tribe have the head very small in proportion to the size of the body, and the neck so long that the point of the bill can not only reach the ground, but command a considerable extent of it when the body is in a horizontal position. The bill is, in most of the genera rather short, arched in the upper mandible, and strong and hard at the tip. Indeed the bill of the common fowl, of which it is unnecessary to give either description or figure, is a very good average type of what may be termed a pecking bill. The two genera which have the bill different are the peacock pheasant (*Polyplectron chinquis*) of the east of Asia, and the genus *Tinamus* of South America, where they are called partridges or quails. Both of these have the bill straight, and longer and more slender than in the rest of the order; and in the American genus it is depressed, but has the upper mandible strengthened by a keel or ridge on the exterior. In their food, manner of feeding, and habits generally, they do not differ much from the rest of the order.

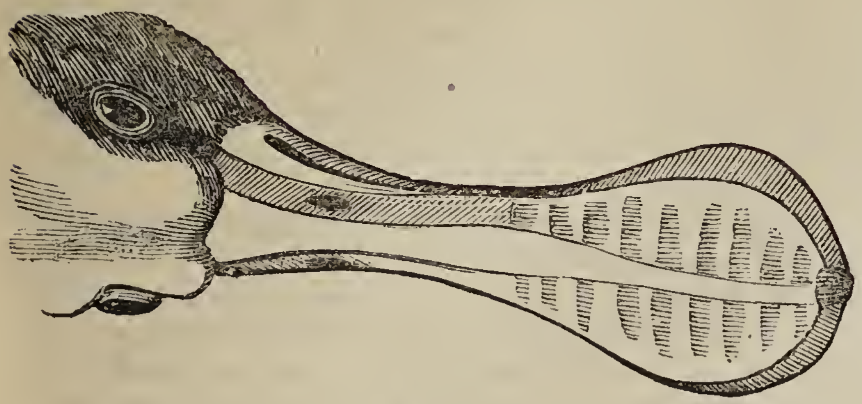
Bills of the short-winged birds. These have the bill very similar to the gallinidæ, which might be expected from the correspondence of their habits in feeding. The bustards, which, though not bad fliers, form the most natural transition from the one order to the other, have the bill strong, conical, or little compressed, and a little arched in the upper mandible. It bears a very considerable resemblance to the bills of those small birds which pick seeds from the stems of herbaceous plants.

The birds which are incapable of flight have the bills a little different. In the ostrich it is of moderate length, depressed, or flattened at the tip, having the mandibles of nearly equal size, and somewhat flexible, with a sort of nail at the tip of the upper one, but the tips are obtuse or rounded. It bears a slight resemblance to the bills of geese. This is the first indication of a grazing bill which occurs in the class, viewed in the order in which we have considered it; and the habit of the bird corresponds. The nhandeu, or ostrich of South America, has the bill shorter, and rather compressed toward the tip, which, however, is obtuse and furnished with a nail like that of the African ostrich. The cassowary of the south-east of Asia, has the bill compressed in its whole length, with a horny knob at the base, and a keel on the upper mandible which makes it stiff; but the lower mandible is flexible. These feed more on fruits and seeds than the others. The emu of Australia has the bill very similar to that of the South American ostrich.

The most singular bill of this order is that of the apteryx. The bird is altogether a singular combination; the body of an ostrich, the feet of a fowl, and a bill more like that of the ibis than any other. See Apteryx.

Bills of the Pressirostres.—These birds all seek their food on the ground, though not in the same places. It consists of worms, and other small ground animals, which are sought for in all places, from the dry waste to below the stones on the margin of the water. The bill is in general slender, and not very long; it is sometimes compressed, sometimes depressed, sometimes stiff, and sometimes flexible, so that it does not admit of general description, farther than that it is adapted for picking up small animal substances from surfaces bare of vegetation.

Bills of the Cultrirostres.—These birds have the bill, in general, very large and powerful, generally pointed at the tip, sharp, and sometimes toothed or serrated in the cutting edges. But though, in all the genera which Cuvier has included in the tribe, the bill is very robust; it differs so much in form and size, as hardly to admit of an average description. Thus the agamis, which are chiefly vegetable in their feeding, have the bill short and conical, not very unlike that of the poultry; the herons and bitterns, the first of which are fishers, and the others rather miscellaneous in their feeding, have it straight, or nearly so; while that of the spoonbills, as may be seen by the following figure, has very little of the knife-shape, from which the group is named.



Spoonbill.

The cranes, storks, and several other genera, all of which act the part of scavengers, and most of them are migrant, have the most typical bills. Among these are the adjutant of India, and the boatbill of tropical America. The latter bill is a very singular one. It resembles two boats applied the one to the other, and while the greater length of the tomia is trenchant, as in the storks, the tip of the upper mandible is hooked, with a tooth on each side, and that of the lower is pointed. It is understood to feed indiscriminately on fresh water crustacea, on reptiles, and on fishes.

There are, however, so many forms of bills among the birds of this very curious division, that no one can be selected as typical of the others, and the whole are by much too numerous to have a place in this short sketch. These diversities in the form of the bill show that, how much soever the birds which are arranged in this division may resemble each other in their haunts, the nature of their food, or their habits, the bill is not the part of their organisation after which they should be classed, though, in proportion as this part of their structure is less fitted for being the character of the group, it is better for distinguishing the genera.

Bills of the Longirostres.—The bills of this group, like those of the preceding one, do not admit of an exact average definition, farther than that they are all of considerable length, and generally less firm in their texture than most of the bills that have been noticed. But though they have no general form, they have a sort of general character. The birds which possess them are all feeders upon animal substances, which they seek upon the ground, generally in humid places, and some of them in the water; or if any of them eat vegetable matter, it is only that which is comparatively succulent, such as the bulbous roots of aquatic plants, or seeds which have been macerated in the water till they become soft. Many of them are flexible, consisting of a cellular bony substance, containing blood-vessels, and covered by a sentient membrane. They are a sort of intermediate between the bills of the land birds and those of ducks, and, as distinguished from the dabbling bills of the last of these, they may be called groping bills.

Some of them inhabit warm countries, and follow the lines of those rivers which are subject to periodical overflowing, picking up as their food the water reptiles, and other small animals, which are either driven from their retreats in the banks as the water rises, or left stranded when it subsides. The most remarkable of these are the genus *Ibis*, which have the bill very long, and bent from the base. In them it is harder than in most of the group, and not covered by a sentient membrane, but the mandibles are weak and flattened, so that, in arranging the birds according to their bills, these cannot be included among the cultrirostres, though, in their general habits, and also in the places which they most frequent, they resemble these more than they do the average of the present group. The more formidable prey, which they cannot so easily master with the bill, they dash forcibly against the ground, or stamp it to death with the foot.

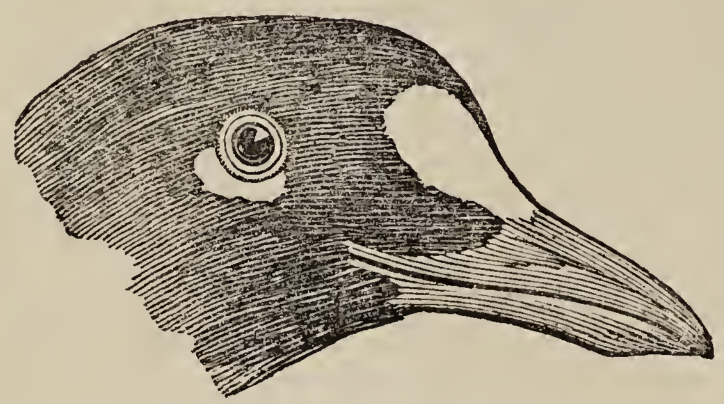
The majority of the group inhabit countries which are not liable to be parched by the sun, or they resort to such countries in the hot season; for, though many of them seek their food chiefly upon sandy or gravelly surfaces, they all seek it near the waters; and in the winter season they either resort to the shores of the sea, or migrate to climates nearer the equator.

Many of them seek their food by boring into the ooze and sludge, and in proportion as they have this habit more, their bills are longer, straighter, and more soft, flexible, and sentient. They are chiefly night or twilight feeders, because the ground animals of marshy and humid places come abroad then, but retreat and are still during the day. The time of their feeding thus renders the sentient bill of more avail to them than a hard one would be. During summer, when food is plentiful, and vegetation rank on the marshy grounds, one may traverse these the whole day without seeing a bird, or even hearing a note or a rustle; but as night sets in, they make the wilds alive with whistling and screaming. The bills of snipes and woodcocks may be considered as typical of this portion of the group. The avocets, which have the most singular bills of the whole, are more of day feeders than the rest. They feed by scooping in the runs of water, not by boring.

Avocet.

Bills of the Long-toed Birds.—These are also feeders on the margins of the waters, and the length of their toes affords them a firm base on slippery ground or upon tall herbage, among which chiefly they seek their food. Those which are less aquatic in their habits have the bill short, compressed, arched on the upper mandible, and sharp at the tip, having some resemblance to that of the gallinaceous birds; and those which are the most aquatic have it depressed, and produced on the forehead in a horny plate. Intermediate between these, there are others which have the bill longer, more slender, and enlarged toward the tip, as in the plover. The most striking character of these birds is the length and narrowness of their body, in consequence of which they can glide through the herbage with great ease and rapidity. The feathers of most of them are waterproof, and though the toes are never united by membrane at their bases, they are more or less margined for swimming. The bill of the coot is one of the most aquatic; and it bears some slight resemblance to the bills of the gulls.

There are two or three other genera of birds which frequent the margins of the waters, and live on food similar to that of the large-toed ones. The form of their bills would thus connect them with these ; but as they seek their food in places bare of herbage, find it less abundantly in any one spot, and must therefore range more on the wing in quest of it, all the other parts of their structure are so different that the connexion is not a natural one. These genera are, the flamingos, which resemble the herons in their haunts and many of their characters, but they live on mollusca and reptiles rather than on fish ; the pratincoles, which subsist chiefly upon insects which they capture on the wing; and they in some of their habits resemble the bee-eaters, and the carrion bird of Australia, *Chionis necrophaga* of New Holland, which has no type among European birds.



Coot.

The bills of which some account has been given, bring us to the margin of the water, and we have only to notice the birds which find their food in that element. The general characters of these depend less upon the bill than those of the land birds, but there are two well marked divisions : those which find their food at the bottom of shallow waters, and those which feed chiefly upon what is buoyant in the clear water,—though the first eat floating substances when they come in their way.

The first comprises the geese, swans, and ducks, which are all really ground feeders, only some of them feed almost exclusively on ground covered with water, and their bill and neck vary according to the depth of water with which their feeding ground is covered. As they are unable in all cases to see their food, they have the bill with a covering more or less sentient. They have the mandibles broad and flat, though often with an enlargement at the base of the upper one.

The gradation is from the geese, which feed fully more on the humid meadows than in the water, to the swans and swimming ducks, which never plunge the body, to the diving ducks which go to the bottom in considerable depths ; and thence it passes to the habitual divers which capture their food in the water, not at the bottom, and thus have the bill of a different form. As this gradation proceeds, the birds become more and more animal in their feeding.

Geese, which feed chiefly upon vegetable substances, have the bill elevated at the base, narrowed and rounded at the tip, comparatively short and stout, furnished with a nail at the point of the upper mandible of harder texture than the rest of the bill, and often of a different colour. The sides of the bill, which come in contact for a considerable breadth, are fringed with cartilaginous protuberances resembling teeth. This form of bill cuts grass something in the same way as the ruminant mammalia, which have the anterior part of the one jaw with cartilaginous ridges in place of teeth.

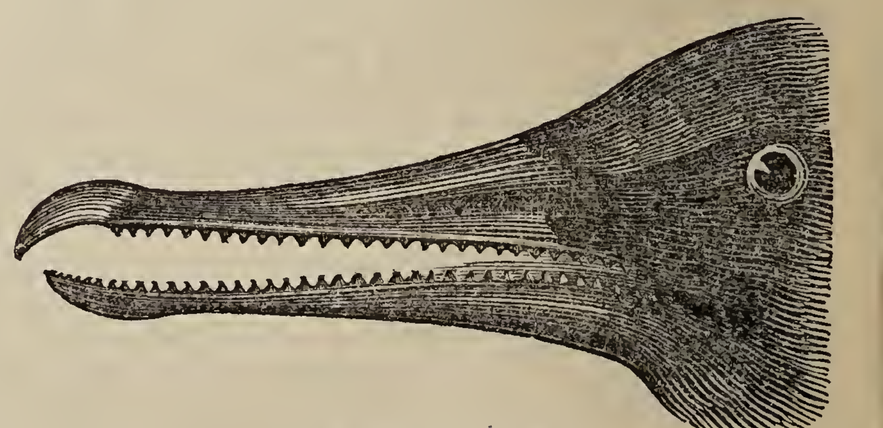
Swans, which are also chiefly vegetable in their feeding, but which feed more upon the roots of plants under water, have the upper mandible enlarged at the base, but the bill is larger than in the geese, of equal breadth throughout its length, and not so firm and robust.

Swimming ducks, which are omnivorous, but prefer animal substances picked up on the land or dabbled for in the water, vary a good deal in their habits, and their bills correspond. The common duck, which may be taken as the average, has the bill most flattened, and of the softest texture. These ducks have the neck lengthened, and plunge the anterior part of the body in the water till the axis is nearly perpendicular ; but they do not get so deep as to have the joints of the tarsi immersed.

The diving ducks have the neck and bill shorter than the swimming ones ; but still they feed not in the volume of the water, but at the bottom, and upon mollusca, worms, spawn, and other soft substances, and rarely if ever upon fish. This is the chief reason why their flesh is much more juicy and finer flavoured than that of the true aquatic feeders.

But there is a gradation in the diving ducks, the pochards, who resort more to the fresh waters, and the rich mud banks on the estuaries of rivers, have the bill much broader and flatter than the gannets, which may be reckoned the most seaward of all the duck tribe ; and there is a considerable trace of the fishy flavour in the flesh of the latter.

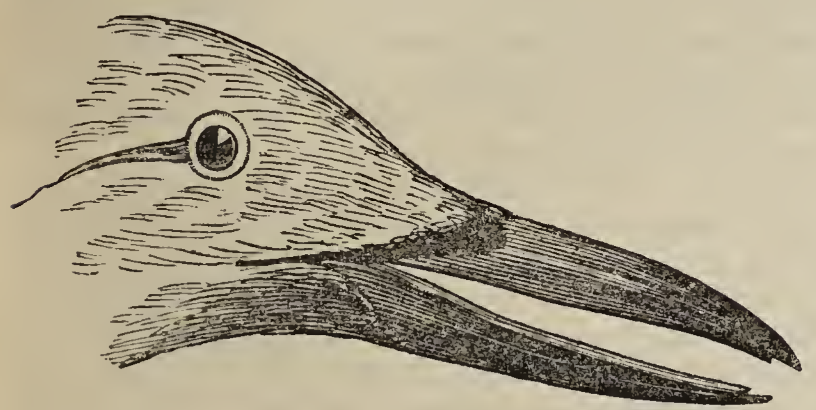
The mergansers combine the characters of the diving ducks and the true divers ; they catch their prey in the water, and not at the bottom ; but they are not formed for following it like the divers. They therefore require to have the bill of a more prehensile form than the one, and better able to retain its hold than the other. Accordingly, they have the bill lengthened, firm in its texture, nearly cylindrical, hooked at the tips of both mandibles, and serrated with reflected teeth along the cutting edges. They live upon fish and reptiles, and their flesh is rather rank in flavour. The following is a sketch of the bill of the red-breasted merganser.



Mergus serratus.

The divers and guillimots drive through the water with great rapidity, and transfix their prey with the sharp points of the mandibles, or wound it with the snap of the tomia, which in some of the species are furnished with a notch. This notch, which is of a very peculiar form, quite different from that in the bills of the rapacious or the insectivorous birds, is well shown in the bill of the foolish guillimot (*Uria troile,*) of which a figure is annexed.

In proportion as those birds which are dependent on the sea for their subsistence, and capable of following their prey to some distance under water, become less capable of motion on land or on the wing, their bills increase in power. We have examples of this in the razor-bill and the puffin, which though they can fly, do not habitually perform that operation; and still more in the great auk and the penguins, which have very powerful trenchant bills. With these one set of the sea birds may be said to terminate; and they bear nearly the same relation to the water that the ostrich and apteryx bear to the land—it is their principal, and almost their exclusive element.



Guillimot.

In the rapid sketch which we have taken of them, we have traced the birds in their regular gradation, from those that feed on foot upon the land, to those that feed by swimming and diving in the water. But the birds bring us out to sea on another element—the air; and there are tribes which take up the connexion from the heron and the kingfisher, which fish in the fresh waters only, and the succession continues till we come to races which are as discursive over the sea as the swallows and swifts are over the land.

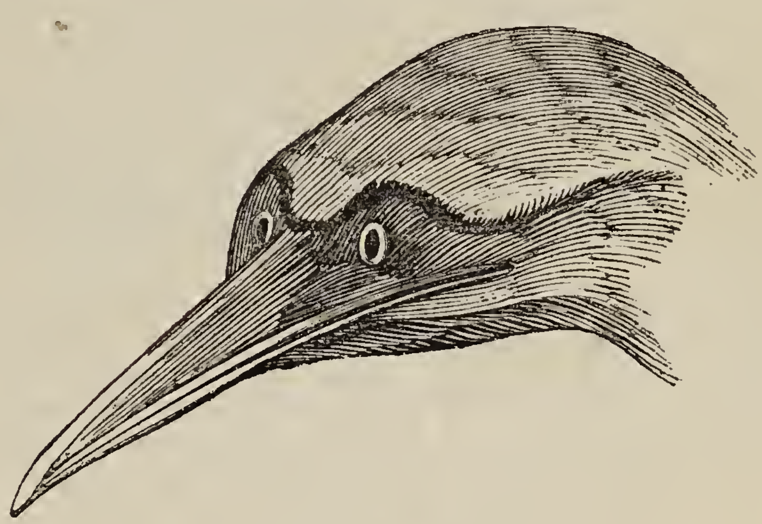
But as all these nestle on the shores (for there is no bird that breeds in the water), and as none of them can be insect feeders on the wing over the sea, there being no insects there, there is not the same diversity of habit among them as there is among the air-feeding birds of the land. The living produce of the shoreward parts of the sea, the waste and refuse which the sea casts up, and the waste which floats on its surface, are the three principal classes of the food of marine birds.

There are none of these birds which prey directly upon other birds, as the accipitres do upon land; and therefore there are none of them which have crooked talons or beaks like these. It is true that several of the eagles fish, and, though none of them refuse land prey when they can obtain it, there are some which depend more on the sea than on the land; but they are land birds, clutching their prey with the feet, and altogether unfit for swimming. Some of the sea-birds also prowl along the shores, and eat the eggs and the unfledged young of other birds: and there are some which rob others of the prey they have taken, by making them disgorge it from their stomachs; these last are birds of strong bill and powerful wing, but still their characters, though different from those of all land-birds, resemble those of the omnivora more than the accipitres.

The birds which make the most natural transition from the herons and other tribes which fish in the fresh water, are those which Cuvier calls *totipalms*, or entire-footed, from their having all the toes included in one web. These, though not the birds to which the name of "sea-eagles" is usually given, are the ones which in their habit much resemble the eagles; they dash into the water, and seize that prey which they have previously discovered by the eye, only they seize it with the bill. But most, if not all of them have a double habit; as they also catch prey while swimming on the surface; but they live more upon live fish, and less upon the offal of the sea than most of the other races.

The bill of the gannet, of which a figure is given, may be considered as the most characteristic of these bills.

It will be seen that it is stout at the base, nearly straight, has both mandibles serrated, and both tips a very little bent. Its outline is that which gives the greatest stiffness with the same quantity of materials; but the upper mandible, as in all bills which act very powerfully, has a little motion. When the bird descends with velocity, this bill transfixes like a spear,



Gannet.

and retains its hold like a barbed hook. The darter and the tropical bird have their bills formed in a manner similar to that of the gannet, and they also dart or descend on their prey; but the darter is a more landward bird, perching on trees, and fishing chiefly in the fresh waters, or in those salt lagunes where there are mangroves; and the tropical bird is more discursive over the sea.

The cormorants, which fly lower, have the bill less capable of thrusting with the point, or of resisting a strain on the base. Its thickness is more uniform, and the upper mandible is much more hooked, while the lower one is truncated, and a small portion of the bill has an oblique cutting motion. There is a trace of the carrion bill in it, and the mandibles are not serrated. The birds which have this bill do not fish in the same style as the gannets and darters. The bill of the albatross, which is a very wide-ranging bird, has still more of the carrion shape; but it has also a sort of tooth on the bend of the mandible, and thus can lift prey out of the water.

The true scavenger's bill on the "high seas" is that of the petrels, of which the fulmar's is typical.

The angular portion at the tip of the upper mandible of this bill, and the bend on the lower, which acts against it, are both very strong and hard, so that it is well-adapted for tearing the flesh of whales and of the larger fishes when their carcasses float dead on the sea. By that most efficient part of the bill being carried at an oblique angle to the water, while the bird swims or skims the surface, it can easily pick up all manner of garbage, however minutely divided, and even sip the oil which floats on the sea.

The numbers of these petrels are immense, far greater than those of any other birds—a single flock is sometimes seen as numerous as would cover the surface of a county. They afford a very striking instance of the vast productiveness of the sea; for they, numerous as they are, are only one of the races that subsist on its refuse. But when we consider that the sea is more than twice as extensive in surface as the land, and that it is inhabited to the depth of many fathoms, while the land can (as the barren places compensate for the elevations, whether of hills or of vegetables) be reckoned only as the one surface, we are within the limits when we say that the productive power of the sea is a thousand times greater than that of the land; or that, if its productions could be arrived at, and their nature would suit, the sea might support all the life that *could* exist upon the land, and never feel the burden.

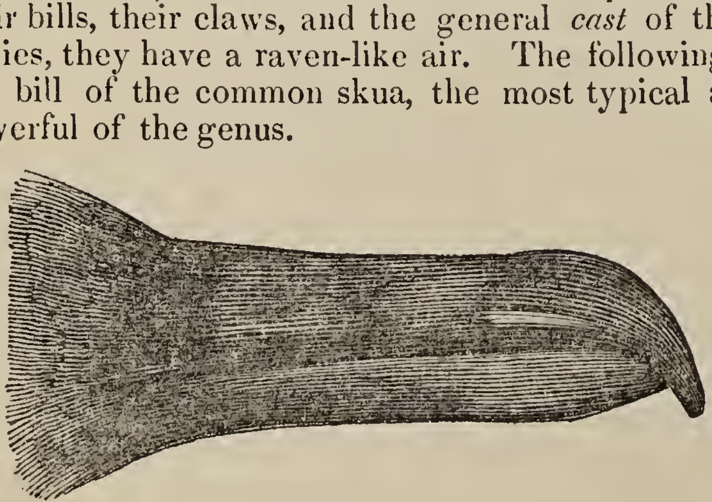
The storm-petrels are lighter birds, and of more rapid wing than the common petrels; but they have the bill of the same form, though weaker. They subsist chiefly upon the smaller garbage, and especially upon oil, which they collect from the water on the feathers of their breast, and then remove with the bill. All the petrels have the nostrils enclosed in separate tubes—sometimes single, and sometimes double; but the use of these in their economy is not known.

With the storm-petrels one group of sea-birds, classed according to their habits in feeding, and the structure of their feeding organ, may be said to terminate; but there is still another, the commencement of which may again be taken from the shore, and traced to the more extended pastures of the other.

The group which has now been mentioned as extending from the gannet to the storm-petrel inclusive, may be regarded as having a relation (such a loose relation of mere analogy as can exist between preyers at sea and preyers on land) to the birds of prey—the gannets and races which have similar habits to the eagles, the petrels to the vultures, and the storm-petrels to the birds which catch insects on the wing. The analogy is, as has been said, a loose one; but it is of use in forming a relative estimate of the economy of the sea and the land.

We may, therefore, continue it with the remaining sea-birds, which are principally the *lestri* or skuas, the gulls, and the terns. These are the omnivorous birds of the ocean; but the term, as applicable to that element, does not include vegetable food, though many of these sea-birds feed on land during the breeding season, and also when the sea becomes too stormy for them.

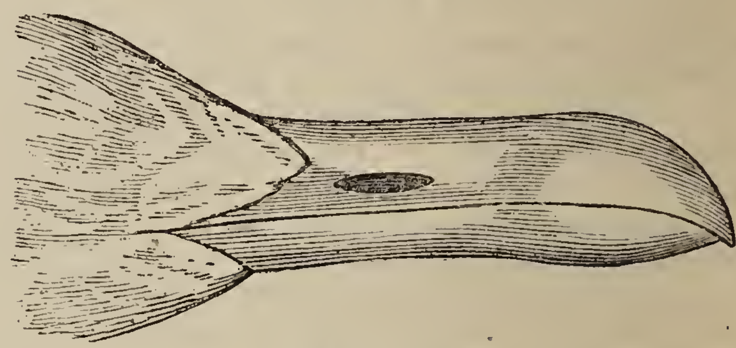
The *lestri*, though called eagles (the real sea-eagles are land-birds), are the ravens of the deep; and in their bills, their claws, and the general *cast* of their bodies, they have a raven-like air. The following is the bill of the common skua, the most typical and powerful of the genus.



Common Skua.

This bill is very strong, coulter-shaped, hard in its texture, and considerably hooked at the tip of the upper mandible, though nearly straight for the greater part of its length. But it is not a murderous bill or a very prehensile one. It has no tooth or notch, or even the sliding motion at the point which characterises gnawing bills. Accordingly, though the skuas are strong and bold birds, they do not kill full-grown prey, neither are they very dexterous in catching their own fish. They rob the nests of other birds, and they rob the gulls of the contents of their stomachs. They are, what their systematic name expresses, *lestri*—robbers, takers of that which belongs to others. They seek not the shore-bird, they seek its eggs; they seek not the sea-bird, they seek its food; and even among mankind, it has always been reckoned more cowardly to attack the infants than the father, and baser to injure "the means" than openly attack the man.

The gulls follow, as the rooks and crows of the sea, fishing occasionally, but only for fry and the smaller fishes, and living on carrion, mollusca, worms, and "whatever they can find." Some of them come occasionally on shore and clear the ploughed land of larvæ and worms along with the rooks; and not a few breed in small lakes and marshes many miles inland, and find marsh food for themselves and their broods. Their bills correspond, as may be seen in the following figure.



Common Gull.

The terns take up the succession from the gulls; and, in the gull-billed tern, which may be considered as the commencement, there is much similarity not only in that organ but in the general air of the body; and as we trace them to the more typical terns, the bill does not assimilate to that of the swallows (though the terns have—not very discerningly—been called "sea-swallows"), but to that of the pratincole, which may perhaps be considered as the last of the omnivorous feeders among the land-birds, and the most powerful on the wing. And it is not a little remarkable, that when this rare but beautiful stranger makes a dash over from the Danube to the Hebrides or Zetland, by way of a morning trip, it is found in the company of gulls and *terns*.

The storm-petrels are the real swallows of the sea—the birds which feed upon the lightest and highest production of the waters, just as the swallows and swifts are the last of the land tribes which feed exclusively upon living creatures; and, although the food is different, and requires a different form of bill, it is not a little remarkable that the general structure, air, and even colour of the storm-petrels, resemble those of the swallow tribe; while those of the terns have more of the pratincole in them.

Notwithstanding the length to which this part of the subject has already extended, there are still some very striking analogies of which it may be desirable to take notice, the more especially that they have not, so far as we are aware, been previously noticed by any naturalist who has treated of the feathered tribes, and also because we cannot with propriety introduce them into the particular account of any one group or genus. They are briefly as follows :—

In the first place, the flat-billed birds, which find their food at the bottom of the waters, have a very striking analogy to the ground-birds that feed upon land. Their flesh resembles the flesh of the grazing mammalia, the more exclusively that they are vegetable in their feeding, as in the case of the goose. The ducks, which are omnivorous, have more the flavour of poultry; and those which feed chiefly upon mollusca, ground worms, and the spawn of fishes, partake of the racy flavour of the land "gut-birds." As they become more and more feeders upon fish, they acquire more and more of the rank flavour ; and the auks and other species which scarcely fly at all, abound very much in oil.

It is not a little singular that it is in the two corresponding divisions of the sea and land birds, where we meet with the species which are confined to one element, and lose the grand characteristic of birds, the wings, though they retain the general structure and habits. The feathery covering is never wanting; but in the extreme of ground birds upon land it has much of the loose character of fur, while in the extreme of the divers at sea, it is so close and compact, that it has the appearance of one unbroken covering, in which the individual feathers cannot be distinguished.

In the second place, those sea-birds, from the marsh-breeding-gulls, or rather from the skuas, to the terns, which bear a resemblance to the *omnivora* among land-birds, are all, like these, good walkers, quite as much at home upon the shores as they are in the water or on the wing. This coincidence is the more worthy of being borne in mind, that the omnivorous birds are the only land ones which have the two motions of walking and flying nearly equal throughout the group ; and the corresponding group of sea birds are the only ones which possess all the three in equal perfection.

Those birds which are the most general in their feeding, are thus, also, the best fitted for reaching their food in all sorts of places ; and not only this, but they are the most generally distributed over the globe, and resemble each other the most in all latitudes. They are not the most numerous at particular spots, though many of them assemble in great numbers at their breeding places.

Between the air-feeding birds of the sea and the land, there is not the same perfect correspondence, because there are among sea-birds no literal preyers on the wing. There cannot be, for there is no food for them, as the sea sends up into the air nothing upon which a bird can subsist. The level of the waters is the upper level of sea-food, unless in that portion of the food of those birds which is cast up by the waves. But still there is a correspondence : they keep more to their own element, and have their motion more fitted for that, and less for the other two. Those sea-birds which seem never to tire on the wing, are all imperfect walkers ; and though they float very buoyantly, much more so indeed than those which are habitually on the water, they are by no means so expert at swimming.

The most perfect flight and the most expert action in the water are indeed incompatible with each other. Birds which float about the livelong day require to be light for their bulk and extent of feathers, though a heavier bird succeeds better on a momentary rush ; and the air birds which fly over the sea in search of their food do not require the same rapid motion as birds which fly in the air in pursuit of their food. But a bird which is to have the most perfect command of itself in the water, and be able to dive, and come up, and drive along, sometimes wholly immersed, and sometimes not, must, in order to perform its various evolutions with as little muscular exertion as possible, be of nearly the same specific gravity as sea water.

It is absurd to say, as has sometimes been said, that if birds have not a certain specific gravity they cannot dive. The lightest substance, the lightest gas, can be forced under water by mechanical means, and it is rather too much for us to suppose that we can beat nature with our small second-hand mechanics. But still it accords with general principles that that which is the most nearly of the same specific gravity as water, should admit of motion in all directions in water with the least effort. This principle is traceable in aquatic birds; for we find that the diving ducks ride deeper in the water than the swimming ducks, and the divers still deeper than they.

Then there is the difference of form. The motions which a diving bird performs in the water are so varied that to determine the solid of least resistance with regard to them all would be no easy matter. But the boat which rows fastest, keeps course or turns most easily, and lives in the roughest water, is an approximation. That boat is one with the two ends nearly equal, and of an average length. If too short it " yaws like a tub," and will not keep course, and if too long it turns wide. This is the form which we find in those birds which have the most complete command of the water. If they go on long courses after fish, as is the case with the divers, they have the body elongated ; and if they search about among the rocks after mollusca and crustacea, as is the case with the puffin, they have it shorter. These last, by the way, have the most powerful bruising bills of any of the sea birds, just as the parrots have among the land ones ; and it is curious to notice that there is a considerable resemblance both in the appearance and in the harsh screaming voice, so much so that the puffin is sometimes called the sea-parrot.

The boat shape of those birds, and the backward position of the feet, with the weight of muscles necessary for moving them, are incompatible with that structure which answers best for powerful flight. That, in order to be performed with the least effort, requires the weight to be concentrated near the centre of motion in the wings.

From these few observations, short and imperfect as they are, it will perhaps be seen that there might be a much more natural arrangement of birds founded upon their *principal habit* than any which can be founded on a particular part of their organisation. Air birds, ground birds, and those intermediate races which have the double motion in the case of land birds, and the triple one in the case of sea birds, might form the leading divisions.

An air bird is one which uses the wing in immediately obtaining its food ; thus an eagle which stoops to ground prey, a falcon which captures in the air but eats on the ground, a gannet which plunges in the water, and a swift or other insect feeder which feeds on the wing without stopping, are all equally air birds, arriving at their food by the action of the wings in that medium. So also a bird which immediately finds its food with the wings closed, or only with a partial use of them, subordinate to that of the feet, as in the birds which chase their prey under water, those that perch upon flexible stems and twigs, and a few others, is a ground bird. No matter whether it walks the bare earth, the vegetable surface, the boles or branches of trees, or perches, or climbs, or swims, or dives, if aerial motion does not form part of the act of capture, it is not an air bird. Many ground birds range far on the wing in search of places where they may feed or nestle; but the distinction between that and feeding on the wing, that is, arriving directly at the prey from the air only, is obvious enough. If the bird moves anew from any support but that of the air, that element has, as it were, rendered it up; and be the support rock, earth, plant, or water, there is an unbroken connexion with the ground.

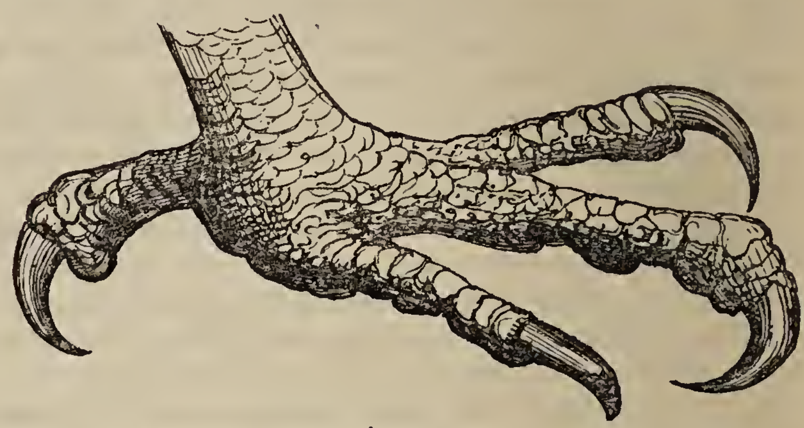
The distinction between omnivorous birds and either of these divisions is not so clear. But this is what might be expected: the air and the ground are the extremes, and in comparing them we have the advantage of the greatest contrast of which the class admits. There are some birds which have both habits, and they are chiefly miscellaneous feeders; and, if we had only two divisions, there are very many species which would belong equally to both; to the observer of the one habit they would be air birds, but they would be ground birds to the observer of the other habit.

With the three divisions there would still be difficulties on the confines, nor could we avoid similar difficulties though we made three hundred divisions; for in nature there are no absolute divisions but those of species, or perhaps individuals. Natural divisions are, therefore, out of the question in this or in any other department of natural history. But there is a natural gradation, and that gradation we can approximate, and approximate the more nearly the better that we understand the whole; but completely to reach it would require a degree of knowledge which man in this world never can possess.

The primary divisions in the arrangement which has been hinted at would be as unnatural, as artificial as those in any of the systems. But there would be at least one great advantage, we should have the whole bird presented to us in the general definition, and not a mere bill, foot, or wing, as we have at present. Thus we could, from a sort of general enunciation, proceed equally to all the parts by analysis, whereas, as matters stand at present, we have to collect the knowledge of all the parts, in perfect ignorance of the use which we are to make of this knowledge, till we are in possession of the whole. This is a very discouraging mode of going to work; and if we are compelled to stop short of the whole, all the labour which we have taken is without purpose and without profit; the subject remains unknown, and the mind has not profited by the exertion. But we must stop here; some further observations will be found in the article CLASSIFICATION.

VI. FEET OF BIRDS. From the notice which has been taken of the habits of the more remarkable birds in the preceding observations on the structures and uses of their bills, we shall be enabled to reduce this and the following branch of the subject to little more than mere catalogues; and all parts of the subject would have the same brevity, if a system could be formed as above suggested, free from all structural details; because then we would have nothing to consider along with any organ but its own immediate function.

The feet of birds are used in the air, on the earth, on vegetable supports, and in the water. The only feet which are, strictly speaking, used in the air, are used in the capture of prey, or they are *clutching feet*, the feet of all birds of prey, diurnal and nocturnal, but the feet of no other birds. The typical foot of these is the foot of the jer falcon.



Jer Falcon.

The character of this foot is to have four toes, all free to their bases, and three turned to the front and one to the rear, in the general habit; but those species which fish have the exterior front one reversible, so that the toes act two against two, and thus lift the prey more easily out of the water than if they had the common position. When the toe is reversible it is generally the largest in the foot, and the claws upon these feet have their under sides smooth and rounded as well as the upper ones; whereas those birds which use the feet only in killing, have the under sides of the claws grooved, or with two cutting edges, by which means they inflict much more lacerated and mortal wounds.

The claws of the more typical birds of prey (which are the only ones which get the name of talons) are used only in killing the prey, or in holding it while depluming, skinning, or tearing asunder, by the beak; but the vultures and other less typical species which eat carrion, and rarely kill living prey, use the claws more for retaining their hold, while they stand on the bodies of dead animals.

Size is not so much an indication of power in these feet as compactness and symmetry; the tarsi of the more powerful ones are all short; and in proportion as the preying of the bird becomes what is called more ignoble, the tarsi increase in length. Thus in the secretary falcon (*Serpentarius*) of Africa, which feeds much upon reptiles, and often upon poisonous ones, the tarsi are as long as those of the wading birds. This, however, is not to answer a wading purpose, but to raise the body of the bird above the reach of the envenomed prey, as this falcon (which, by the way, is not a falcon) kills by the clutch or truss of the talons, after the general habit of the order.

As walking is not much a habit with birds having this description of foot, the femur, or thigh bone, has not a great deal of motion or of muscle. The largest muscles are those which work the toes and claws, and they are situated upon the *tibiæ*. They are always protected by a thick feathery covering, and in the species which inhabit cold countries, the feathers are continued on the tarsi, or they hang down and shelter those parts of the feet, so that the tendons and ligaments may not be stiffened and rendered unfit for action by the cold.

There is considerable freedom of motion laterally in the toes of these clutching feet. When they are employed in violent or excited action, the four claws are nearly equi-distant, and all their points are directed toward the same centre, so that in whichever direction the prey writhes, it always runs itself more and more upon the point of a portion of the claws, and the trenchant edges at the same time tear and mangle its flesh. The same position of the toes enables the birds to perch on the points of rocks and other places of observation, from which they can discover their prey. But such feet are not well adapted for walking; and when the birds have to change their place even for a short distance upon the ground, they always raise or move the wings. Thus, though the foot of birds of prey is used for various purposes upon the ground, it cannot be regarded as a foot well adapted for any kind of progressive motion. The feet of ravens, and several other omnivorous birds, partake a little of this character, and hence they hop rather than walk, and partially raise the wings to balance themselves.

Ground Feet. Birds have so many different actions upon the ground, and the ground itself offers so many different kinds of surface, that it is not very easy to reduce the feet to any thing like an explicit system. If the bird is a swift runner, the tarsi are long, the thigh bones articulated a little farther forward, and their action more free; but then the termination of the foot, which is usually attended to in the descriptions of the feet of birds, varies with the ground on which it is to be used, and this again causes a modification of the other parts of the leg. If the back toe is long, and articulated at the same level with the other toes, then the foot must be placed farther forward, in order that the axis of the body may be carried horizontal, than when the hind toe is weak, or wanting, or articulated higher on the tarsus than the other toes. Feet also combine other actions, such as scraping in the earth, or swimming with their action of progressive motion upon land, and this farther embarrasses us in our attempts to classify them; so that, without writing almost as many volumes as there are kinds of feet, little else can be done than simply to mention the description of surface and motion, and notice the form of the foot.

For swift motion over arid surfaces, covered with dry sand, the foot of the ostrich is best adapted.

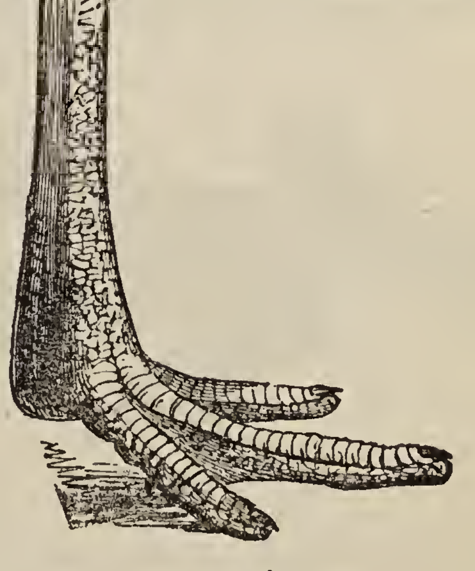
Ostrich.

This foot has only two toes, both thick and strong, the inner short, and without any claw; the outer longer, and furnished with a broad blunt one. The tarsus is very thick as well as long, and the muscles on the tibia are large, and extend as far down as the tarsal joint. The joints have little lateral motion, but the progressive motion is extensive, and the foot is lifted clean and high above the ground. As the ostrich is the swiftest of all running birds, we must conclude that this is the best running foot upon dry surfaces; but it cannot be considered as the normal foot of the group, for the others have three toes, and the cassowary has a long nail on the inner one, and the tarsi feathered a great way down.

The swift-footed birds which frequent the dry shores and heaths, but which have occasionally to pass over surfaces more or less humid or soft, have three toes before, and none behind in some species, a mere rudiment in others, but not a very large toe in any. They have the middle, or outer toe, more or less united by membrane at the base, according as the surface on which they generally run is more or less soft. They are all birds of flight, not having the muscles concentrated on the hind legs, like the ostriches, and their legs are in general slender; and though many of them run fast, the tonat take comparatively as long strides as the ostrich tribe. The foot of the common plover is nearly an average example.

Plover.

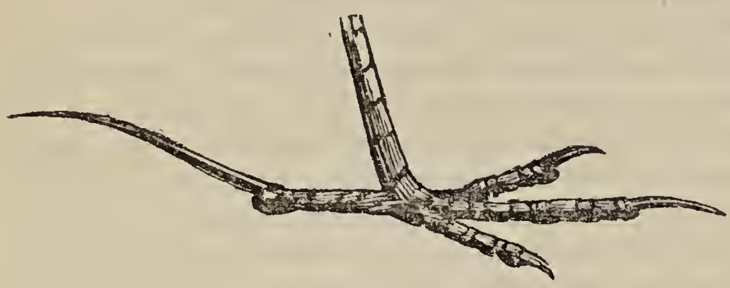
The bustards form a sort of connecting link between the "stilt" birds, which run upon dry and naked places, and the gallinidæ, which frequent richer and softer ground. They can fly, and flight is their means of escape from serious danger, and also of transport on their longer journeys; but in ordinary they walk or run. The following is the form of the foot, three toes before, with short membranes at the bases, and a sort of cartilaginous heel, but no back toe.



Bustard.

Birds which frequent very soft surfaces, have generally the toes larger, and bordered more or less with membrane; but unless there is another action besides walking to be performed, the difference of structure in the feet is not, in the case of winged birds, very great, whether they walk on the earth, or wade in shallow water over surfaces of the same kind.

Feet for walking on grassy surfaces. These have the three front toes free to their bases, and the hind toe articulated on the same level. The claws long, the hind one especially, but not much bent. These feet extend over a large base, and the elasticity of the grass assists the bird in jerking upwards till it can take wing. The foot of the skylark is an instance.

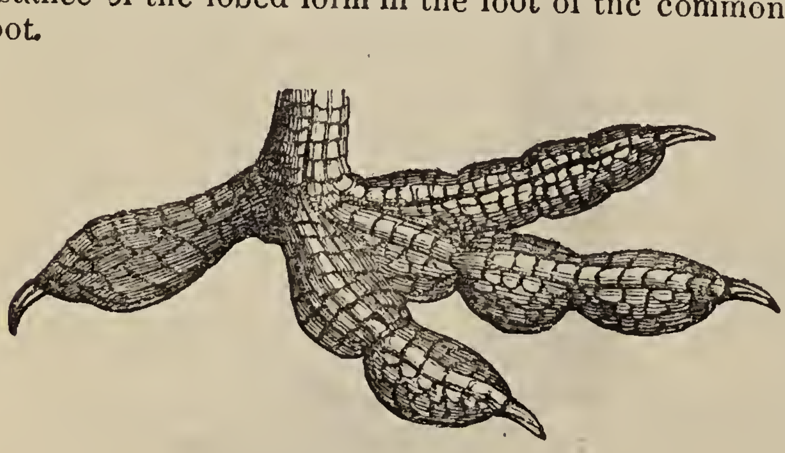


Sky-lark.

Feet for walking upon aquatic plants have the toes very long, and the birds which have them can generally swim. The common gallinule, or water-hen, is an instance of this form of foot.

Gallinule.

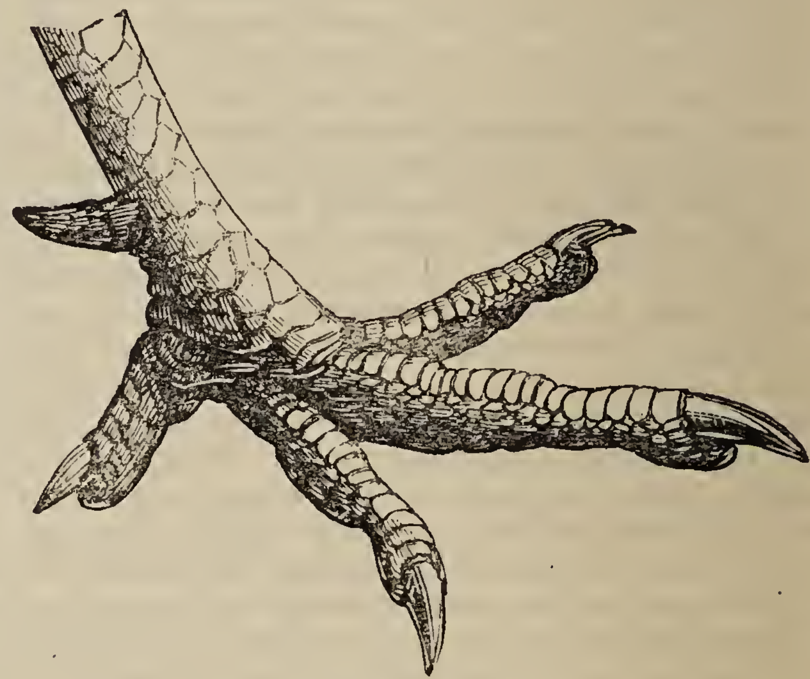
Some of the foreign birds of the same group (*Macrodactyli*) have the toes much longer in proportion. The length of the toes enables these birds to walk tolerably well, though the legs are articulated so far back as to give them the position of those of a swimming bird; and while all the species inhabit closer to the water than any other birds which have not the feet webbed, some of them have the toes lobed, and are excellent swimmers, though even these are most partial to those places of ponds and lakes in which there are aquatic plants. There is an instance of the lobed form in the foot of the common coot.



Common Coot.

Walking and scraping feet. These are more peculiarly the feet of the gallinaceous birds, all of which walk slowly on the ground, or standing on that reach the seeds of herbaceous plants, when they feed in a state of nature. They also scrape the ground with their feet, not only to lay bare seeds, worms, insects, and other substances upon which they feed, but to detach the small pebbles which they swallow to assist the gizzard in the process of digestion. The nails to adapt them for this operation, are rather broad and concave on their under sides.

These feet are all of the same general form, three toes before, and one behind, the front ones generally united by short membranes at their bases. The partridges have the membrane extending as far as the first articulation from the base, and in one South American genus, the hoazin, which is more aquatic than the others, the connecting membrane of the toes is altogether wanting. Some have the toes with tuberculated margins, and others have them smooth; but it does not appear that there is any particular difference of habit, for the smooth and rough toed ones indiscriminately perch or "roost" during the night, though they generally nestle on the ground. Those which roost have the feet stouter and the toes longer than those which squat on the ground; but those which squat are the swiftest runners. In general, however, their walk is slow, and in some it is stately. They always walk or run, and never hop, or raise both feet from the ground at once, unless when they are alarmed; and then, if they do not get fairly on the wing, they flutter, and lose command of themselves. The foot of the common domestic fowl is an average instance.



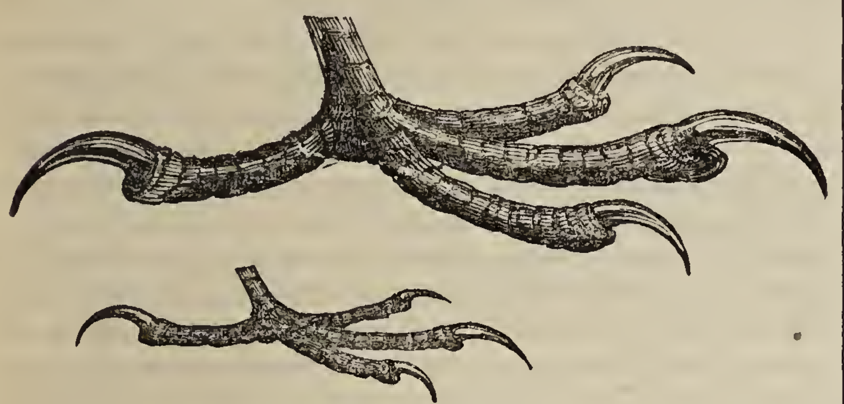
Common Fowl.

Some have the tarsi plain, some with a soft tubercle, and some with a hard and sharp horny spur. These naturally belong to the males only; but, from physiological causes, they are sometimes produced on females.

Feet for walking and perching. The feet of the omnivorous birds are generally of this description, and also most of those of the granivorous—as all of them feed on the ground at some seasons, and most of them perch occasionally. The foot has three toes before, and one behind, all articulated on the same level, and divided at their bases. This is not so firm a foot upon the ground as that of the gallinaceous birds; and the march of none of them is so stately as that of some of these. The axis of the body rolls more when they walk; and many of them, when urged to speed, hop, and also call in the aid of their wings.

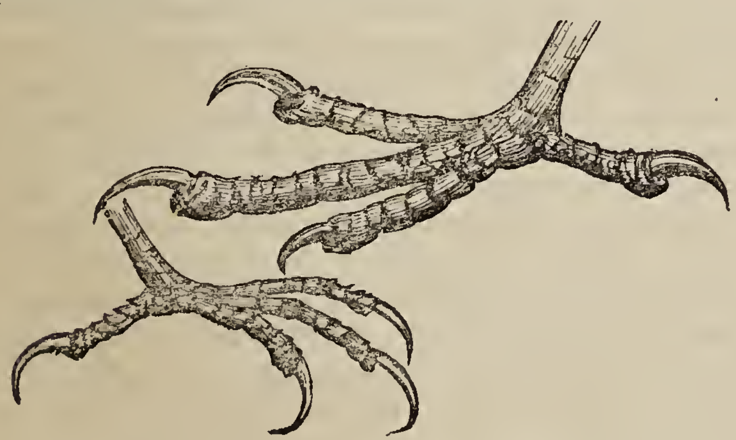
This want of firmness in walking arises from the absence of the connecting membrane at the bases of the toes, and also from the toes themselves having more play at their articulations. But the very same circumstances render it much more efficient as a perching foot; and while the gallinaceous birds can, in general, only roost across a perch of considerable thickness, many of the free-toed birds can hang in all positions, and by one foot or both, as need may be, from a slender vibrating stem.

Generally speaking, the omnivorous birds are the best walkers, and those which eat small seeds from the stems of plants the best perchers; but there are exceptions. The rook is one of the best walkers; and the tits are among the most dexterous perchers: so that their feet may be taken as examples.



Rook and Blue Tit.

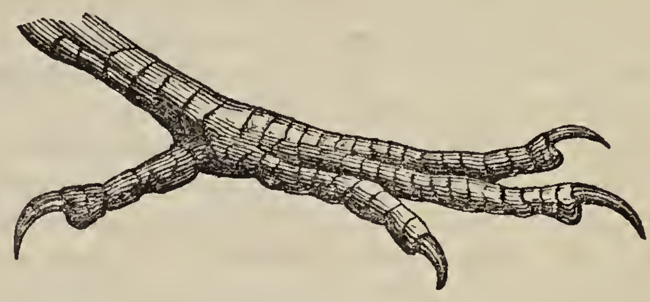
Feet better adapted for perching than walking. Birds with feet of this description are generally those tribes, wholly or chiefly insectivorous, which seek their food partly on the ground and partly on the leaves of trees; which are generally seen on trees and bushes, but which perch generally, and have no peculiar mode of action on the trees. This foot has three toes before and one behind, but the outer front toe is more or less joined to the middle one at its base—sometimes at the base only, and sometimes as far, or nearly as far, as the first joint. This structure of foot gives the bird more firmness when perching across a twig than those birds have in whose feet all the toes are free; but they have not so much action on their perch, and cannot swing about so much as the birds with free toes; and they are by no means so good walkers. There are, however, considerable differences among them; as, for instance, the song-thrush, which finds its food on the ground, is rather a good walker, while the crested wrens, which reside almost constantly in trees, have not much less command of themselves than the tits. The feet of these two species will serve as illustrations.



Song Thrush and Golden Crested Wren.

All the migrant, and some of the resident warblers, which sing from the groves and copses, and make the vernal season so lively with their music, have feet of this structure; and they all sing on the perch, and not on the ground or the wing.

Syndactylic feet. These have all the three front toes united together. They feed chiefly on the wing, use the perch only for rest, and walk little on the ground, for which the form of their feet very ill adapts them, though they usually have their nests in holes, and often in holes excavated by themselves, for the digging of which their united and spade-like feet are by no means ill adapted. The foot of the kingfisher will illustrate this structure.



Kingfisher.

Crab feet. These are feet of a very peculiar structure, to which writers on ornithology have given no name; and yet they are distinct from any other feet, and their mode of action is very peculiar. They belong to the *Fissirostres* of Cuvier—the *Chelidonian* birds, or swallow tribe, which are so well marked, and so distinct from all others, both in their structure and their habits, that they ought not only to stand as a separate family, but as a separate order; and the three genera, of which the group is composed, are so different from each other, that each ought, in strict propriety, to form a separate group, or even sub-order.

The birds to which they have the nearest resemblance are the fly-catchers, but the resemblance is not a very close one, except in some of the foreign species of goat-sucker; and then, so far as the habits are known, even these are very different.

All the three leading organs, the bills, the wings, and the feet, are so peculiar in these birds, that almost any of them might be made the ground of classification. The wings are the most powerful part of the organisation, more especially of the diurnal ones; but even the feet are very characteristic. They are not walking or perching feet, they are simply adhering ones; and though both the tarsi and the toes are comparatively small and feeble, they are very beautifully adapted for retaining their hold, be the position of the body what it may.

Though the description of prey is very different, and the feet are probably never used in the capture or the killing of it, yet there is a remarkable analogy in habit between these birds and the birds of prey; and this analogy holds even in the division into two sections. All the swallow tribe are diurnal feeders, feeding wholly upon insects, and capturing them on the wing only, and by the snap of the bill, the sound of which may be often heard when the birds are on the chase. They are thus hawks, only they are hawks in miniature; and there is nearly the same distinction between the swifts and swallows as there is between the falcons and the short winged hawks. The habits of the nocturnal ones are not so well known, as the habits of nocturnal birds are much less open to observation than those of diurnal ones; and, therefore, it is not ascertained in what manner they capture their prey, though probably by the bill, which is even wider in the gape than in the day-feeding species; but as the foot of some species at least is different, they *may* use that in some instances in the capture of their food. As they feed in the twilight, they must feed in part on moths; but that is also the time when the larger coleopterous insects are on the wing; and these may require preparations for the stomach different from what are requisite in the case of the naked winged insects, which form the principal food of the swallow tribe. Still, in the form of their bodies, in the texture, and even in the colouring of their plumage, the nocturnal species differ from the diurnal ones much in the same way that the owls differ from the nocturnal birds of prey.

There is even a similar distinction in respect of habitation. The diurnal species, like the diurnal birds of prey, are all dwellers in open places, and they do not nestle in trees: the nocturnal ones are copse or woodland birds; and though some of them are understood to nestle on the ground, the greater number certainly nestle in trees and bushes. Yet further: the diurnal ones have a harsh, sharp scream, which though not exactly like the chirrup of hawks, has some resemblance to it; and they are in general silent: the nocturnal ones, on the other hand, have a more continued and stridulous cry; and in the depths of the tropical forests, especially those of America, they keep not only the common night, but the sultry and otherwise silent night of the burning noon, alive with their cries.

Being all chiefly insect feeders, they are most abundant in tropical climates; and those which frequent cold and temperate regions in the summer always quit them before winter. The nocturnal feeders, being birds of less firm feather and less powerful wing, are by no means so migratory as the diurnal ones. These last, as will be more particularly shown when we come to give some account of wings, are among the most exclusively wing-birds, and the best winged in the whole class. Their food is in smaller portions than that of any of the class, and therefore they have more labour in the procuring of it. Not only this, but many of them have much labour in the construction of their nests, whether they build them of mortar in the crevices of rocks or the apertures or angles of buildings, or excavate them in the banks; and all of them have much to do in the rearing of their broods, which, as is general with birds that have very perfect feathers, continue a long time in the nest.

Their feet more resemble the syndactylic ones than those of any other form, though these have the toes united, and consequently a narrow foot, while the birds under consideration have one remarkably broad for its length; but they both agree in this, that the tarsi and toes are short, and they use the feet only for resting or holding-on, and rarely if ever for progressive motion. It is worthy of remark, as a striking instance of agreement in two very important habits, that though the syndactylic birds build low, and the ones under consideration build high (for even the sand-martins, or bank-swallows, build in lofty banks and rarely in low ones), they should both have covered nests, and both feed their broods for a long period, as well as both capture their prey on the wing. And the height at which they build corresponds to that at which they fly. The kingfishers and bee-eaters never have their nesting-hole far above the surface of the water; and their flight, when in search of food, is invariably low. Of the swallow tribe, again, the sand-martin, which builds in holes of the banks, is the bird of lowest flight; and the flight and position of the nest rise together, till we come to the swift at the top of the sky with the one, and the top of the rock or the tower with the other.

The feet correspond: the syndactylic foot, with its soldered toes, forms a steady base for resting by pressure upon a horizontal perch; and the foot of the swift, which is the opposite extreme in all the birds which prey upon insects on the wing, is the best adapted for holding-on upon the slightest inequalities of an upright surface. Although, therefore, the feet of all these birds are small, apparently feeble, and not adapted for locomotion, there are no feet better adapted to the habits of their owners.

The general character in which the "crab" foot, or foot of the *Fissirostres*, differs from that of all other birds, is the equality of the three front toes, and the reversibility of the back one. In most birds the middle toe and the external front one, have each four phalanges of bone, while the inner one has only three, and in some of them, more particularly in the zygodactylic birds, the feet of which remain yet to be noticed, the outer toe is reversible backwards, so that it acts in concert with the hind one and in opposition to the other two. But in the crab foot, the back one is reversible, so that all the four points can be turned forward, or rather into the circumference of a circle, in which the articulation of the toes with the tarsus forms a fifth point.

The feet with the reversible outer toe, have the strongest action in opposite directions toward the centre of the foot, and therefore they grasp firmly any substance to which that is applied, although the tarsal joint is straight, or even the bird suspended by the leg at full length, or standing up with it in the same position. But the greatest action of the crab foot is concentrated upon the articulation of the tarsus in one direction only, and that is the direction against which the weight of the bird pulls. The tarsal, and also the tibial joints are bent as far as they will bend, when these birds hold on upon the upright surface of a rock or wall, and the articulation of the toes is, at the same time, in contact with that surface. Therefore, if there is the least hold for the points of the claws, the strain upon them is always such as to make them retain that hold the more firmly the greater the strain.

Upon carefully examining these feet, of which the most perfect is that of the swift, a figure of which will be found in the sequel, it will be perceived that, while the spread of the toes gives great stability to the individual foot, the two are, when the bird hangs, or adheres by means of them, so placed as that the greatest resistance of each is in the direction of the centre of gravity of the whole bird, so that the weight actually draws them into close contact with the surface of which they have hold. If in common mechanics, it were required to find an instrument consisting of hooks which should be the best for holding on against a strain, parallel or nearly parallel, to the surface on which it held on, the very best model would be the foot of the swift. The pull upon the individual toes, being toward the point of their general articulation, draws them together so that they clutch the surface upon which they have a hold; and then the strain of the bird's weight pulling upon each foot toward the centre of gravity of the whole body, acting in two lines, which, produced, pass a little outwards of the average hold of the feet, makes the whole bird hold on with the feet, as if it were grasping or embracing a substance between them.

The goat-suckers, being more woodland birds, have the feet better adapted for perching on twigs or other horizontal supports, than the swallows. They have a short membrane, connecting all the anterior toes at their bases, and the middle front toe is longer than the others, and the claw pectinated.

There have been various speculations about the use of this pectinated claw, some of them more and some less ingenious, but none of them very much to the purpose. That it does not in any way assist the bird in perching, is proved, not only by the fact that the toe which has it does not close so completely on the terminal phalanx as the other toes, but by the general principle in nature that animals never hold on firmly by means of teeth or pectinations in one continuous inflexible member, in maintaining the stability of their own position. A single adhering point to each moveable part of the organisation, is that which makes the hold the most secure, because it is the one which allows the greatest play in all directions. Accordingly, in the articulation of animals, whenever we find a joint upon which there are to be cross motions, we always find the socket, and the head which plays in that socket, simple, while, in those which have motion in one plane only, the head and socket are often both double, and not unfrequently ridged in addition.

The speculations which have been made with regard to the use of this pectinated claw, are hardly worthy of repeating. That of White is the most sagacious, because most agreeable with the general analogy of nature. He says merely, that it appears to be to aid the bird "in taking its prey;" as the heron holds its slippery prey with a pectinated toe, and mergansers and several other birds hold theirs by serrated mandibles. But it has been also said that this toothed claw is used in trimming the vibrissæ or hairs at the sides of the gape, and also in clearing the bird of troublesome insects.

The hint thrown out by White is that of a naturalist—of one who seeks a new use for a new form of organ; the other conjectures hardly deserve that character, as they point at no additional use for the additional structure, inasmuch as there are birds with plain claws which live on similar food, and are more infested by nirinides than the goat-suckers. White's hint points to inquiry, the other conjectures do the reverse—they lead from nature to art.

The goat-suckers themselves, though otherwise noisy enough, are silent upon this subject; and as the mode of their preying, from the time at which it usually takes place, is not very open to observation, it is difficult to come at the truth by observation. But, from the time, and, as far as it can be observed, the manner of their feeding, the goat-suckers must feed upon beetles and moths, insects on which there is a considerable quantity of substance not available as food; and as, though there are *some* points of resemblance between goat-suckers and owls, no mention is made of the former returning the elytra of beetles and the wings of moths in castings, as the owls do the indigestible parts of their prey, it is not improbable, though certainly not proved, that they may use the pectinated claw in removing the indigestible parts before they swallow the rest. It avails little, however, to speculate upon the use of a structure which we have so limited means of observing; but we may observe in passing, that though Wilson saw these birds scratching their heads with the pectinated claw, that proves nothing as to the specific use of the pectination, because birds which have not their claws pectinated, scratch themselves in a similar manner, and this one cannot alter the form of its claws while performing this operation. It must, to use a homely phrase, scratch itself with such claws as it has; and as no bird appears to have claws specially formed for this secondary purpose, the analogy is against such being the principal intention of this toothing of the claw of these birds.

Upon looking back at the figure of the goat-sucker's bill, it will be perceived to be very *fissirostral;* and that, though it might be capable of transfixing a tough coated insect with the sharp points of the mandibles, it cannot bruise any thing between the tomia. The sharp points are obviously for capture; for though there are vibrissæ along the edge of the upper mandible, there are similar hairs at the junction of the upper mandible with the front, where they cannot by any possibility assist in the capture of the prey, and there are also similar bristles at the base of the bill in many birds which do not catch insects or any thing else with the bill while they fly open-mouthed; so that it is at least probable that while the coleopterous insect is seized and held between the hard and sharp points of the mandibles, the parts that are unfit for food are stripped off by the pectinated claw of the foot, which is certainly borne less bended, or in advance of the other claws. The following figure is an accurate representation of the foot of this bird.

Goat-sucker.

The swallow-tribe all have the foot less firm as a perching foot, that is, less connected by membrane between the bases of the toes, than the goat-suckers; and the articulations of the toes with the tarsi have more of the ball and socket form, and consequently admit of more motion. This motion increases, and the tarsus and toes become shorter, and the claws more crooked, from the lowest building swallows to the swifts, which have the most perfect crab foot, that is, the one best adapted for individually holding-on upon slight inequalities of a perpendicular surface, and at the same time the least fitted for perching on a twig, or walking upon the ground, for which last office they are not at all fitted, and the birds are consequently quite helpless there.

The feet, admirably formed as they are, are not the only organs by means of which these birds maintain their perch upon perpendicular surfaces. The flying feathers of their wings and tails are remarkably stiff in the shafts and firm in the webs; and though they cannot, of course, take hold with their feathers, unless when they, as it were, embrace a projection, yet the pressure both of the wings and tail assists in tightening the hold taken with the claws; so that, even though the surface to which they cling overhangs, these birds can stick to it very firmly. The annexed figure of the swift's foot will show the structure.

Swift.

Anisodactylic feet.—As "crab" feet, more especially in that form which they have in the swallows and swifts, are the best fitted for holding-on while the body generally of the bird is steady, upon an upright or an overhanging surface, so feet of the form now to be described are the best adapted for motion upon such surfaces. Birds which have them are all, generally speaking, tree birds, or at all events woodland birds. But, like the birds with feet of the immediately preceding form, they admit of subdivision into those which feed more exclusively upon the bark of trees, and those which feed more exclusively on the wing. They are the same or nearly the same as the tenuirostres of Cuvier.

But, although that illustrious naturalist has taken the form of the bill as their distinguishing character as a tribe, and though their wings, which are in general very powerful, might also be made both a general character of the whole and a means of dividing them into different sections, yet the foot is unquestionably their most prominent and remarkable character. Their feet are entitled to the preeminence, not because they are, as in those birds which cannot fly, the only active organs except the bill, and not because they are efficient organs of locomotion upon the ground; for, generally speaking, these birds are not only very bad walkers, but they are seldom, if ever, found upon horizontal surfaces. Indeed they are not at all adapted for such surfaces, and those of them which have their own peculiar feet in the greatest perfection, are as helpless upon the ground as the swifts.

But their feet can adhere to, and, with the assistance of the wings, move along any surface, be its form or position what it may. Those which are bark birds can run along the boles of trees, upwards, downwards, or round by a circular motion; and others, again, can hang by the feet to the petals of flowers, while the bill reaches the bottom of the nectary, and sips the sweet juice which accumulates there, as is well exemplified in the humming-birds and the nectar-suckers.

The structure of foot, by means of which this singular command of all manner of surfaces is obtained, is apparently a very simple one; and if we had not so many instances in nature of the cleverest action performed by organs apparently the most simple, we should never imagine that the apparently small difference of structure that there is between the feet of these birds, and the feet of birds which cannot climb at all, could be sufficient to effect so great a difference of action. The ordinary appearance of the foot, when in a state of repose, is three toes to the front, and one behind, the same as in an ordinary walking foot, only the middle and external toe have a union at their bases which appears to be something more than a merely membranous connexion, like that of many of the insectivorous birds. It is, however, in these two toes, their union and the peculiar mode of their articulation, that the whole peculiarity of the foot, that to which it owes its wonderful climbing power, consists. These two toes form a sort of second foot, which can act upon its own articulation in opposition to the two remaining ones, that is, to the interior front one and the back; and the joint by which the two are articulated on the tarsus admits of so much and such varied motion, that the one part of the foot can act in any direction against the other. Owing to this, the action of the foot is universal as to direction, parallel to the axis of the body, or almost at any angle to it. Thus the birds can run upon the bark of trees in any direction, holding on upon the irregularities of the bark with each foot, and at the same time embracing the convexity with both. This can be easily understood, when it is considered that both the recurved toes of each foot press inward towards the centre of the body; and this action of the two feet in opposition to each other converts them into a sort of one clutching foot, which acts without any direct exertion of muscles, and therefore holds on for a long time without being in the least fatigued.

Anisodactylic feet are thus formed for concentrating their action upon the centre of the body, without any reference to the direction in which the weight presses, just in the same way as the crab feet of swifts concentrate their action so as to support the centre of gravity in the most effective manner.

The best native example which we have of a bird with this clever species of foot is the creeper, or the common tree creeper (*Certhia familiaris*). It is a very small bird, the smallest that we have in these islands, with the exception of the crested wrens, which, like it, are tree birds, and very clever on their feet, although they are perchers and not climbers. It is a resident bird in Britain, and by no means a rare one, and its motions upon the trees are well worthy of observation. The direction in which it runs (for its motions, though aided by the wings, have more the appearance of running than of any thing else) appears to be of little consequence. Upwards or downwards upon the bole of the tree, outwards or inwards upon the branches, with the back or the belly uppermost, appear to be all the same to it; but, from the celerity of its motion, and its diminitive size, it is not easily seen. The nuthatch, of whose foot a figure is annexed, is the only other species resident in Britain, though the hoopoe, which is a very handsome bird, with feet nearly of the same character, appears not unfrequently as a summer visitant.

Nuthatch.

The hoopoe differs, however, in many of its habits, for it is more of a water bird than a frequenter of trees, and its bill is incapable of performing labours so severe as those of the nuthatch, or even of the creeper; for though the last is an insectivorous bird, and not able to hew the shells of nuts to pieces like the nuthatch, it has to dig its food out of the crevices of trees.

The different substances upon which birds with feet of this structure feed, is strong evidence against the classification of them by the form of the bill; because, if such a classification is to mean any thing, it should mean similarity both of food and of manner of feeding. But though most, if not all, of the birds which have feet of the structure under consideration have slender bills, their food is very varied, and the only habit in which they all agree is that of being able not only to adhere by the feet, but to move about upon almost any form of surface, or in almost any position.

Considered as mechanical structures, acting in concert with the whole organisation of the birds, these are, perhaps, the most extraordinary of all the varied forms which birds possess. They act in concert with the whole structure of the birds; and thus, though the mechanical contrivance that appears in them, taken singly, is not very striking, yet it becomes remarkably so when we consider bird and foot jointly, and notice how the varying pressures which the weight of the body gives in all the numerous positions which it can assume, contribute almost equally to render more firm and sure the hold taken by the feet. One of the greatest beauties in those displays of the mechanics of nature, and one of the greatest superiorities which they evince over all that human ingenuity can contrive, is the wonderful simplicity with which what, to us, seems the most difficult of all purposes, is accomplished. When we have a mechanical difficulty to overcome, we complicate part upon part, and often defeat our object, because the artificial clogs and hinderances which we thus produce, are greater than the difficulty which we sought to overcome; and thus we produce a negative effect instead of a positive one, and are further from our object at the end of our labour than at the beginning; but when we examine nature, we find that the very difficulty itself becomes one of the most effective means by which it is overcome,—as in the case of these singularly footed birds, the weight which the feet have to sustain is actually converted into a means of sustaining it.

Scansorial or climbing feet.—The principal object to be accomplished by these feet, is not simple adherence to an upright overhanging surface, as in the case of the swallows and swifts, or progressive motion along the boles and branches of trees, as in that of the *anisodactyli*. It is, in the more perfect specimens, motion from branch to branch, and in the others stability on the boles of trees, with the body in an upright position. Feet which accomplish these purposes are all *zygodactylic*, or yoke-toed, that is, they have the outer toe very readily reversible, so that the foot presents two toes to the front and two to the rear, both nearly of equal power; and where there is a different function to be performed, that is done chiefly by modified articulations of the other parts of the foot and leg.

The extremes of this kind of foot are perhaps those which are found in the woodpeckers and the parrots. The woodpeckers are trunk birds, and when upon trees, they are insectivorous; the parrots, on the other hand, find no food upon boles or large branches, but subsist chiefly upon fruits, and ramble about among the smaller twigs and sprays in quest of them. Thus, though both are climbers, they climb so very differently, that when they are described as birds of the same habit, a person who knew only one of them would be apt to form a very inaccurate notion of the other. The woodpecker cannot climb as the parrot climbs, neither can the parrot climb as the woodpecker. The woodpecker is a bark bird; and though it can adhere to the bark of a tree, so as to leave its bill, neck, and head free for other action, it cannot adhere in an inverted position; and unless the crevices of the bark are particularly favourable for its claws, it must use the stiff feathers of the tail as a prop. Whether it requires to do this or not, it must always bend the joints of the leg so as to make the claws hold with the requisite firmness. Its foot is in fact a sort of double crab foot, the two parts of which hold on in opposite directions. It is by the claws which are turned to the front that the weight is suspended; and those which are turned to the rear, have their principal action in tightening the hold of these. Then the line of the body and tail acts in the same manner as a diagonal strut under a beam; and every one knows how small a hold in the wall will support a beam if such a strut is applied to it. The painter's scaffold, used in cleaning or repairing windows high above the ground, which one sees every day in the streets, acts upon a principle nearly similar to that of the woodpecker. The following is the position of the foot when in the act of holding on.

Woodpecker.

The foot of this bird has other functions to perform besides keeping its hold on the bark of trees. It is an insect-feeder, and at certain seasons these are much more abundant on the ground between the trees, than in the trees themselves. The seasons when the larvæ are in the bark or the decaying wood, and when the mature insects resort thither to deposit their eggs, are those at which the woodpecker is most active upon the bark; but there is an intermediate time during which the bird is on the ground picking up beetles, and especially ants, which last are gregarious or social insects, and great frequenters of forests. In temperate countries, woodpeckers answer, at those times, nearly the same purpose which ant-eaters answer in more tropical climates.

This habit in the woodpecker requires a command of itself upon the ground for which the parrot has no necessity; and which, indeed, would be incompatible with perfection in that peculiar structure of foot which the parrot requires. Accordingly, although the woodpecker does not require to be a runner, inasmuch as food for it is very abundant at those times when it is on the ground, yet it stands well on its legs, and is a tolerable walker; while on a level surface the parrot makes sadly shambling work of it—much like that of a climbing ape, and it very soon gets fatigued, which the woodpecker does not.

Though three toes before and one behind, all free at their bases, be the normal foot for a continued slow pace on the ground, yet the form of the toes is not that which constitutes a walking foot. The relative lengths of the bones, and more especially the articulations of the foot and leg, are the chief points which render the foot either a good walking one or not. If these joints have these motions only in the vertical plane and parallel to the mesial plane of the body, without any lateral flexure, then the bird will walk firmly; and whether its march shall be quick or slow upon one kind of surface or another is made out by the details, the relative length of the member, and the form and magnitude of the toes and claws. If a man has his knees or his ankle-joints with lateral play, or with a twist inward at the knees, or more especially with a twist either way at the ankles, he walks never a bit the better though his feet may happen to be, as is often the case with inward-twisted ankles, as broad as shovels. It is also impossible even to imagine members more finely organised for their proper use than the toes of long-armed apes and spider monkeys; and yet, from the twist of the ankle, which is an outward twist, or one which turns the sole of the foot inwards, they walk not only with great awkwardness but with great pain.

The articulation of the toes of a bird, answers in anatomical arrangement to the ball joints of the toes in man; but in the act of walking it answers to the ankle-joint. If this joint is firm, and the joints above it so articulated as that the weight of the bird comes perpendicularly upon its centre, then the step of the bird will be firm; but if this joint is loose, or even if the strain takes it in an oblique direction, the bird will wriggle or waddle, and waste in rolling from side to side great part of that muscular exertion which would carry a better set bird straight forward on its way. The woodpecker is straight and firm on these articulations; and even its capacity of holding-on upon the trees, requires that it should be so. It is not, as we have seen, a clutching climber, which holds on by grasping with the foot,—for even when the woodpecker perches upon a branch for repose, it does not perch across, as most perching birds do, but lengthways, or with the axis of its body parallel to that of the branch,—it holds on by a combination of mechanical resistances, acting all in the same plane, though in different directions; and therefore any lateral motion in the joints of the foot or leg would turn that foot into an instrument of positive instablity—a crowbar to wrench the bird from the tree.

But when we consider the style in which the parrot climbs, we can easily perceive that that looseness and twist, of the articulation of the toes especially, which make it so bad a walker, are the very best for its proper habit. It is the same with the twisted-limbed mammalia to which allusion has been made for illustration; they could not have performed their part in the system of nature, unless they had had that very formation which makes them appear so awkward when out of their proper sphere. When we come to notice the feet of the water-birds, we shall find instances of structure differing from each other to the same extent, and nearly in the same manner as these differ; and if it lay within our province, we could easily show the very same differences of adaptation and use, and the same perfect accordance of the one with the other in all animals endowed with locomotion, whether vertebrated or invertebrated, and whether of the magnitude of whales or the minuteness of animalculi. Throughout the whole there is the most complete evidence of mechanical perfection, always competent to effect its purpose without supplemental aid. And among most of those cases, probably indeed in every case of an articulated animal, whether articulated internally in the skeleton, or externally in the crust, where it has been supposed that suckers and cements and other clumsy contrivances have been resorted to in order to enable the animal to keep its hold, a very few simple claws, or elastic pads, applied with nature's mechanical skill, are not only all that exist, but all that is necessary, and that more would be an absolute incumbrance.

Those attempts at explanation by such supplemental aids as have been alluded to, are found in numbers in very many of the books (even those of no measured pretence) which profess to treat of the mechanics of the living world. But the accounts of such structures always point out the origin of the structure: it is a bungle; therefore it is the work of man: were it the work of God, it would be perfect in its single and simple organisation, and more, even could it be added, would overload and weaken it, just as a machine of human invention is overloaded and weakened when it consists of too many parts. That joiner is a bungler in his art who must upon all occasions use the glue-pot; and that is the most perfect piece of carpentry which stands firm without glue or nail or any other supplemental fastening; and when we come to nature we find no such fastenings; the parts themselves have the requisite form, the requisite adherence to each other, and the whole, by means of its own organisation, has the necessary adhesion to whatever kind of surface is to support the animal in its ordinary motions.

And here, as the subject presents itself naturally in consequence of the explanations which have been given of these feet, we cannot resist calling the attention of such readers as may not generally be in the habit of attending to such subjects, to the very wide and wonderful field for mechanical study which the animal creation presents. Yet ample and apparently exhaustless as it is, it is all acquireable knowledge, as far as the telescope can survey in the one direction, and the microscope in the other.

The organisations of animals do not partake of the unseen and therefore the mysterious nature of that energy of life by which they are evolved and put in motion. They are, in all their parts, wholly material, and every motion, and every position of rest, of which they are capable, admits of as certain explanation—an explanation as simple, if we would go the right way to it, as the putting of a common balance in equilibrio, by placing equal weights in both scales. A leech may proceed by suckers, but no animal proceeds thus, unless its principal action in motion is a lengthening and shortening of the body; and when we say of a swift-footed animal, that it must pause at every step, and either fasten its foot by glue, or by pumping out the air from under it, we afford a very certain proof, not only that we are imperfect in the knowledge of nature's mechanics, but that we do not understand the meaning and application of those common laws of mechanics, which are set down in the books, although we may be able to parrot the enunciations. When we do not understand by what means, or in what manner, an animal, or a particular organ of an animal, which is new to us, and, philosophically speaking, everything which we do not understand is new to us, though we should have been in the habit of seeing it daily for the longest life—when we do not thus understand, the most candid, and by far the wisest plan, is to say so, because all mankind like candour in others, and thus we win the applause of the whole world, without any admixture of that envy or jealousy, which is just as apt to follow a false discovery as a true one; and besides, we leave uncloyed, and in full vigour, that appetite by which alone we may come at the true knowledge. But to return to the scandent feet.

The foot of the parrot is a foot which climbs by clutching—a "tying" foot, as one would say—and not one which holds on by a combination of "counter-strains," like that of the woodpecker; and it is so, in order that the owner may find its food in situations where a woodpecker, or, indeed, any bird differently organised to a parrot, could not subsist. The pasture of the parrot is among the sprays or smaller twigs of large spreading trees, and not exactly at the extremities of them, because the fruit which is fit for the parrot's eating is rather farther in, there being a new shoot beyond the fruit before it is ripe, in most fruit trees, and a new shoot with green fruit, and often another with blossoms beyond it, in many of the fruit trees in parrots' countries. Besides, many of those trees bear their fruit at the axillæ of the twigs or leaves; and as the same point of a vegetable never blooms or fruits twice (so that the most perennial trees in duration are really annuals in their most important functions), the successive fruits or flowers are, even in these, without the place where the parrot feeds. Some of the allied genera alight on the tops of the trees, but these are the long-tailed ones, which are better winged, more in the habit of flying, and less expert climbers than the true parrots; and even they do not penetrate so far into the sprays as where the parrot feeds, and they feed upon fruits of a different character—fruit of which the pips, not the pulp, is eaten.

Now, any one who examines a tree, when so cleared of leaves as that the twigs can be seen, must perceive, that at about the situation of the previous year's shoots, the twigs, even when leafless, are so tangled, that no bird half the size of a parrot could use its wings among them, unless to pass through at some opening; but the parrot has to range the tree in all directions at the very part of it where wings cannot be used; and it has to range minutely, because there are always leaves upon those trees, and the leaves of tropical trees are often broad and close. Thus, though the parrot is a tree bird, it seeks its food much in the same manner as a partridge seeks among the corn, or a grouse among the heather; that is, by comparatively slow motion, and prying about on all sides as it goes along. Consequently, the organisation most essential to this habit is the one which enables it to get most readily from twig to twig without the use of its wings in any other way than partially opened to assist in keeping its balance.

The foot, to possess this property, must have the whole of its prehensile action in the toes; and the leg, instead of maintaining one invariable position in assisting the foot in holding on, must be free to move to its utmost stretch in all directions. It is also evident, that unless the parrot could hold on by one foot, and hold on with that foot in any direction, above it, below it, or laterally, it could not make its way; and even in addition to this, the bill of the parrot is prehensile, and affords the same assistance to the feet as the prehensile tails of those climbing mammalia and reptiles which have that character.

To accomplish these purposes, the joints in the leg and foot of the parrot must have rolling or oblique motions, in order that, while it holds on with the one foot, it may extend the other as far as its length will permit in any direction; and it is especially necessary that the joint at the articulation of the toes should turn the foot outwards, because that is the best position for its readily laying hold. When the necessity that there is for its action is known, the action itself may be easily inferred from inspection of the annexed figure.

Parrot.

Swimming Feet.—There are not so many diversities of form in the feet of aquatic birds as in those which inhabit the land, whether they seek their food on the earth itself, or upon vegetable substances. The element is the same, or nearly the same, in all water birds, so that the only thing which remains to which the feet have to be adapted is the difference in habit among the birds themselves. There is, however, one difference of element which requires a corresponding modification of the foot: there are some birds which are very exclusively in the water, and, as such, water birds, in the form of their bodies and the manner in which their feet are articulated; but they frequent those waters which are full of the stems of reeds and other aquatic plants, among which the structure of foot which is best for action in the clear or open water, would, of course, not be the most convenient. The foot for action in the open water is a continuous web of membrane between the toes, which varies with the habit of the bird; but among stems this web could not be so conveniently used, as it would be liable to get entangled or interrupted, if not torn. Accordingly, these birds have the toes only lobed, so that they can be drawn through between the stems with the less opposition. Some of the birds which have these partake of the character of shore or bank birds, and can walk upon the land as well as swim upon the water. These are the coots and phalaropes, which continue the succession from the gallinules, which, through the landrails, have some relation to certain species of the gallinaceous birds. They, when on land, carry the axis of the body in nearly a horizontal position; and the lobes on their toes are divided into segments answering to the phalanges. Of these the foot of the common coot is an instance.

Grebes, though chiefly frequenters of fresh water lakes, have much more aquatic habits. They have the body of the true canoe shape, and the legs articulated so far backwards, that they cannot support the axis of the body in a horizontal position upon land. They accordingly walk with the spine nearly erect; they walk with difficulty, and are never found far from the water. Their feet have complete lobes to all the toes, and even the tarsus is flattened, and has a membranous margin, so that the foot is a swimming foot all over, though one adapted to peculiar places. The articulations of the tarsi have a rolling motion, and those of the tibia also work outwards when the feet act in swimming. The looseness of these two joints renders the bird incapable of moving along the ground with the legs steady; and this, more than the mere form of the lobed toes, is the reason of its being so bad a walker.

But the feet are admirably fitted for aquatic motion. They turn their thin edges nearly in the direction of the resistance when they are drawn forward, but they strike back with the full breadth of their webs, and they can turn on the joints so as to give the stroke in a variety of directions, and thus impel the body upon any course which may be necessary to the bird in following its prey in the water. The wings also come into action in swimming, though more as points of support, against which the legs act, than as propelling organs. But the birds are altogether excellent swimmers, or rather coursers through the water with great speed. They do not dabble like ducks, but plunge freely into the water, and dash along, not by alternate strokes of the feet, as in a common walking motion, but by striking with both at once, as a frog does. It is to enable them to perform this motion that the wings are brought into action as well as the feet; and the same kind of motion could not be performed, and the intended course kept, without the wings. This is, in part at least, the reason why those aquatic birds, which are incapable of flight, have the wings, though destitute of flying feathers, much more produced and capable of motion than those of the running birds upon land. The different styles of motion through the water, whether on the surface or below it, can, however, be more briefly, as well as clearly explained, when we come to consider the habits of those birds which have entire webs on the feet, and range the water in places where they are not liable to interruption from the stems of plants.

Grebe.

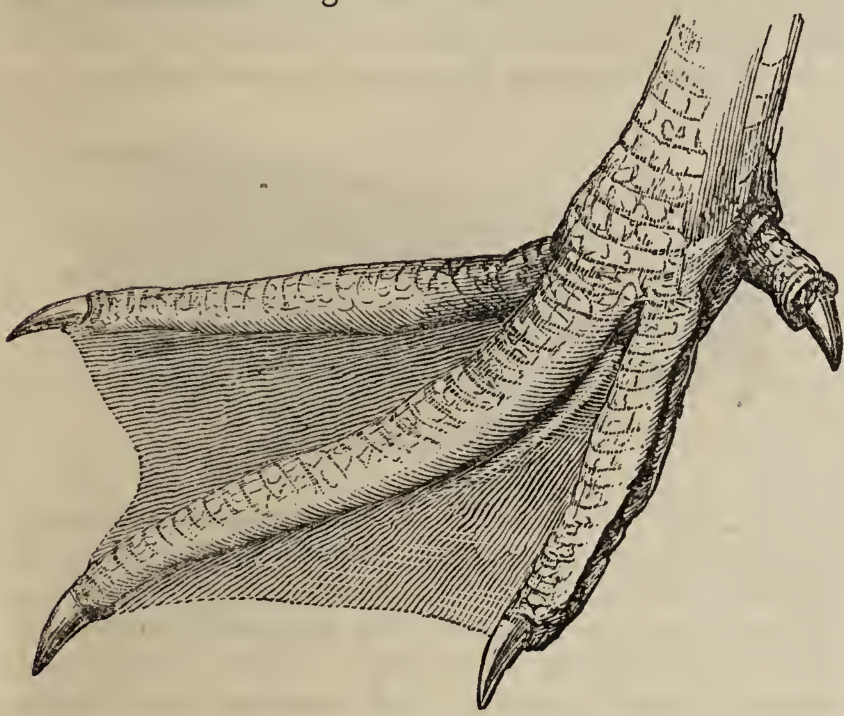
What may be considered as the normal swimming foot consists of three toes directed to the front, and one small one to the rear. There are always webs of membrane between the front toes; but in the species which swim only and do not dive, there is no web to the hind one. Divers have it marginated with a small web; those birds which Cuvier styles *totipalms*, or entire feet, have the hind toe much longer and stronger, and included in the same web with the anterior ones, and they have the whole foot turned in a particular direction, the purpose of which will be explained afterwards; and there are some genera which are in the habit of tipping the surface of the water with their feet, while their bodies are nearly or altogether supported by the wings in the air, and these have the hind toe merely rudimental, and the foot narrower in proportion than any of the others.

In order clearly to understand the uses of the different forms of web feet, it is necessary to consider the other actions of the bird to which the foot must be subservient, or at least with which it must be in accordance. These actions are of course either walking or flight; though they also admit of modification. Thus, if the sea-bird alights only on solid surfaces, it requires the feet to be somewhat different than if it alighted on soft ones; and if it dash at once down on the water from high flight, it requires the feet to be different from what would be more convenient if it launched itself in a direction nearly parallel to the surface. Also if the bird is in the habit of walking much, it is necessary that the feet should retain a considerable degree of that action of all the joints in one plane, which we have already shown to be necessary to the stability of a walking motion. If the bird combines the three motions of walking, flying, and swimming, in nearly equal perfection (and there are many birds which do so combine them), it is necessary that the feet should have a different structure; and if the motion is in the water only, the structure of the feet requires still to be modified according as it is more of a straight forward motion, or of an ascending and descending one.

There is, however, no bird with webbed feet which can have that perfect adaptation of the feet for walking, which is possessed by ground birds upon land; because every bird with webbed feet is a swimmer; and though the swimming motion should be merely a modification of the walking one, that is, by alternate strokes of the two feet and never by both at once, yet the articulation necessary for swimming is somewhat different from that which answers best for walking; because the swimming feet must throw out a little in order to clear the body, and this very throwing out, which does not cause the body of the bird to vibrate when it is supported by the water, does make it vibrate when it is in the air. Sea birds as well as sailors, may thus be known by the style of their walking; and though the causes be different, and the one habit and the other structure, there is such a resemblance between the rolling motion of the seafaring bird and the seafaring man, as alone would, to careful observation, point them out as dwellers on the same element.

The web-footed birds which may be considered as the least aquatic, at least among the flat-billed division, are the geese, especially such of them as, like the domesticated goose, graze the meadows, or otherwise find the greatest part of their food upon land. These have most of the walking character in their feet; and when they swim they never use any other than the walking motion, or that of paddling alternately with the feet.

But the body of the goose has a sort of boat, or rather punt shape; the sternum extends far backwards, and the tibiæ are so articulated that the tarsal joints project much farther from the sides than they do in land birds. Thus, though the axis of the body is borne in a position nearly horizontal, the advance of the foot, wide apart as the feet are from each other, does not carry the centre of gravity directly forward, but swings it round; so that, unless when the motion is very slow and the bill in contact with the ground, as is the case in feeding, the goose swings along with not a very graceful motion. Besides, though geese in their domesticated state are not much in the habit of flying, they are birds of long-continued and moderately rapid flight when in a state of nature. From this combination of feet and wings, and adaptation of the feet both to walking and to swimming, these birds have their muscles distributed over the body much in the same way as common poultry, and thus neither their feet nor their wings are very remarkably characteristic. The foot is a swimming foot of the simplest kind, and may be understood from the annexed figure.



Common Goose.

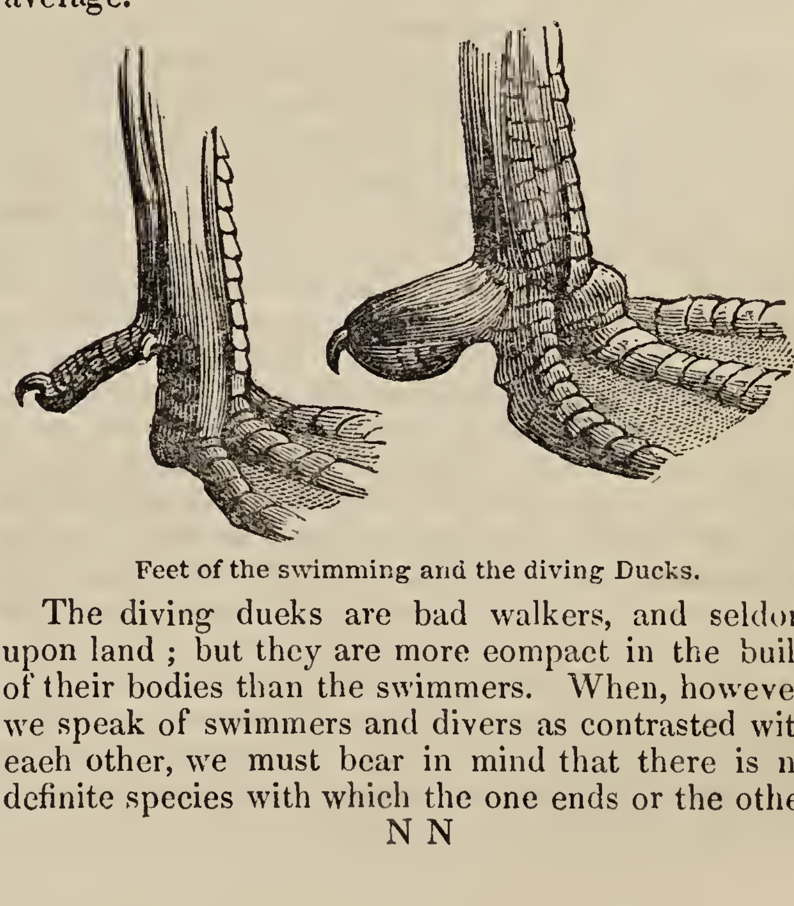
All merely swimming birds, which float along with part of the body above water, have the motion of the feet more nearly in the vertical plane than the divers. But there is, even in them, a very beautiful action of the foot, brought about by the mere bending of the leg, without any additional exertion of muscular power. The moment that they begin to draw it forward, after it has made the stroke, it begins to contract, by the bending of the tarsal joint pulling the tendon. The surface which the foot presents to the water in the direction toward which it is pulled, is thus not only constantly diminishing, but it is convex in its form, and yielding as the joints are relaxed, so that it "comes home" through the water with very little effort on the part of the bird. When, however, it begins to act in the taking of the stroke, it presents the concave side, and that side keeps enlarging till, at the time when the stroke is given, it has attained its greatest breadth. It then comes to nearly a horizontal position of the feet, and from this it is drawn forwards with not much more breadth than the edge to the water.

This foot is exactly a paddle, only it acts better both on the stroke and the return than any paddle which man can construct. No doubt the paddle which man uses is recovered through the air, and thus the resistance of the water is wholly avoided during that part of the operation. But still the exertion which has to be made in raising the paddle is much greater in proportion to the effect produced than that made by the foot.

The swan, though nearly or altogether equal to the goose in flight, is much less upon land in its ordinary habit, and it is accordingly better adapted for swimming, and, as a necessary consequence, a worse walker. Swans, indeed, stand in much the same relation to geese (taking them on the average) as the diving ducks do to the swimming ones. Their tarsi are shorter, the webs of their feet larger in proportion, and the joints have rather more oblique motion. As neither dive, the comparison of them is of course made as surface swimmers; and the attitude of the swan upon the water has been a favourite theme with poets and picturesque describers in all ages: and the bird is stately as well as graceful, both when it moves with closed wings and smooth plumage against the breeze, and when it hoists sail, and takes the wind in its raised wings, to aid or relieve the labour of its feet. From its beauty, its size, and its tameness, the swan is the best subject in which to study or observe the action of surface swimming. All its evolutions upon the water are worthy of notice, and its style of doubling and of backing is particularly so.

All those surface swimmings in which there is smooth motion are of course made with the alternate foot; for, as the feet are considerably in the rear of the centre of gravity, if the bird was to attempt leaping on both without something to hold on, the hinder part would be jerked out of the water, and the fore part plunged into it, by which means the progress would become both unseemly and fatiguing. When alarm, or any other cause, impels these birds to more rapid motion along the water than they can accomplish with the ordinary swimming motion at its full stretch, they take to the wing, and if they do not get so high as merely to tip the water with their feet, as the skimming birds do, they make the same flutter, and generally utter painful cries, as barn-door fowls do when forced to the wing.

The swimming ducks are less upon the water than swans, as a considerable part of their food is found on land, and they are incapable of reaching the bottom in so deep water. Their bodies are also not quite so well trimmed to the action of the swimming feet, and they labour and wriggle more both laterally and vertically, so that, though they can float about for a considerable time, they are much sooner tired when they attempt to swim upon a stretch. These ducks have the tarsi longer, the toes shorter, and the action of the foot in swimming not so much to the rear. The sheldrake is the most landward; but the foot of the common duck is perhaps very nearly the average.

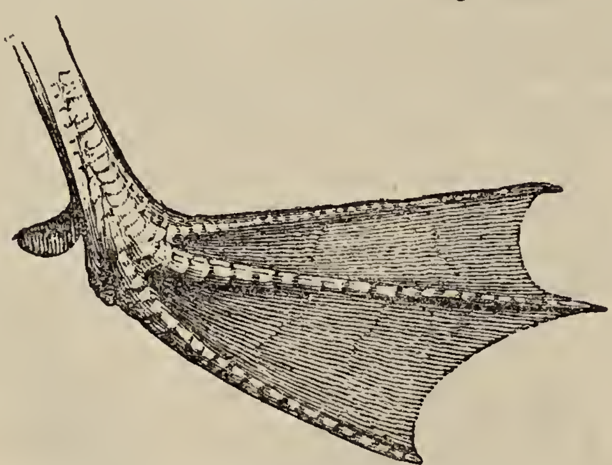


Feet of the swimming and the diving Ducks.

The diving ducks are bad walkers, and seldom upon land; but they are more compact in the build of their bodies than the swimmers. When, however, we speak of swimmers and divers as contrasted with each other, we must bear in mind that there is no definite species with which the one ends or the other begins; for there are species in the middle of the group, partaking in nearly an equal degree of the habits of those at both extremities. The divers have the tarsi short, the tibiæ rather lengthened, which throws the joint of the tarsus backward; the toes and webs larger, and the hind toe with a little web. They do not dive habitually; for though they are less fitted for dabbling than the others, they do practise it a little, and they also feed along the strands; but they often appear to get down for change of motion, as well as for food; and on such occasions they move more quickly below the water than they can on the surface.

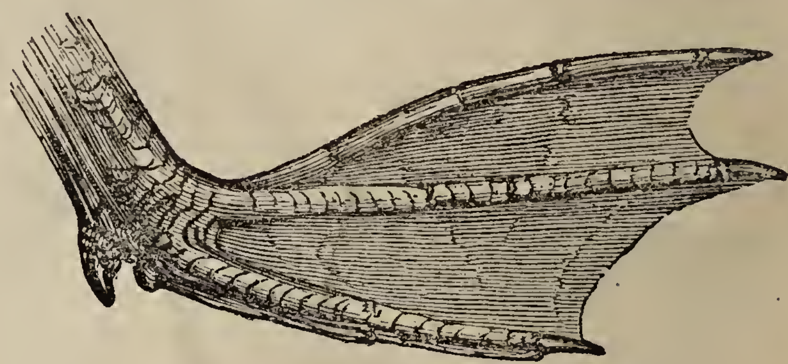
Of course when they are once down, and the water has closed over them, there is no more paddling with the alternate feet. That is properly a land motion, and can be used as the sole means of progression only when part, at least, of the body is in a rarer medium than that against which the foot acts. Thus, when the bird is under, it immediately brings all the four extremities into action, in the same manner as is done by frogs, water-tortoises, and all other animals which have four extremities and swim immersed.

This is the style in which man swims, and also those mammalia which have not a trotting pace between the slow walk and the gallop, the common pig for instance. It is also the style of all aquatic mammalia, and indeed of all vertebrated animals which inhabit the waters; for those which have no fins of any sort cannot advance with one flexure of the body, but must twine in two or more, eel-fashion, according to their length. The golden-eye is the duck, visiting the British shores, which has this action in greatest perfection; and the following is the figure of its foot.



Golden Eye.

But even in the birds last mentioned, progressive motion under water is only an occasional action, and therefore they have it not in the finest style. The grebes which, notwithstanding their merely lobed feet, and their inhabiting ponds rank with vegetation rather than the ocean or even the larger lakes, are much more aquatic than the golden-eye; and the rate at which they get on under water would not be believed by those who have not actually seen it. It is frog-like, to be sure, from the way in which the feet are worked, and the nearness to which the plane of their action approaches to that of the body, but it more resembles the rush of a bird through the air than the swimming of any ordinary air-inhabitant in the water. Among all the diving birds, from the merganser to the penguin, which, although not the swiftest, perhaps, in the water, is the one which depends most exclusively upon aquatic motion, there is not much difference in the feet, so far as can be shown by a figure. The chief distinctions consist in the legs being placed further backward, and the tarsi being shorter and stouter, the more exclusively that the bird is restricted to the motions of swimming and diving. The joints have also more oblique motion, and there appear to be some peculiar muscles upon the tarsus, which assist in the curious twisting motions of the feet, which of course increase as the wings become less efficient as organs of support and balance. But the most curious motions of these birds are all performed in the sea, and under water, so that they are rarely seen, and the subject is one upon which it is by no means safe to speculate, as we have not upon land any analogy to which we can trust. The following is a sketch of one of the feet; but we should not be able to illustrate the mode of action, even if we gave ever so accurate a figure of the bird itself.



Diver.

The feet which have been now described, or rather simply noticed, carry their owners down into the depths of the ocean as far as winged creatures can descend; and as the knowledge of them is nearly as dark and downward as the places of their resort, it is rather pleasant to escape from them, and once more visit the sun and the sky, the cheerer and the abode of the more typical birds.

We have, next in order, to notice those feet which are entirely webbed, that is, which have the hind toe included in the web as well as the three front ones. At first, one would be apt to conclude that these, as being the most webbed, are the most aquatic, or the best swimming feet of the whole. But such is not the case in fact; and when we come to consider the matter a little more closely, we find that such ought not to be the case, according to the structural analogy. The back toe of a bird, whether its path be upon the land or the water, is never an auxiliary to the foot in merely progressive motion; it is always rather the reverse, and placed there in accordance with something else; and thus the produced hind toe, which is rudimental or wanting in all birds which have their motion confined either to the surface of the earth or to the water, indicates an aerial character in this group. Accordingly, the pelicans, cormorants, darters, and several others which have feet of this description, often migrate inland, and perch and also build in trees; and even those which never or rarely quit the sea, build high upon the cliffs, and take their repose upon the land, while some of the swimmers fold their head under their wing and sleep in safety upon the water.

These birds have the feet differently articulated in the different genera; as, for instance, the cormorant has them much farther back than the gannet, and is not able to carry the axis of its body in so horizontal a position. But they all "stand well" on their legs, only the feet, in consequence of that form which is required to answer the habit of the bird in feeding, come rather into contact with each other, and render the walk awkward and swinging. The tarsi are perpendicular or nearly so; but they are thrown wide of each other by the position of the tibiæ; and it is to this wide setting of the tarsi, and not to any want of firmness in the articulation of the toes, that the birds owe their rolling gait when they walk. The foot is nearly a semicircle, or rather a semioctagon of unequal sides, of which the outer toe (which is generally very long) and the back one form the largest diameter. This is articulated upon the tarsus, intermediate between the directions of inward and forward, as may be seen in the annexed cut of the foot of the gannet, which, as one of the most active and best known birds of the group, may be taken as the type, in as far as the foot is concerned.

Gannet.

The birds which have this structure of foot are all fishers, and most of them (the gannets especially) dash down almost perpendicularly from great heights upon their prey, and seize it with the bill. The gannet is curiously provided against any injurious effect from these headlong plunges. On the breast and throat of this bird there are three great air-cells between the integuments and the muscles, the two largest divided (but not shut out) from each other by a perforated septum along the keel of the sternum, and tied to the enveloping membrane of the muscles by a number of small straps of membrane; and the smaller one anterior of the furcal bone, and not communicating with the other two, though all the three have communications with the air-cells in the interior of the bird. When the bird dashes down at a fish, the air in those cells breaks its fall; acts like a parachute in preventing it from going too deep; probably invigorates its vital system by the application of a portion of air, condensed by the resistance and cooling effect of the water, to the coats of the arteries; and, what is more to our present purpose, assists it in recovering its position, in order that it may remount the sky, after it has either caught its prey or failed in doing so. This quantity of air is of course condensed by the collision; but when that is over it expands and raises the anterior part of the body, and at the same time throws the centre of gravity further backwards, or more in a line with the feet. These at the same time press downward with their curious webs, both brought under the body by the position in which the toes are articulated on the tarsi, and so heave the body upward in the same manner, or at least upon the same principle, that ordinary swimming feet impel the body of a bird forward. Thus, what with the action of the air, and what with that of the feet, the bird is able to regain the wing without any difficulty.

When the proper action of the foot is connected with some action of the wings of the bird, as adapting the foot for some particular kind of surface, or to accomplish some other object in the general economy of the creature, it always lessens the perfection of the organ as a foot, whether for swimming or for walking.

Concentration upon one single part, or upon the smallest number of parts possible, is always the structure of maximum action in nature. We find it in the wing of the swift, in the foot of the ostrich, in the feet of all the swifter running birds, and in the more perfect swimmers; for though these have the back toe with a marginal lobe, which appears to answer some purpose in the oblique motions of the foot, just as the bastard wing appears to assist in the oblique motions of the main one, though what the specific motion or assistance which this partially developed part gives in the performance of it, can be found only by a more nice and thorough analysis than has hitherto been applied to the mechanics of animals.

This delightful study is, indeed, as humbling to the pride of human learning as it is gratifying to the spirit of more lowly but more reverential inquiry; and the man who comes to it mailed and cuirassed all over with the forms and the formulæ of the schools, is much in the same predicament as the young Israelite when he put on the armour of the king to combat with the giant Philistine—he is encumbered and oppressed; and if he would hope to conquer, he finds that "the smooth stone from the brook"—that which nature affords to observation, must be the true weapon of his warfare, and all his learning only "the sling," by means of which it is sent to its destination with the requisite force.

And if they who weary their days under the load of the armour, had not their eyes dimmed and dazzled by its glitter, they would see that such must be the case: that natural action—the action of that which has life—must have a way of its own, according to which, and only according to which, it can be studied. In a machine of human contrivance, not only all the parts, and the precise degree in which each part contributes to the compound effect of the whole, can be determined, but the *motive* power can also be estimated with the greatest accuracy, and the whole can be planned, and what it could or could not accomplish known, before there is one peg of it in existence, and though it never should exist.

In the animal structure we can also examine all the parts, and, comparing them with what they do in one case, we can form an appropriate judgment of what they can do in another. We can say, for instance, of the action of a foot in swimming, that it is a "function" of certain bones, and muscles, and tendons, and membranes, and other parts, all of which may be *eliminated* by the knife of the dissector. But we do not thus arrive at the specific action of the foot, either in power or in mode, for that is also a "function" of the energy of life in the animal; and so far from being able to express this energy in terms of any known or measurable quantities, we have no expression at all involving it, but that very compound action, the principles of which we seek thus in vain to analyse.

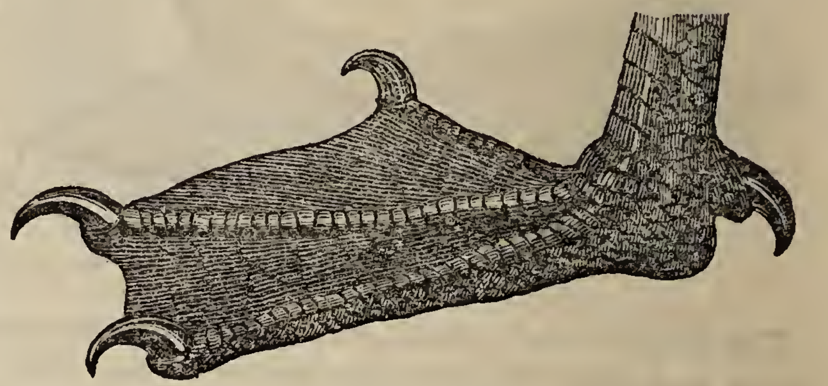
But even this, mortifying as it is to those who labour to appear wise, is fraught with the same advantages and pleasure which are found everywhere in nature. The animal cannot be wholly brought into the closet, so as that the scientific recluse can become fully acquainted with it there, at the sacrifice of much of his health, usefulness, and pleasure. He must go to field and flood, and see the creatures, otherwise he may dream out the years of Methuselah (if the canker of his seclusion shall not eat him up in the twentieth part of that long period), without one moment of awakening to reality and knowledge. Thus, as it were, the coyness of nature is one of her principal fascinations, and he who would secure her favour must woo her as a bride, which, both in the fact and the figure, is the only path in which pleasure and profit are inseparable.

Feet of the Longipennes, or long-winged birds. As the birds of this group all depend more on the wing than the feet for the aquatic part of their food, and as many of them alight on the water chiefly, or exclusively, for the purposes of rest, and not of feeding, they have less of positive character in their feet than the swimming and diving birds, and less even than those birds which, like the gannet, use the feet in working upward to take the wing. These feet are accordingly less stout in the tarsi, and less produced in the toes and webs, and they are without the oblique motions, and have the toes and webs turned nearly in the direction of the front: the outer and inner of nearly the same length, and the middle one little different. The webs, too, are much narrower in proportion to the length of the toes than in the swimming birds, and the hind toe always very short, sometimes a mere tubercle, or a rudimental nail, but differently placed according to the habit.

These birds can all swim, and most of them ride very buoyant on the water, and they sometimes feed as well as rest there; but as their neck is short, and they do not dive, they command a very limited range of the water when they are on its surface. One principal use of their feet is in alighting and rising from the water, which they do more readily than any other birds. They come down with a twitch, halt on the surface, and are on the wing again almost in an instant. In alighting, they advance the feet flat under the body, with the anterior edge of the webs in advance of the centre of gravity; and as the principal joints act parallel to the mesial plane, the least exertion in pushing down the webbed feet, reacting on the centre of gravity, and raising it a little backward as well as upward, throws the bird so clear of the water, that its open wings take the air and it is instantly in the sky. All this is accomplished without occasioning the least splash or disturbance of the water; whereas those birds which feed on or in that element, and use the wing only in journeying from place to place, always make a splash when they alight, and have some trouble before they get on the wing. The length of the tarsus is the principal character of the foot, by which those of different habits may be distinguished. It is, of course, longest in those which walk most on the ground, whether inland or along the beaches, and gradually shorter in proportion as they are more exclusively occupied in skimming over the surface of the sea.

The gulls have it the longest, but it is slender and a portion above the tarsal joint is bare of feathers. Their front toes and webs are of moderate length; but the hind toe is very short, without any web, and articulated higher up than the front ones. The feet are placed considerably forward; and although there is an obliquity of the tibiæ which throws the tarsal joints a little outwards, the birds walk with less of a rolling motion than any of the swimming birds.

The skuas have the feet nearly of the same form; but the hinder toe is a mere tubercle, articulated on the same plane with the front toes. They also have the claws considerably hooked, which agrees with the raven-like habit of the birds, which displays itself in eating carrion, and plundering the nests of birds which build in the banks; and which they have in addition to their peculiar and more characteristic habit of attacking other birds (gulls chiefly) and making them deliver up the contents of their stomachs. The length and crookedness of the claws might lead to the supposition that the skuas, which are very bold birds, use these instruments as hawks do; but such is not the case, though they may assist the birds in holding-on upon oily carcasses which they find floating in the sea, or on land carrion, to which they have no objection, if it comes in their way. Some of them also eat crustaceous animals and shelled mollusca; and they may very naturally be supposed to hold these with the claws while they break or divide them with the strong bill. The annexed is the foot of the common species.

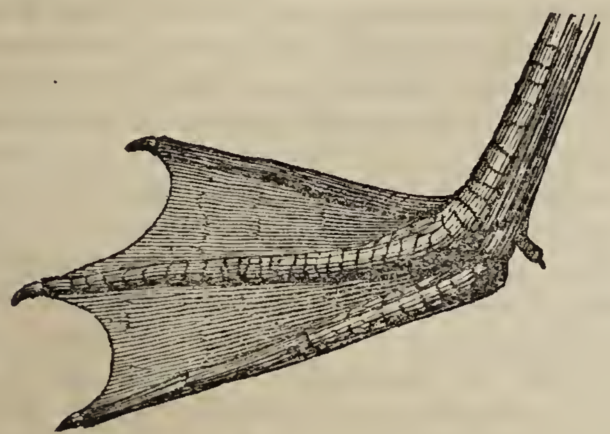


Common Skua.

The terns, which have very much the form of the swallow tribe in the body, the wings, and the tail, and also in style of flight, though the bill and the food are different, have the tarsi shorter, and the feet altogether smaller than any others of the group. They at the same time, however, preserve a certain degree of likeness to the gulls, and, like these, many of them are discovered inland upon the fresh waters.

Terns are the birds most peculiarly adapted for twitching small prey out of the water, which they do with wonderful celerity; and their feet, with very short tarsi, and articulated forwards upon the body, enable them to alight and arise in the swift and easy manner formerly alluded to. Their front toes are all nearly of equal length, their hind toe very small, free, and pointing downwards.

The petrels have the feet with the tarsi considerably longer than those of the terns, and generally compressed in the direction of their action. They have three toes to the front, webbed like those of the terns, and a small claw in place of the hind toe. These feet are, like those of the others, only auxiliary to the principal natural action which is performed by the wings, and they are adapted to a different sort of flight. The terns, though not birds of lofty flight, fly moderately high, and catch those substances upon which they feed by twitching down, snapping with the bill, and instantly rising again. The petrels skim along the surface, and pick up the lighter substances without altering their motion. On these occasions they often, but not always, tip the water with the webs of their feet, to aid the motion of the wings, or sometimes to render it unnecessary. The length and compressed form of the tarsi fit them well for this purpose, while their lightness of structure, in proportion to the strength of the muscles by which they are put in motion, enables them to move with great celerity, and yet occasion little fatigue. At the same time, the action of tipping is done in so clean a style, that the water is not disturbed, and the motion of the legs is not seen unless when the observer is very close to the bird. Some of the larger species, which are found on the Antartic ocean, are nearly of the same dimensions as a wild goose, and yet they will let themselves down, with the wings fully expanded, till the points of their webs touch the surface of the water, and then they will glide along without a movement of the wing till they are lost in the distance. The cut represents the foot of the fulmar petrel, which is very common on the seas to the northward of the British islands.



Fulmar.

Such are a few of the leading distinctions in the feet of birds, whether those feet are in themselves the principal organs of motion, or whether they are made use of as auxiliary to other organs; but the parts of a bird act so much in concert, that no one of them can be fully understood without a knowledge of the others.

VII. Wings of Birds.—As wings are the grand characteristic of birds—that which more especially distinguishes them as a class from all other vertebrated animals, one might naturally suppose that in these organs would be found not only the best means of subdividing them into orders, groups, and genera, but also the best indications of the habits of even particular species. De Blainville was, we believe, the first to suggest such an arrangement ; and an outline was subsequently given by Dr. Lherminier, in the Transactions of the Linnæan Society of Paris, and afterwards in a separate pamphlet, in the year 1828.

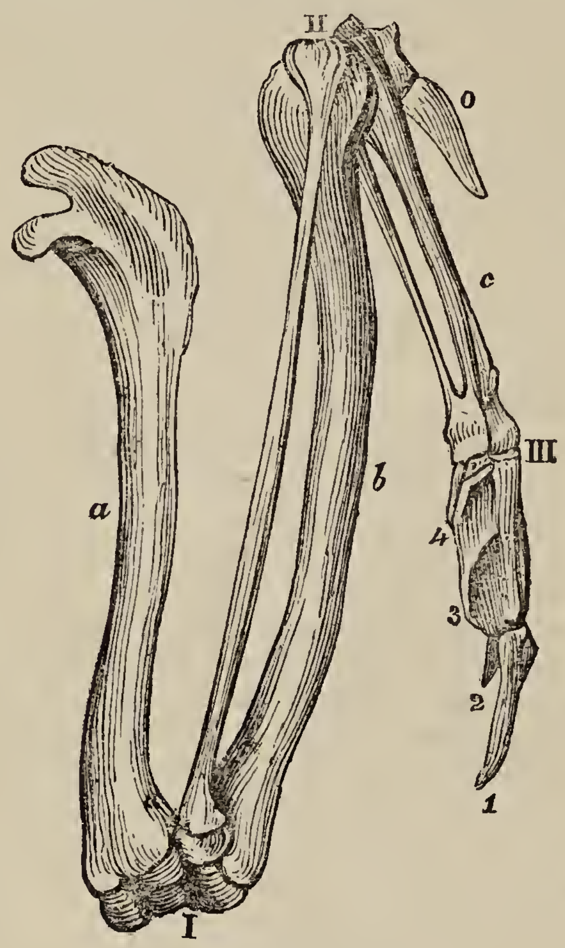
There is a great deal of merit in M. Lherminier's little work, the size and science of which are well worthy the attention of all writers upon similar subjects. But still, though a system could unquestionably be founded upon the wings of birds, or even, as the Doctor's is, founded upon the sternal apparatus in the skeleton, as giving insertion and stability to those muscles which perform the grand motions of the wing ; yet that, after all, would be a system of flying, and not a system of birds, because all birds must eat ; and there are no birds so absolutely destitute of feet as some birds are of wings. Notwithstanding, the wings, and especially this part of them, and not merely the numbers, lengths, and arrangements of the flying feathers, which are almost the only characters usually noticed even by those who profess to write scientifically upon this class of animals, are highly important toward the formation of such a systematic arrangement as shall be of use—that is, which shall direct and shorten the labour of the student who seeks for a knowledge of the characters and uses of these highly interesting creatures.

The mass of the body in birds is, from the inflexibility of the spine, what may be called passive, or rather consenting, in those actions wherein the characters of birds are displayed, as it does not directly perform any of those external operations which are open to observation, though there is no doubt that it is always of that form which gives greatest facility to the more active part of the animal, whether that part be bill, or foot, or wing. To enter minutely into the anatomical structure of a wing, so as to make all its parts intelligible to common readers, would require far more space, and more illustration, than are compatible with the nature and design of this work ; and without a perfect knowledge of the parts, it would of course be impossible to give any idea of their individual action. Then, as to the joint-action of the whole, that is a matter which cannot be expressed. There are twelve distinct moving forces all acting, in one way or other, upon the first, or shoulder-joint of the wing. Those forces are all different in what may be called their structural energy—in the power they derive from their manner of application—in their effect in different positions of the wing—and in their energy from different degrees of excitement in the bird ; so that, when we take those causes of difference, and consider them in all the combinations and changes of which they are susceptible, we are within the truth when we say, that, counting from morning to night every day for a thousand years, would be insufficient simply to enumerate all the motions and positions of which even this joint of one wing of a single bird is susceptible.

Still, in order to be able to observe birds with advantage, as they appear to us in every-day nature, so as to turn them to those purposes of instruction and companionship to which they can so easily and pleasantly be turned, it is necessary to have some general notion of the parts of a wing. These parts, considering them simply according to the substances of which they are composed, are, first, feathers, which being palpable to the eye without much, or even any separation of parts, may be ranked among the mere external appearances, as noticed in a former section; secondly, the substance of the solid wing which is made up : these are the bones and muscles, of which some notice has also been taken, but it may be necessary very briefly to revert to them.

The jer-falcon, to which we have already alluded as the most typical of birds in their general character as flyers, may be again advantageously used as a model, and the figure of the bones of its wing examined in comparison with the corresponding portions of the human arm. The figure on the next page represents the bones of the right wing in half the lineal dimensions of nature.

The position is nearly that of the closed wing ; and it can be understood by bringing the elbow against the side, the wrist to the shoulder, and bending down the hand on the fore-arm. The portion marked *a* answers to the humeral part of the human arm, that is, from the shoulder to the elbow, and consists of a single bone, the humerus. The portion marked *b* answers to the fore-arm, or cubit, the part of the arm from the elbow to the wrist. This part consists of two bones, a larger and curved one, the radius, and a more slender and straighter one, the ulna. The portion marked *c* answers to the hand in man ; *o* is the thumb, which in the bird carries the bastard wing ; in this wing it is tolerably developed, and consists of two phalanges of bone soldered together, the union of which may be seen at *o*. The metacarpal bones, answering to the palm of the hand, extend from II, the wrist joint, to III, the knuckle joint ; and this also consists of two portions, extending the whole length, and united at both extremities. From the knuckle joint at III to the point at 1, answers to the fingers in the human hand. The fore-finger, from III to 1, consists of two phalanges soldered together. The distal phalanx forms the tip of the wing, and terminates at 1. This phalanx consists of only a single bone. This bone consists of a longer thickened portion, the fore-finger ending at 1, and a shorter, the second finger, ending at 2, with a thinner portion of bone between them. The second phalanx, which is broad and flat, is marked by oblique thickened portions ending at 3 and 4, and answering to the third and fourth fingers, only the whole is one plate of bone, thickened and strengthened by the oblique ridges terminating at 3 and 4, which proceed from a thickened portion continued along the other side.



Jer-falcon's wing.

It will be seen that all the bones in this wing which have moveable joints are very much enlarged at their extremities; and that, with the exception of the joint at the head of the humerus, one part only of which is seen, as the socket in which the shoulder joint moves is not shown in the figure, have their motions chiefly in one direction or plane only.

When the wing is extended, the upper process of the head of the humerus is brought considerably within the centre of motion of the shoulder-joint. To it the tendons of the muscles which raise the wing are attached, and its projection, increased beyond the centre of motion, gives the lever power, by means of which these muscles act. The muscle which depresses the wing, or gives the stroke in flying, has its tendon attached to the under side of the flattened portion of the head of the humeral bone, farther without the centre of motion than the others are within it, and therefore it acts upon a longer lever of power, and has a shorter lever of resistance to overcome than the muscles which elevate the wing.

All the round bones of the wing are hollow, or tubular, which makes them much lighter than if they had been solid and of the same dimensions, and much stronger and stiffer than if they were solid with the same quantity of bone. But at all places where there is either a muscle or a tendon inserted, the action of which would be upon one side only of the tube, there is a tie, or septum of bone extending from the one side to the other, so that it may throw the strain equally upon both sides of the tube. If this strain is great, these ties are branched, so that they throw it upon a considerable portion of the bone, and as they are ties in the one direction and struts in the cross one, and all gradually run into the bone by heads enlarging in curves, they give the same strength as if the bone were entirely solid throughout. Indeed, for maximum of strength and stiffness, with minimum of weight, these bones are quite a study.

The elbow joint, I, is very beautifully constructed. It is a sort of triple hinge; and when the humerus and radius are brought into the same line in the stretching of the wing, the processes, as may be seen from their form, stop it from having the least flexure in the other direction, while the head of the ulna comes over the centre, between the double processes of the two principal bones, and wedges it against all bending upwards, something in the same manner as the keystone of an arch.

The wrist-joint at II, is also both very peculiar and very firm. It admits of extension till the metacarpal bones (the whole hand in fact) be nearly in the same line with the fore-arm, but beyond this it cannot be stretched without breaking the wing; and here the other end of the ulna, together with the bones of the thumb, offer the same resistance against bending in the wrong direction that is offered by the elbow-joint.

The knuckle-joint, III, has little or no motion in any direction; and it rather gives a little elasticity to the bone, which is very hard and firm in its texture, than answers any other purpose; but, though very light, that portion of the wing is, from the way in which the thickened parts are placed, actually stronger in rapid motion than if it were all as thick as those.

The form of all the bones, indeed, is such as to give them the maximum both of stiffness and of strength. The humerus, which is the only single bone, is very strong, both from its shape and from the cross pieces inside the tube opposite to the insertions of the muscles and tendons; and even these are additional means of support. This bone, too, is so near the centre of motion, that the resistance of the air acts much less powerfully upon it than upon the others. The fore-arm, having to sustain the broadest part of the wing, is very strong: indeed it is the strongest form which, combined with the same lightness, could be given; and lightness is as essential as firmness in all the parts of a wing, because weight would be a source both of weakness and fatigue. The radius, or larger bone, has the form of a bow, and the smaller one, the ulna, that of a bow-string; and any one who places the tips or horns of a bent bow on the ground, and tries to crush it by pressing down the middle of the bend, will find it much stiffer and stronger than a straight stick of twice the thickness. A very portable bridge is often made upon this principle, of a thin plank, bent into the form of a bow by a cord tied to the two ends; and when tied in this manner, a plank which a man can carry without fatigue, will enable him to cross with safety a chasm ten or twelve feet wide.

But the bow and the bridge are very imperfect pieces of mechanism, as compared with this portion of the wing. They are strong in one direction only; that is, when the strain or pressure is upon the outside of the bend, and this is in them the position of least stability. If its position is reversed, the bow bridge is weaker than a straight plank by the whole extent to which it is bent, as the string offers no resistance to further bending. But it will be seen, on looking back at the figure, that the radius, which answers to the bow, is one of very curious curvature. Though less in diameter at the middle than toward the ends, it has its stiffness there greatly increased by being not only straight, but a very little bent the other way. This against a single strain would give it the same strength as a bow has by being thicker, and consequently bending less toward the middle than toward the ends. But the bone has to bear strains and twists in all directions; and therefore, though the double curvature cannot be shown in a figure, it will be found, upon examination of the bone itself, that some part of it is a bow in what direction soever it is turned. The ulna is also both a tie and a strut, and resists equally the drawing asunder and the pressing together of the ends of the larger bone. It is nearly straight, which is the form of greatest strength against both of these; and it is spindle-shaped, or thickened toward the middle of its length, which is the form of greatest stiffness. But we must not proceed much farther in the consideration of this exquisite piece of mechanism:—it would not only afford study for years, but remain in great part an unexplained wonder after we had exercised the longest life upon it.

But, admirable as is the structure of this moving part of the wing, it would fail in producing its office if the point to which it is attached, and the organs by which it is moved, did not partake of the same character: for without this it would be like a well-made tool or a powerful weapon placed in an unskilful hand.

The sternum is the grand bone upon which the articulation of the wing at the shoulder-joint, and the muscles which move that joint, are founded; and therefore, the general power of every wing may be judged of more from that bone than from any other single part.

But, in order to have a clear understanding of the relative power of wings, it is necessary to examine carefully all the bones which support the point to which the wing is articulated, or which afford insertion to the muscles by which it is moved. It has been already mentioned, in the general notice of the structure of birds, that the three bones which support that point are the coracoid, the scapula, and the branch of the furcal. The articulation is more immediately upon the coracoid, though the shallow socket in which the head of the humerus plays, is often in part formed by the scapula, with the arm of the furcal bones against the other two on the inside, beyond the socket, and as far as their extremities; and immediately behind the head of the coracoid, to the outside of which the scapula is applied, there is a foramen or hole, which serves as a pulley, through which the tendons of the muscles that raise the wing pass. The firmness with which these three bones are united to each other is always in proportion to the power of flight in the bird. In no bird of powerful wing can any of them be dislocated from the other two without fracture; and in old eagles and hawks, the portion of cartilaginous matter by which they are united passes so completely into bone, though bone which remains a little flexible, that they cannot be detached from each other by maceration in water.

It is worthy of remark, as affording a beautiful instance of that provision of nature by means of which the vital parts of animals are always protected from injury even in their most violent actions, if those actions are natural, or essential to the accomplishment of those purposes which their Creator has ordained them to accomplish, that the anterior extremities of no vertebrated animal are articulated upon the spinal column. This is very remarkably the case in birds of very powerful wing.

In mammalia, the articulation of the humerus is always upon the scapula only; they want the coracoid bones entirely, and in bears, and other species which grasp or hug between the fore legs, the clavicles are wanting. Even in those species, as in the quadrumana, which have the clavicles most perfectly developed, the office of these bones is secondary, chiefly that of keeping the shoulder-joints apart from each other, so that the animals may stretch their fore-legs, or arms, at right angles to the mesial plane of the body, and not use them parallel to that plane only, as is the case with those mammalia which employ the fore legs only in walking.

In the mammalia, the scapular bone is flattened and extended to the shape of a triangular plate, and it is furnished with a septum, or elevated keel of bone, to each side of which there are muscles attached, which move the bone backwards or forwards, according as is necessary to the action of the other parts of the limb. But in birds the scapula is never furnished with a ridge or keel of this description; and it is most developed and enlarged at the end farthest from the joint in those birds which make the nearest approach to the quadruped action of the mammalia,—as for instance, in the grebes, which use the wings and the feet, with nearly equal energy, as they make their way under water. In those land-birds, such as the ostrich, which cannot raise the wings, but use them only for balancing the body as they run, the scapulæ are less developed; but even in them, they are more so than in the birds of the most powerful flight. These birds have not the clavicles united in front into a regular arch, as in powerfully-winged birds, or even into a fork with the branches nearly straight, as in the gallinidæ and other bad fliers; and in some of the species they are little else than mere processes on the anterior edges of the coracoid bones.

In no case, however, of these short-winged birds are the coracoid bones, which connect the scapulars with the anterior part of the sternum, wanting: and in no case, even of those of most vigorous flight, in which the furcal bone is the most developed, are the humeral bones of the wings articulated directly upon that bone.

It is here, that we find one of those strikingly distinctive characters from which we can at once pronounce a bird to be a bird, whether it has or has not the power of flight; and here, that we are enabled to see which is the characteristic bone in this part of the skeleton which is possessed by birds and never by mammalia. On this point it would be unjust not to acknowledge the merit due to the science and the sagacity of Cuvier. Before his time, those who treated of the structures of animals, and of the structural differences of the several classes of vertebrated ones, were somewhat at a loss which to consider as the additional bone in birds, and which as the true clavicle; and the furcal bone, as being the most anterior one, and the least connected with the sternum, was generally considered as the additional one, and the coracoid bones, which have nearly the same relative position with regard to the sternum, as the clavicles of mammalia, as the true clavicles of birds.

But when we examine, with due attention, the skeletons of all birds, whether capable or not capable of flight, and if capable, whether they fly with more or less power, we find that the coracoid is the true distinguishing bone of the winged race—the bone which connects the anterior extremities with the sternum as their grand support; and that the furcal bone is more or less perfect, or present, or wanting, according to the difference of habit, as in the mammalia—we must admit, with the illustrious author of the *Regne Animale*, that that bone is really the clavicle; and that the coracoid bone is just as essential to the existence of a bird as the scapular bone is to that of the mammalia. The humerus of the wing in birds is as constantly articulated (that is, *chiefly* articulated) upon the coracoid as the fore leg of the mammalia is articulated upon the shoulder-bone, or blade-bone; and the furcal bone is present in the one class when the joints of the shoulders require to be kept asunder, and absent when they do not, just as it is in the other.

Thus, in birds, we have the wing as uniformly referred to the sternum, by means of the coracoid, as we have the fore-leg referred to the muscles of the shoulder and the spinous processes by which they are supported in the mammalia; and though both are so placed that neither the one nor the other directly disturbs the vertebral column, so as to derange its important contents, yet they are very beautifully arranged so as to suit the different systematic habits of the animals. In the mammalia, an action of the thorax in heaving and falling is required, in order to carry on the process of breathing by means of lungs and a moveable diaphragm exclusively; and therefore neither the weight of the anterior part of the body, nor the motion of the fore-legs, could be, in them, supported from the sternum, without confining and disturbing that action. Thus the mammalia, when they bear the weight on the fore-legs, have the thorax free as it were, and suspended upon these fore-legs as props, the muscles and other soft parts, which attach the scapular bone to the body, affording an elastic support, similar but superior to that of the springs upon which the body of a carriage is hung.

Birds, on the contrary, never have any support, except by the feet, upon substances which are not in themselves elastic, as the air or the water, and thus the anterior part of their bodies is carried on the sternum, as a basket or boat, that bone being always more produced and developed in proportion as the weight of the body is borne more upon it. If the bearing is chiefly upon the wing, then the strength of the sternum is concentrated forwards; but if upon the under surface of the body, as in the swimming birds, then the sternum is produced backwards, or has more of a boat shape. In birds that fly little, the sternum is weak; and in those which cannot fly it is short, that it may be out of the way of the more vigorous action of the legs which is required in them. In both, and more especially in the latter, it serves more as a breast-plate or buckler for supporting the anterior part of the body, by reference to the spinal column, and by means of that to the legs, than as the ultimate fulcrum of every sort of motion; and in these birds the scapular bones, by means of which the anterior part of the sternum is supported, or rather by means of which it is suspended, are more produced, and have their forms better adapted for a firm imbedment among the muscles of the back, than in habitual flyers. So marked does this character become, that in the ostrich tribe, which, as they do not require the furcal bone to keep the heads of the scapulars asunder have it only in two rudimental processes, the coracoids and scapulars have much the character and office of two hooks, which, taking hold by means of their imbedment in the flesh, bear up the anterior part of the sternum.

This enlarged and basket or boat-shaped sternum, together with the coracoid bones, are therefore to be regarded as the most typical part not only of the skeleton of birds, but of their whole organisation. The form of the sternum varies much with the habits of the different species; but it is, in all cases, the characteristic sternum of a bird, and in no species, which has been examined, has it been found without coracoids, though in those species where these do little else than suspend the sternum they are united into nearly one continued flat piece with the scapulars.

It is to be regretted that, hitherto, there has been no opportunity of completing this part of the series by examining the sternal apparatus of the apteryx, which, as the most wingless of the class, and as being, from the structure of its feet, a bird of slow motion, must be the one which has the sternal apparatus most exclusively formed for the support of the anterior part of the body only. Thus in it we should have a real analysis of this most characteristic part of the structure of birds, not by mere dissection, where we are left to guess at the use of the organ from its form and its connexion with other organs, but actually in the living bird. By this means we should be able to separate the two functions of the sternal apparatus—the simple and more general, which supports the body of the animal, and the more complicated and variable, which relates to the operation of flying.

Sterna of Wingless Birds.—Wingless, though the epithet commonly given to those birds that are incapable of flight, is by no means an accurate one. There is no bird absolutely wingless, even though it should have the bones of the wing wholly within the integuments. When we reflect a little on the matter, we find that such might be expected. A wing is an organ of flight, and the performing of that operation is the chief apparent use of the wing. But the wing is also, independently of its action in flying, an integrant part of the structure of a bird—a part which the bird has, whether it be in motion or at rest. Now, it should always be borne in mind, that an animal is a perfect structure, and that all its parts are in concert, whether it be in a state of action or in a state of repose. One part does not, therefore, merely press up, or move the other, as in the case of our structures and machines. In our moving structures we have to apply some *external power* to put the structure in motion, after all its parts are completed; but the motive force of the animal is *internal*, and we cannot locate it to one part of the organisation. The animal has, therefore, the whole of its structure *consenting*, and not merely consenting, but *co-operating* in all its actions and all its positions of repose; and it should seem that the shoulder-joint of a bird is incapable even of supporting the sternum, and with that the under part of the body, so as to make the horizontal spine stable upon two legs without the addition of a rudimental wing. Thus there is a harmony and reciprocal action in the parts of the bird, so that while the one assists the other in its operations, it receives assistance in return: as in this instance, the shoulder-joint supports the wing, and the articulation of the wing is necessary to the perfection of the shoulder-joint. This mutual or reciprocal assistance of the parts of an animal to each other is one of the more remarkable points of difference between the mechanics of the living body and of dead matter, and it is one of which we should never lose sight, when we speculate about the former.

We have no practical knowledge of a bird with a perfectly immoveable wing, but we have a very near approximation in the emu, which, although a long-legged and swift-footed bird, has its covering, and probably also its food, much more analogous to that of the apteryx than the true ostriches have; and it is curious also that the two, the one in Australia and the other in New Zealand, are more nearly neighbours, and inhabit climates which are much more nearly similar than those inhabited by the others. On this account we shall, before proceeding to take a very short glance at the comparative structures of the sterna of some of the more remarkable flying birds with reference to their forms of flight, notice that of the emu, as being nearly confined to the supporting of the anterior part of the body.

This sternum is oval, without any keel, and bears some resemblance to the breast-plate of a tortoise; and the coracoids, whose principal use is to support the bone, and preserve the form of the anterior part of the chest against the weight of the bird, the presence of the atmosphere, and casualties, without having any direct strain to bear when the bird is in motion, are short, broad, and flat.

The following figure is a side view of this sternal apparatus.

Emu.

The outline of the sternum of this bird is, it will be seen, very convex, with merely a trace of a keel at the anterior part, near the junction of the coracoids. The ribs are articulated far forward, and they are much thicker and stronger than in flying birds. There is not, upon this bony structure, any place where muscles capable of giving motion to a wing could be inserted. The strong articulation by the coracoids and the ribs, and the length of the scapulars which suspend the former, enable this form of bone, however, to give the most efficient support to the body, as a basket in which the thoracic viscera are carried; and its convex form renders it a most efficient breast-plate against any external injury to which the bird may be exposed.

Those who consider flight as the essential characteristic of birds, sometimes regard this structure as an imperfect one; but when we examine it with regard to the offices which it has to perform, we find the same perfection of adaptation in it as in that form which affords a fulcrum to the most active wing, and insertion to the most powerful muscles. The species of land birds incapable of flight are so few, and their natural pastures on the earth so peculiar and so limited, that we can with difficulty so connect them with the rest of nature as to understand the part which they act in the general economy. But though they are thus, in a great measure, a sealed book to us, we find that, in as far as we can study them with relation to their haunts, they afford as irresistible evidence of that perfect knowledge of all the circumstances, at the original formation of the creature, which inscribes the name of God upon all that God has made, in characters so plain that he who runs may read, as any other race that can be named. The ostrich on the arid expanse of the African karoo, the nhandu among the tall herbage of the American pampas, the emu on the "hummocky" plains of Australia, and (as we have reason to suppose) the apteryx by the shingly bases of the New Zealand cliffs, are all as much in harmony with the scenes in which we find them, as the parrot is with the perennial bloom of the tropical forest, or the albatross or the petrel is with the expanse of the world of waters. Wings are not wanted upon extended flats of firm surface; they are for the "ups and downs" of feeding grounds; and, therefore, those birds to which wings would be an incumbrance have them not, but in their stead organisations better suited to their haunts.

Sterna of winged Birds. In considering the sterna of birds as indices to their different powers of flight, the elevated crest or keel is certainly the most important; while of the other bones which form part of the sternal apparatus, the most important is the clavicle, for as we have seen the coracoid bones are constant, not very much dependent on the rate or style of flight, and the scapulars, though of weaker structure, and less fitted for bearing cross strains, are often more developed in birds which fly heavily than in those which fly well.

But still the form and consistency of the sternal bone itself, independently of its ridge or its appendages, vary considerably in birds of different powers of wing. The firmer the sternum is, that is, the more completely that it consists of one plate of bone, without apertures, and with the different pieces in which ossification begins in the young birds, united by bone, the bird flies the better and the more powerfully; and of course, in proportion as the sternum is deficient in those qualities, the flight of the bird is less elevated and less capable of being continued. If the sternum, besides being of solid bone, is of considerable breadth, and curved in its section as well as in the principal line of its crest, the bird is one of the most powerful wing, and whether its chief exercise be in long flight, or very rapid flight of shorter continuance, depends a good deal on the number, form, and arrangement of the feathers. Generally speaking, however, birds which do not require the violent rush of the accipitres, have the sternum straighter and narrower, though a little longer in proportion. Sterna which are very broad, with the crest low, always indicate bad fliers. Here, however, the adaptation of the sternum for flight, begins to be combined with that for swimming; and, as those two habits occur in many proportions with regard to each other, it is not very easy to frame such a general description of the bone as will apply to all or even half the varieties. When birds of this description come to have the two motions of the wings, the flying one in the air, and the swimming one under water, the form of the external part of the wing is adapted to the one or the other, according to the habit, while the form of the sternum itself remains nearly the same.

Sternal muscles. In order that the action of wings, and the influence which the different modifications of the sternal bones have in that action, may be more clearly understood, it is necessary to say a little more respecting the muscles by which the wings are moved than the mere enumeration which was given in a former section. This may have somewhat the appearance of repetition; but, in treating of complex structures, so much of repetition as shall keep the several parts constantly in the reader's view is not only excusable but necessary; and when the object is to communicate information, that is not the very best taste which sacrifices perspicuity to mere nicety, and plainness of expression to what is (often very falsely) considered elegance of style.

The first set of muscles are those which have their insertion in the sternum, the coracoid bone, and the clavicle, and their tendons attached to the humerus; and these are the muscles which perform the grand operation of working the wing. They are four in number.

The first, the great pectoral muscle, is situated externally toward the anterior part of the sternum, where it has the freest action. It is inserted on the keel and body of the sternum, on the side of the coracoid, and also on that of the clavicle; and its tendon, which is particularly strong and firmly united by a large extent of surface, is attached to the extended crest of the humerus on the lower side. When this muscle contracts, it bends down the humerus on the shoulder-joint; but as it is inserted in all the bones by which that joint is supported, the very same action which bends down the humerus on the joint, tends to push the joint upwards, which not only renders the effect of the pulling of the tendon more steady, but actually increases its force. This is the grand muscle in flying, and it is impossible to imagine an organ better situated or altogether better adapted for its purpose than it is in birds of powerful flight.

Immediately under this there is situated the middle pectoral muscle, which is the antagonist of the former. This muscle lies in the angle formed by the keel and body of the sternum, and is attached also to the coracoid, and partly to the clavicle on the angle of its inner side. It passes under the coracoid, and the tendon in which it terminates, passes through a hole which is formed by the uniting of the coracoid, the clavicle, and the scapular, and returning outwards, is attached, by an extended termination, on the upper side of the crest of the humerus, rather inward of the centre of motion of the shoulder-joint. This is the principal muscle employed in raising the wing; and the mode of its action is a little curious. Its insertion is nearly the same as that of its antagonist, the great pectoral muscle; and when it acts, it tends to raise and keep steady the centre of motion in the shoulder-joint, just as that does; but as its tendon passes through the pulley, or foramen, above-mentioned, its power to produce motion is reversed, and though similarly inserted, and as a muscle acting in the very same way, it produces exactly the opposite effect upon the humerus. The tendon which passes through the pulley is, in many birds, in great part ossified, so that, besides having additional firmness from that structure, the upper part of it acts as a more powerful lever in the raising of the wing.

The action of these two muscles, which are the most important ones in the operation of flying, is one of the most beautiful in the whole range of animal mechanics, wide and varied as it is. The great pectoral which, by depressing the wing, gives the stroke, and therefore performs the most essential operation in flying, is the most free in its action, as it is pressed by the integuments only. It also pulls the wing downwards with the greatest advantage, as its tendon goes directly to the lower part of the humerus without the joint. Its antagonist, which raises the wing, does it by the reversed action of the tendon passing through the pulley; but it acts more rapidly, and it has the same tendency to support the centre of motion as the other: and though there must be some of the power lost by the reversing of the tendon, that is more than compensated by the steadiness given to the joint, and the increased rapidity of the upward motion. That motion is also greatly facilitated by the structure of the feathered part of the wing, which is so formed that while it takes the greatest hold possible on the air when striking downwards, takes the least possible in rising upwards.

Immediately above the mean pectoral muscle, there is a third and much smaller one, which is most conspicuous in those birds which get suddenly on the wing from the ground. Its tendon also passes through the pulley, and is attached to the upper part of the head of the humerus. Its office is to assist the middle pectoral in raising the wing.

The fourth and last of this group is the small pectoral muscle, which is inserted on the sternum to the rear of the others, and also partially to the upper and exterior edge of the coracoid. Its tendon is attached to a tubercle on the lower part of the head of the humerus, and its office is two-fold,—when the muscles which are more immediately employed in moving the wing during flight, are not in action, this muscle draws the humeral part of the wing toward the body by a peculiar twist of the shoulder-joint; and when they are in action, it exerts a sort of twisting influence, by means of which the posterior edge of the wing is prevented from turning upwards, and a sort of rotatory motion is produced, which has considerable influence in the ascent or descent of the bird, and also in the altering of its course while on the wing.

The articulation of the wing with the coracoid is a very peculiar form of joint. It is not a hinge joint, neither is it a ball and socket, but something intermediate between the two, and partaking of the properties of both. The average line, or axis, of its motion is oblique, elevated to the front, and depressed to the rear, but both the principal head of the humerus and the socket have their outlines curved, so that the wing may be advanced or drawn backward at the same time that it is elevated or depressed, and by some of the muscles acting more and some less, all the motions of the shoulder-joint, which are requisite both for the action of flight and the direction of that action, are performed. The double head of the humerus, which may be understood by looking back to the wing of the jer-falcon, or forward to the sternal portion of the skeleton of the golden eagle, assists very materially in both the direct and the oblique motions of this joint. In proportion as the action of the wing is more powerful, the crest of the humerus, that is, the process or portion of the head which is toward the convex side of the bone, or that which is most in advance when the bone is in its natural position, is more produced. It is more so in the humerus of the jer-falcon than perhaps in that of any other bird, and more so in the falcons which prey on the wing than in any other genus of birds.

The second set of muscles in the wing are those which are inserted on the coracoid, and attached to the humerus and the radius. There are two of them attached by a common tendon to the external part of the extremity of the coracoid, near the glenoid cavity, but below it. The coraco-branchial is attached to the crest of the humerus, and acts as the antagonist of the third pectoral, and extends the humerus from the body. The biceps is attached to the radius, and extends the fore-arm or great medial portion of the wing.

There is only one single muscle inserted in both the shoulder-bone and the coracoid. It has its insertion in the lower side of the shoulder bone and the upper edge of the coracoid, and its tendon is inserted in the head of the humerus, on the lower side, by the edge of the insertion of the smaller pectoral muscle. Its office is to close the wing toward the body, but it of course acts only on the humeral portion.

The next set of muscles are those which are attached to the scapula or shoulder-bone only, and act between that bone and either the humeral or the radial portion of the wing. They are three in number. The first is attached to a greater or smaller portion of the external edge of the scapular bone, sometimes in two separate fasciculi of fibres, and sometimes with the two fasciculi united by a tendinous septum. When the latter is the case, it is inserted by one tendon in the posterior edge of the humerus, below the cavity; and in the former, by a tendon and a fasciculus of muscular fibres to nearly the same point. The use of this muscle is to draw the humerus toward the body of the bird, and at the same time to raise it upwards. The second of these muscles is inserted by a very strong tendon to the glenoid cavity, and it is attached to the humerus. Its office is to draw the wing toward the body, and raise it, and also to extend the fore-arm, or radial joint of the wing. The third of these muscles is a long and slender fasciculus, which, originating in the lower and exterior part of the scapular bone, behind the last-mentioned one, is attached to the scapula, and appears chiefly an auxiliary to the former.

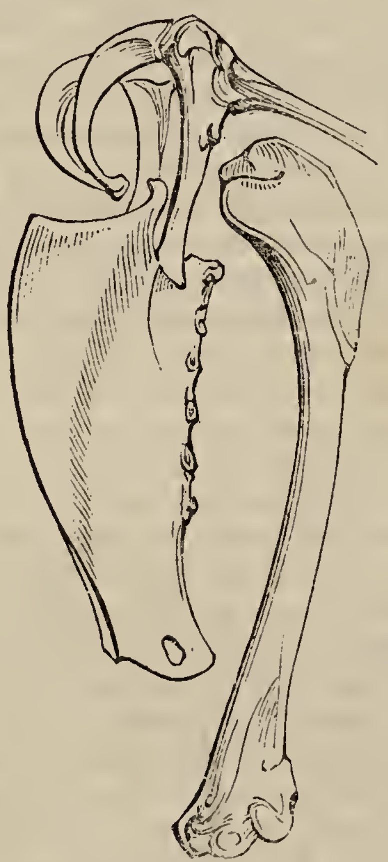
There are two muscles originating in the scapula, the clavicle and the coracoid, which chiefly assist in elevating the wing, or in advancing it, or bending it to the rear, when the bird is in flight. But the actions of these secondary muscles, which are efficient chiefly in altering the direction of the birds in flight, upward, downward, or laterally, cannot be fully explained without more space, and more illustrative figures, than are compatible with the nature, and indeed the purpose, of this brief sketch. The whole of the muscular actions of a wing form a very extensive as well as a very nice subject for study, and one which can be very imperfectly comprehended even by those who devote their whole time and their best attention to it. The reason is obvious: the actions of the numerous muscles of the wing are so combined with each other, and the action of the one modifies that of the other so much, that the most minute definition, and the most careful study, are incapable of informing us how the wing acts in all its varied motions; so that the utmost which, in the present state of science, we can expect to obtain, is a very rude and imperfect estimate of the relative powers of wings, derived fully as much from what we see them performing in the living bird, as from any thing apparently more scientific (and it is mere appearance rather than reality) which we find in dissecting the dead one.

In giving a few examples of the form of the sternum, and its apparatus, the coracoids, the clavicle, and the scapulars, as illustrative of the power of flight in birds, we shall not attempt to follow even the outline of a system proposed by M. Lherminier, because that is incomplete, as treating of the sternal apparatus with reference to flight only, and not combining the general character of the class, the support which the body receives from the sternal bones, altogether independent of power of flight; and also because, though very ingenious and scientific so far as it goes, the sketch which he gives is not perfectly satisfactory, even in so far as the mere action of flying is concerned. The sternum and the sternal apparatus, whether of bones or of muscles, are not the whole organs of flight, we have still to take into account the bones and muscles of the wing, and the character of the feathers with which that wing is furnished; and even if we were put fully in possession of these, there still remains the accordance of the other structures of the bird with the entire wing, as relates to the style of flight, and also to those other actions of the bird with which the flight is always in accordance. In consequence of these difficulties, which volumes of writing would not explain away, we must content ourselves with a few short notices of the sternal apparatus of the leading division of birds, as formed on the usual mixed characters.

Sterna of the Accipitres. This is firm, though the thicker parts of it are full of air-cells, more especially the enlarged base of the keel, which passes, by a gradual curvature, into the surface of the sides of the sternum, without any corresponding cavity on the upper side, or side toward the interior of the bird. Its form is nearly that of a parallelogram, with the length exceeding the breadth, concave on the upper side, and convex on the under. The keel generally large and elevated, but always lower the broader the sternum is in proportion to its length. The anterior margin of the keel is concave, and the under one convex: the anterior angle sometimes even with the anterior part of the bone, and sometimes in advance of it, with the edge thickened, as if it consisted of two pieces united together; the keel much higher at the place where the great pectoral muscle is inserted than at the insertion of the middle one. The sides are a little concave, and the ribs vary from five to seven; the posterior edge generally nearly straight, with a lateral hole in each angle, but these are often nearly, and sometimes wholly, obliterated by bone. There is not, even in the youngest stage of the more typical birds, any appearance of distinct bones forming the sternum, as there are in birds of some other orders, but the process of ossification begins at the fore-part, and proceeds regularly backwards.

The coraeoids are shorter than the sternum, but very strongly formed, and their internal angles, where they are attached to the sternum, often meet each other. The clavicles form a complete arch, more or less depressed toward the centre, having its depth placed in the direction of the strain; of nearly equal strength throughout its length in the falcons, which are the birds of most rapid and continuous flight, but diminished toward the middle in most of the others; and firmly united at both extremities to the scapulars and the coracoids.

The scapulars are a little longer than the sides of the sternum, oval in their section, slightly curved, pointed at their extremities, and firmly united with the coracoids and clavicle at the angle of the shoulder, a little above the articulation of the humerus, to which they afford a very firm point of support, and to the tendon of whose elevating muscle they furnish a very perfect pulley.



Golden Eagle.

We have given in the above cut a profile of the sternum of the golden eagle, as about the average of the order, and we add the humerus, to show the relative size of that bone, as well as the enlarged processes on both ends, which serve as levers upon which the tendons act in a very powerful wing.

From what has been already said, the different parts of this as well as of the other sterna which are to follow, will it is hoped be understood without the somewhat clumsy expedient of letters of reference.

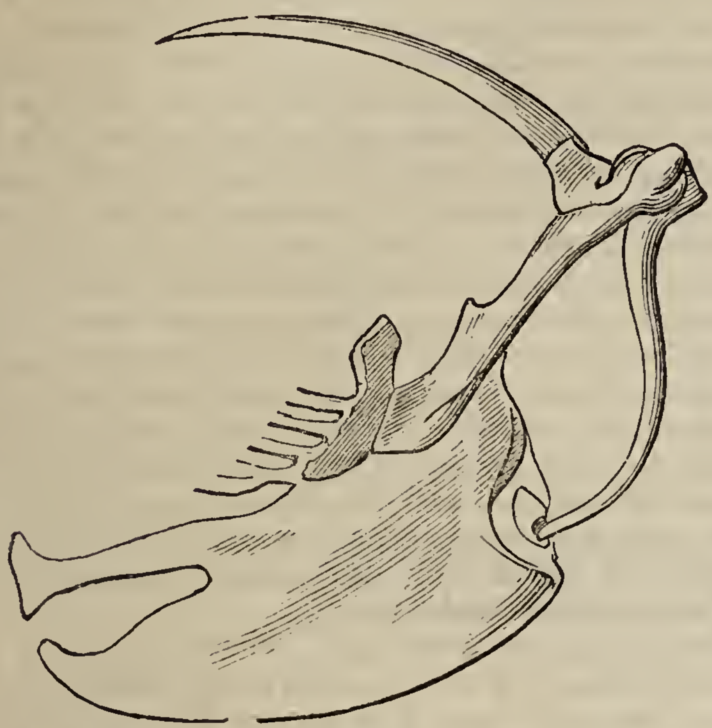
This is the average type of the sternal apparatus of the diurnal birds of prey, to which some are superior and some inferior. The most perfectly formed are the noble hawks or faleons, of which some notion may be formed by looking back at the sketch of the most perfect of the whole, the jer-falcon, at page 405. The short-winged hawks, buzzards, harriers, kites, and eagles follow; and after them the fishing eagles, the vultures, and the skuas, which last, though they do not kill game, yet rush upon the gulls and other birds, which they plunder, with strong and rapid wing. They have, no doubt, their sternal apparatus somewhat modified so as to accord with their webbed feet when they do take to the water, but still they are chiefly and characteristically air-birds.

The secretary falcon, which combines with some of the characters of the diurnal birds of prey some of those of the grallidæ, which frequent not the waters or their margins, has the keel of the sternum less perfect, the posterior edge terminating in a point, and the general outline curved something in the same manner as that of the wingless birds. The clavicle has also an enlarged process at the junction of the two branches, which rests upon the sternum; and the coracoid bones are proportionally much longer than in the typical birds of prey. There is, in short, enough in the structure of this bird (and the habit corresponds) to show that it ought not to be classed with the accipitres; but not enough to bring it properly into any other order or family.

In the nocturnal birds of prey there are also considerable differences in the formation of the sternal apparatus. The snowy and eagle owls, which are more bold and daring than the rest, have the furcal bone formed more into an arch, and the keel of the sternum better developed than in the common owls, which are birds of weak flight, feeding on reptiles and small mammalia, and chiefly in the twilight. But the whole of this division have the skeleton so much more feeble in all its parts than the diurnal preyers that, in a strictly natural system, they ought perhaps to be wholly separated. The common owls have the posterior edge of the sternum with notches, generally two on each side, filled by membranous or cartilaginous matter, and they have the arms of the clavicle or furcal bone straighter, and with its flat side placed more in the direction of the strain than in the diurnal birds of prey. This accords with the comparative slowness of their flight, and the feeble and downy character of their flying feathers.

Sterna of the omnivorous birds. The character of the sternum is much the same in the greater part of those birds which form the extensive and otherwise diversified order of passeres. They have the sternum longer than broad, enlarged toward the posterior extremity, and with two deep notches toward the sides. The keel is moderately produced, convex on its under side, and concave to the front, which has a forked process upon which the middle of the furcal bone rests. The coracoid bones are longer than the sternum, slightly bent, or coulter-shaped, with an enlargement near the shoulder-joints, and narrowed toward the extremities. The clavicle is long and bent downwards at the middle, generally rather narrow, and united to the forked process of the sternum.

The scapular bones are long, bent downwards, pointed at the extremities, but with an enlarged process on the under sides near the middle of their length. The following figure of the sternal apparatus of the jackdaw may be taken as nearly the average of birds of this character.



Jackdaw.

None of the birds which have the sternum formed in this manner capture their prey on the wing, or are very rapid fliers, though they are all birds of considerable power of flight. They are, however, all, at the same time, birds which are tolerably active on their feet; and the large notches in the sternum, posteriorly towards the sides, enable them to make use of their feet, by the flexure of this part of the sternum, while the average production of the sternal crest or keel admits of tolerably powerful muscles for putting the wings in motion. They are so numerous and so diversified in their habits, that no one type can be properly expressive of them all, but their general character is that of uniting habits on the wing and on the ground in nearly equal proportions; and upon comparing their sternal apparatus with those of the birds of powerful wing and the ground birds, it will be found to partake of the characters of both. The different powers of wing in these birds are in a great measure dependent upon the form and distribution of the feathers.

Sterna of the fissirostres. These are all feeders on the wing; but upon comparing their sternal apparatus we find more difference between the diurnal and nocturnal feeders than in the birds of prey.

Day-feeders, or the swallow tribe, have the sternum much elongated, often broader toward the rear than the front, and a little hollow on the upper side. The sternal crest or keel very much developed, concave in its front edge, and convex in its under one, with the angle where these meet very pointed. Front edge of the sternum very narrow, with two grooves separated by a ridge of bone. The outlines of the sides concave, generally with five ribs attached to each, but with six in the white-throated swift (*Cypselus collaris*). Posterior edge slightly rounded, concave on the upper side, and entire, or without any holes or notches toward the angles. The following figure show the sternal apparatus of the common swift of the natural size.

This may, among birds which naturally resort to Britain, if not among all birds whatever, be considered as the typical sternum for continued flight, though not for a powerful but more momentary rush. The sternum of the jer-falcon is the typical or most perfect one for the latter purpose, and the difference between it and the one now given may in part be observed by comparing this figure with the sternum in that of the jer-falcon formerly given; and, if the sternum of the golden eagle is also referred to, the means of judging will be still more complete and satisfactory.

Swift.

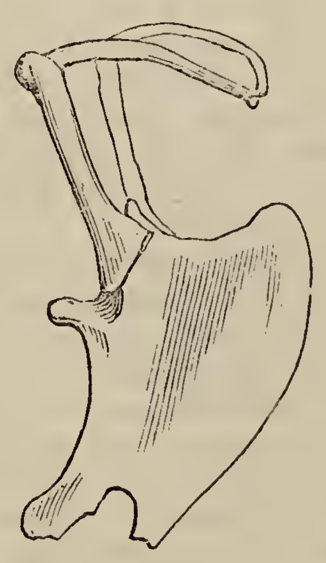
The sternum of the falcon is firmer and more developed in the anterior part than any of the other two, but it is shorter, narrower at its posterior edge, not so hollow, and weaker from the holes at the angles. That of the eagle is larger backwards, more concave, and the holes are nearly obliterated, but still the anterior part of it is broadest. That of the swift has the posterior part broadest, and the angles have no holes. Thus in the falcon the whole strength of the sternum is concentrated upon that part on which the grand flying muscles are inserted; and the more perfect arch and uniform strength of the furcal bone harmonise, and render the whole sternal apparatus the most efficient for powerful flight. There is accordingly no bird which has the same desperate rush as the falcon, and that rush is performed almost exclusively by the effort of the wings, and with comparatively little momentum from gravitation. Indeed a force or momentum produced by gravitation would be a disadvantage to the falcon. She gives chace, and such a momentum would throw her out when her quarry doubles. Thus, though she always attempts to gain and to keep the sky, she never rises to any great height above her prey.

The more produced sternum, and less perfectly formed furcal bone of the eagle, show that her sternal apparatus is not so exclusively, and therefore not so powerfully, of a flying character. The enlargement of the sternum backwards, and the greater strength of the posterior angles, make it more of a carrying basket, though it retains no small portion of the rapid flight character. But strength rather than swiftness is the character of the eagle's wing. The ordinary flight is floating and hovering, and the wings are more employed in bearing her up than in making progressive motion. When she stoops it is always from a height, and no inconsiderable portion of the force with which she strikes arises from the momentum of gravity acquired during the descent. This is further proved by the fact that when the eagle misses her stoop (which, from the goodness of her eye, and the firmness of her body and wing, is not often) she abandons, and takes the sky anew for fresh game; whereas when the falcon misses, she can continue her flight and strike again. The falcon thus more resembles the lightning from the cloud, which produces its effect by its own proper and inherent motion, and the eagle more resembles the ball from a piece of ordnance, which is urged onward by a force not its own.

In the sternum of the swift we have the maximum development of that bone as a carrying basket in the air, but still accompanied with considerable power of wing, though the swift never rushes, either by its power of flight like the falcon, or by a momentum of gravitation like the eagle. Its sternum bears up the whole under-part of the body, and thus it can remain longer on the wing without fatigue than any other bird with which we are familiar. The rest of the tribe are inferior in this respect to the swift; but they all have the same general character of sternum and the same style of flight.

The coracoids in these birds are short and strong; the clavicle open, but an elliptic arch more than a circular one; the scapulars are shorter than the sternum, nearly straight, rather slender, but enlarged a little toward their terminations, which however are pointed.

Night-feeders, or those which feed only in the dusk or twilight, and rest during the day, have their sternal apparatus considerably different. They have the sternum short, widened in front, concave at the sides, and the general outline to the rear convex, but divided into three processes by two large notches. The keel well developed, concave in front, convex in the lower line anteriorly, but becoming straight or even concave toward the rear. The lateral processes with elevated points. The coracoids round in the middle of the bone, but enlarged at the heads, and with a pointed process on their posterior sides, near their junction with the sternum. The furcal bone open, but slender, and the sides not so much arched as in the swift. The following is a representation of these bones in the common goat-sucker of the size of nature.



Goat-sucker.

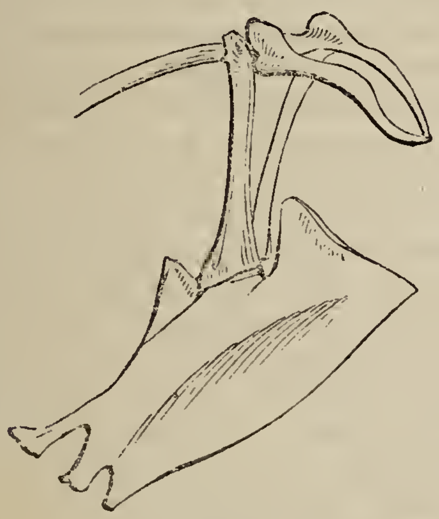
The cuckoo is the bird whose sternal apparatus most resembles that of the goat-sucker; and though the one is a day feeder and the other a night or twilight one, there is a very considerable resemblance in their styles of flight. They are both tree or copse birds, and they never take very long flights when they are in search of their food; and the sternum, from the deep notches in its posterior edge, is not nearly so well adapted for bearing up the body upon long flight as that of the swifts and swallows. Here we may remark, by the way, though the assumption which suggests the remark is now exploded, that there is nothing in the sternum of the cuckoo to prevent that bird from setting upon and hatching eggs in the same manner as other birds do. In their ordinary habit these birds neither fly fast nor take long flights; but the ordinary habit of a bird while resident in one locality is not a certain proof to the full extent of what it can do. The cuckoo flies only from copse to copse, or from one tree in the hedge-row to another; and when feeding its motions are even more limited. But both are very light birds in proportion to their size, and their plumage is soft and loose, so that they float in the air with very easy though not rapid wing. Thus they are able to change their habitat by migration, and appear with us only as summer visitants. In their sterna they bear some resemblance to the owls, with which they also agree in some of their other characters and habits.

Sterna of the syndactyli. These birds are also chiefly dependent on the wing in the finding of their food; but their flight is in general lower than that of the swallows, the prey on which they feed larger, and though not water-birds, or at all capable of swimming, their habits are more aquatic. It is rather a remarkable coincidence with this aquatic habit that the sternum is elongated, and deeply notched in its posterior edge, as in many of the swimming-birds. There is, however, considerable difference between the sternal apparatus of the bee-eater and that of the kingfisher.

That of the kingfisher is more indicative of a power of resisting pressure on the anterior part of the body than of rapidity or even duration of flight; but still it indicates a wing of considerable flying power: the sternum is rather short, and much broader toward the rear than in the anterior part. The keel pretty large, nearly straight in its under edge, and a little concave in front, with the angle advanced a considerable way forward between the coracoid bones. The lateral processes are pointed and produced in front of the junctions of the coracoids. The coracoids are long and strong; and their unions with the sternum are rendered very firm by the projection of the central part of that bone and the lateral processes, which receive and sustain each coracoid as in a fork. The furcal bone is long, open, bent downwards, and much enlarged at the heads of the branches, which are divided into two processes, one in contact with the coracoid and the blade-bone; and the other, which is much larger, passing under and bearing up the head of the coracoid. The blade-bones are also large, flattened, sithe-shaped, and pointed at their terminations.

Thus the greatest strength of this sternum is concentrated upon the coracoids, the furcal, and the blade bones; but when we come to examine the posterior part of it we find it proportionally weaker, so that the keel or origin of the muscles of flight is not so well supported as the shoulder-joint; and that therefore there is, in the sternum of this bird, an indication of some other action of the fore-part of the body besides that of simple flight.

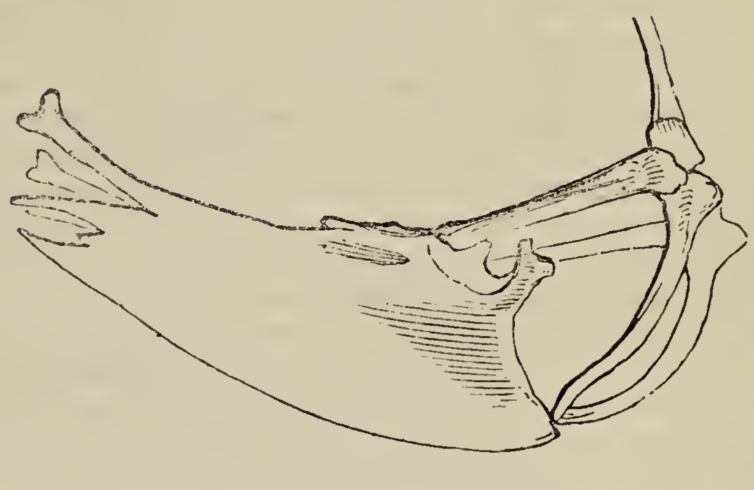
This agrees well with the habit of the bird, great part of whose food consists of small fishes captured when on the wing; and thus the bird has not only to resist the contact of the water with the fore-part of its body, but also to regain the sky with little or no assistance from the feet, while the line of the wings is nearly touching the surface. This is a position from which hardly any bird besides the kingfisher has to recover its flight; for other fishing birds, if we except the eagles and hawks which have that habit, derive assistance either from the bottom, as in the case of the wading birds; or from the water, as in the case of the gannets, darters, and other birds of that tribe. Even the fishing eagles derive advantage from the water in regaining the sky after their stoop. The points of their wings, and especially their broad and firm tail feathers, assist them in working themselves so far out of the water as that they have it under their wings, and thus are able to use these for flight. The twitch which the common kingfisher makes downward upon its prey is performed so rapidly as not to be easily seen; but it is probable that not only the long bill, but also the head and neck, are plunged into the the water, and they are again recovered with equal swiftness, and without materially disturbing the surface; so that this bird requires a very peculiar action of the wing, though it is an action very difficult of explanation. The following figure represents the sternum of the common kingfisher of the natural size.



Kingfisher.

It is found, by examining it in plan, that this sternum is much wider posteriorly than toward the front; but that it is much weakened there, in consequence of the two notches upon each side, the external ones of which divide it to nearly a third part of its length. The difference between this sternum and that of a bird of nearly similar haunt and some similarity of habit, will appear by contrasting the preceding figure with the following one, which represents, of the size of nature, the sternum of the common bee-eater.

This sternum, as will be seen, has some resemblance in shape to that of the swift, only the posterior part of it is rendered much weaker than in that bird by the two very deep notches on each side; the processes that separate which are, with the exception of the middle one which is strengthened by the keel, thin and flexible, though they are widened at their terminations so as to make the posterior line of the sternum nearly a continued curve. The keel is very large, extending the whole length of the sternum, long as it is, and very much curved, both on its ridge, and at its junction to the rest of the sternum. It is, indeed, an exceedingly strong bone, and at the same time a very light one; and if the profile is examined, it will be found that the power of supporting muscles of flight is not diminished by the notches in the sides; for if a straight line is drawn from the anterior process at the insertion of the coracoid to the posterior termination of the keel, it will be seen that this line passes entirely over the solid bone, and that the two processes formed laterally by the notches are not very dissimilar in their situation to false ribs only inserted on the sternum, and not on the spinal column.



Bee-eater.

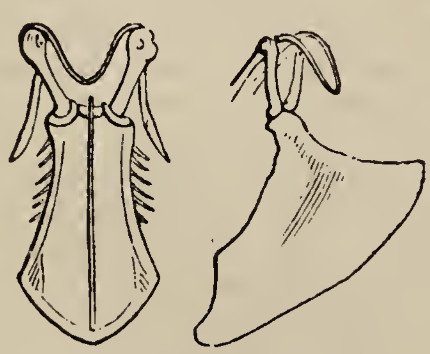
The other parts are equally well fitted for powerful and long-continued flights. The coracoids are long and strongly formed, with their heads much enlarged; the furcal bone is a perfect arch, placed, like that of the falcons, in the position of greatest strength and strongly united to the coracoids. The scapulars also are large and sithe-shaped. The furcal bone is not united to the anterior part of the sternum, though there is a bifurcated process there, neither has it any tubercle or other indication of a junction of two branches at the middle, but consists of one unbroken curve of nearly uniform strength throughout.

This sternum is very beautifully adapted to the habits of its owner. It combines great flying power: length for the support of a body habitually on the wing, and flexibility in the posterior angles, by means of which the bird can better thread its way among obstacles. And the birds of this and the analogous genera are all powerful and long-continued in their flight, although none of them are lofty fliers. Feeding chiefly upon winged insects, by the banks of rivers or over other humid surfaces in warm climates where vegetation is luxuriant, they have to pursue their prey among twigs and branches, the pendent festoons of climbing plants, and the tall stems and large leaves of aquatic ones, so that while they pursue on a swift and smooth forward flight, it is also necessary that they should be able to glide and turn in all directions with the utmost freedom. This facility in turning is very necessary to birds which feed upon insects, many of which are themselves carnivorous, and hawk for their prey in the bushes or on the leaves, and others are to be sought for in the corollas of plants, into which they have plunged for the sake of the sweet juices which accumulate there.

Birds of this family bring us to the margin and surface of the waters, with those races whose habit it is to prey on the wing; but there are still those tribes which feed chiefly by perching on the stems or the twigs of trees, or walking on the ground; and we shall find that, though there are great differences in the sternal apparatus, both of those which have the one habit and those which have the other, according as they combine it more or less with the action of the wings, yet there are characters descriptive of each, that run through the whole.

Sterna of the anisodactyli. Some of these use the wings more and some less, but as they are all more or less walkers on the boles of trees, and other surfaces, on which, from their form, and especially from their position, there can be but little stability arising from the ordinary pressure of gravitation, which is the principal means of stability upon horizontal surfaces, they require to be birds of very ready wing, which can instantly throw themselves upon that part of their organisation, in the event of their claws missing hold. The wing required for this purpose must have muscles of considerable power, and also firm feathers. Such wings have to be used in all positions of the body; sometimes both, and at other times only one of them can act, and they often strike against trees, branches, and other hard substances, so that they require more strength in their whole structure, than wings which are used only in the free air.

Some of these birds also feed on the wing, and feed on the sweet juice of blossoms, to acquire which there must be much use of the wing before even a little bird can procure a meal. Thus, though the wings of these birds cannot be considered as the most general or immediate of their organs in feeding, they are very essential in some, and in all they are auxiliaries which need to be constantly in readiness. As the wings, even of those species which use them the most in feeding, are not used for long stretches, but merely for flitting about from flower to flower, they all have the character of twitching wings, which take the air by sudden jerks more than of wings of forward flight; but notwithstanding this undulating style of flight, some of them get through the air with much rapidity. We shall select as specimens for illustrating the sternal apparatus of the tribe, one of the humming-birds of the tropical parts of America, which is a feeder on the wing, and the common hoopoe, which is a summer migrant in the warmer parts of Europe, and feeds on the ground or on trees.



Humming Bird.

The sternal apparatus of these very small birds is, as may be seen by the figure, remarkably well developed, though, like that of the swallow tribe, it combines not a little of the character of a carrying basket with that of an organ upon which to establish the means of powerful flight. It has a considerable resemblance to the sternum of the swift, being long in proportion to its breadth, and considerably broader in the rear than toward the front. In general it is without notches or holes at the posterior angles. The keel is perhaps more developed in proportion to the size of the whole bone than in any other bird; the coracoids are also short and strong; and the scapulars, from the particular way in which they are bent, take a firm hold in their embedment. The form of the furcal bone is also good, though not a perfect arch; but it is proportionally weaker than the other parts of the arrangement.

We may glean something respecting the highly interesting but exceedingly obscure subject of muscular action, from the study of this sternum. It is higher in the keel in proportion than any other, and the height is continued farther backward than in most birds; but the anterior part, where the great muscles of flight are attached, is narrow, narrower in proportion to the height of the keel than in any other known species. Hence, though the muscles admit of a greater number of fasciculi of fibres than if the relative breadths of the side of the sternum and the keel had been different, yet these fibres must be proportionally shorter.

Now, though muscular action is not capable of being estimated with mathematical accuracy, because we have no measure of any action of the living principle, and the very same muscle is capable of many different degrees of action, arising from health, excitement, and various other circumstances which cannot be reduced to a numerical scale; yet as the action is mechanical in its effects, whatever it may be in its principle, it must follow that the shorter the fibre is the sooner must it be wholly brought into action, and the sooner also must its individual effort be over. All muscular action (as the reader must of course be aware) consists in a contracting or shortening of the fibres, and a proportional increase in thickness. How the shortening takes place is a part of the subject upon which it would not be very wise to offer any conjecture, as it is one upon which we possess no knowledge; but the action itself can be observed, and we may rationally conclude that the times in which equal degrees of excitement are communicated to muscles are in proportion to the lengths of their fibres: that one-half of the length will be brought into action in half the time, and so of all other proportions. This will hold true, whatever may be the absolute length of the time, even though it should be, as it no doubt is in the case of very minute muscles, too short for our being able to measure, or in any way estimate its length in terms of any other motion. But as the shorter muscle must act in the shortest time, so the action of the longer one must be greater, if the requisite time is allowed it—it must contract more, or be capable of moving the same weight over a greater space.

From the indeterminate quantities, which we have no means of separating, or even of expressing, that, as already noticed, enter into the very complex operation of muscular action, what has been now stated can be regarded only as a glimmer in the dark, yet it is far from being without its use, especially in the comparison of structures so varied in their actions, yet all formed on the same general principle, as the wings of birds.

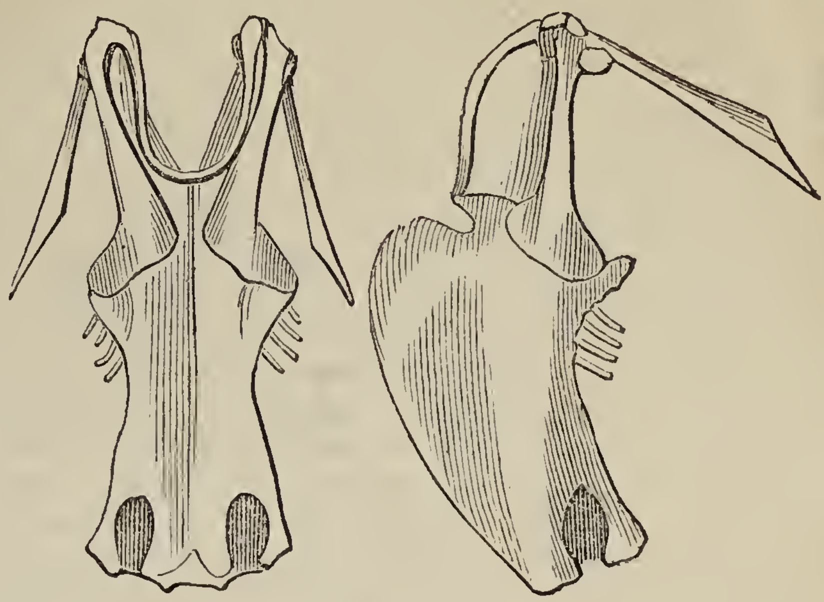
A short muscle will, from what has been said, perform its extent of motion more rapidly than a long one; but it will not move so heavy a member, or move it over the same effective extent at one contraction. Hence we find that birds which rush upon their prey on the wing, have the sternum broader at those parts to which the grand and middle pectoral, which depress and raise the wing in flight, are applied; that (though its tendon is longer, from passing through the pulley) the body of the middle pectoral is shorter than that of the grand, having a lighter labour to perform, but having to perform it more quickly; and that birds which have this habit have the wings, and indeed the whole frame, more solid and heavy than other birds. But we find that in those birds which make no rush, but capture their food in the air at the speed of ordinary flight, as in the swallows and bee-eaters, or which flit about, not in chace of their food, but simply in quest of it, as the humming-birds, the sternum is narrowed in these parts so as to adapt it to the action of shorter muscles, without the load of an additional portion of tendon; and that, in proportion as the habit of these birds requires the action of the wing to be more powerful, the keel is deepened to admit the insertion of a greater number of muscular fibres, or fasciculi.

In birds which fly with equal speed on a level, or an ascent or a descent, the raising of the wing with great rapidity and considerable force is much more necessary than in those which get their most rapid motions upon a descent; and it is especially necessary in the group of birds under consideration, which always have to hold the wings in readiness for being expanded, while they are adhering by the feet to upright or sloping surfaces. Accordingly, they have the middle pectoral larger in its volume, and also in the surface to which its origin is attached, in proportion to the grand pectoral, than birds which have a descent in their rushing motions.

The different style and direction of the flight are not, however, the only circumstances to which the muscles have to be accommodated. The bird requires to be able to make its way through the air the more easily the greater length of time that it spends on the wing, and this easiness of the motion has reference to the respiratory and circulating systems of the bird, as well as to the fatiguing or not fatiguing of the muscles. Now, if we may judge from the analogies, which, as far as we can trace them in all living nature, agree, we must conclude, that, up to a certain rate of speed, the short muscle, moving the comparatively light member, is that which can continue longest in action without fatigue to the muscles, or derangement to any part of the system; but that, beyond a certain rate of motion, the long muscle is the best for speed, though the continuation of its action is shorter than that of the other. We find this in the limbs of the mammalia, and in the feet of birds, whether used in walking or in swimming, as well as the wing, and the principle is one of considerable importance in the economical use of animal power.

The hoopoe, which we shall select as a specimen of anisodactylic feet, with the habit different the most from that of the swimming birds, has the tarsi much longer and stronger, and instead of walking with difficulty on the ground, it walks with a sort of strut, as if it had more power there than what is absolutely necessary for moving it along. The following figures represent the sternal apparatus of the natural size.

It will be seen that the general form of the sternum is nearly the same as that of the humming-bird, but that there are very marked differences in particular places; the keel is lower, but the anterior part of the sternum is better developed; the lateral processes are much larger, and there is a process in front which approaches the furcal bone. The posterior angles are weakened or rendered flexible by two deep notches, and there are only four ribs on each side.



Hoopoe.

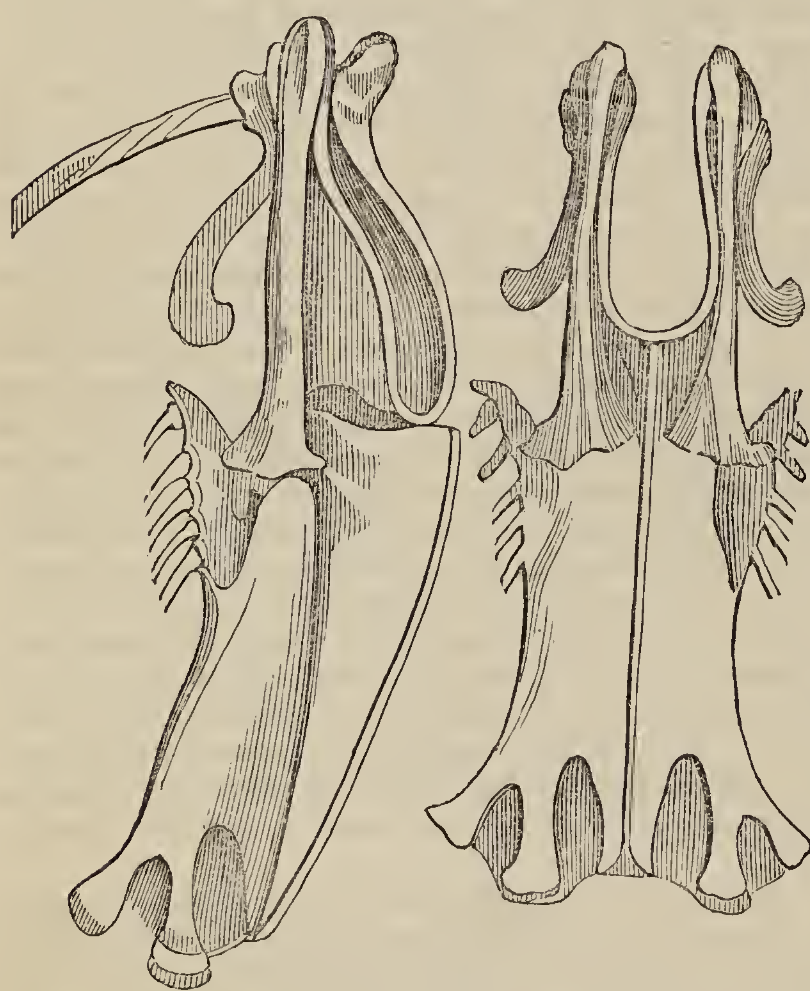
Thus the body of the bird is much more yielding than that of the humming-bird, and bears nearly the same relation to it as that of the swift bears to that of the goat-sucker. The anterior part of the keel is much rounded, and the furcal bone is much bent toward the coracoids, though it does not proceed so straight backward as in the parrot tribe. There is, however, a considerable resemblance in the anterior part of the sternum to that of the parrots, while in the posterior part there is a slight approach to the character of the ground birds. The style of their flight corresponds. It is unequal and jerking, performed with much flutter of the wings, as if the down stroke of these were not very effective, which might be inferred from the rounding away of the anterior part of the keel and the feebleness of the furcal bone. But they can raise the wing with great quickness; and, though their flight is far from being so graceful as their form, they make way with considerable speed. They are birds of the margins of the waters, and especially resort to rivers which are subject to flooding; but they also sometimes hunt for beetles by running along the bark of decayed trees, and often choose the holes of these for nestling places.

Sterna of the Zygodactyli. Of these we shall give as specimens, the sternal apparatus of the common green woodpecker, as being chiefly a bank bird, and resembling in some of its habits the anisodactylic birds, and of the common jacko, or grey parrot, which is one of the most scandent. The cut on next page, that of the woodpecker, is of the natural size.

This is a very peculiar sternum; and upon looking back to what is said of the foot, or, far better, by watching the habits of the bird itself, it will be found to be one of very peculiar action. The bird, while it seeks its food in the holes of trees, or excavates them in making a resting hole for its young, rests chiefly with the sternum pressed against the tree; and it will be seen, upon examining the profile, that the bones are fully as much suited for answering this purpose as they are for flight, though the great length of the sternum, and the production of the keel for the whole of that length, though not very high at any point, still enable the bird to use its wings with considerable effect.

The posterior angles of the sternum are divided by two deep notches on each side, the processes between which are enlarged at their extremities, and, except the middle one, padded with cartilaginous discs; they thus protect the flanks of the bird far backward with a strong cuirass, though flexible or elastic at the sides. The continuation of the keel, however, renders the central part stiff and firm throughout its length, so that it admits of flexure in the flank angles only.

Upon examining the anterior part we find the coracoid bones produced in the direction of the sternum, and as long as that bone; while the furcal bone is nearly a continuation of the line of the keel, and, though not wide in proportion, it is longer than in any example which we have yet adduced. The lateral processes are also very much produced, and two of the five ribs on each side are articulated upon them. The blade bones are of very peculiar shape, being curved downwards at the terminations in the shape of blunt hooks, as if the coracoids, which lie nearly parallel to the axis of the body, instead of approaching it obliquely, as in most birds, were hooked to the muscles near the spine.



Woodpecker.

And this is a highly typical sternum, and one upon which, if space permitted, many observations might be made. Though its peculiarities have much less reference to the style and manner of flight than to the action of the bird when upon the bark, with closed wings, yet they show, and perhaps on that account show more clearly, that the sternum of a bird, that organisation which supports the body, having the spinal column in a great measure bare, is the grand characteristic portion of its structure—the essential part by which a bird is distinguished from every other animal—and the basis, as it were, upon which all the rest of its organisation is built, and in accordance with which the whole of the minor parts are formed.

The main office for which the structure of a woodpecker has to be adapted, is that of maintaining with the under part of the body a vertical position on the bark of a tree, in such a manner as to have the head, the neck, and the spine as far as the lumbar vertebræ (which have a little more motion in this bird than in some others), perfectly free, so that the point of the bill may command the largest possible surface which is compatible with the length of the neck, or move with that force and velocity which are necessary for hewing holes in the wood with the greatest certainty and expedition. For this purpose, the long sternum and coracoids, with the keel and furcal bone on the exterior side of them, form a flat arc with its chord,— the former applied to the tree, so that the fixed point upon which the head and neck move in pecking may be brought nearer to the surface, or moved farther from it, according as may be necessary. If this part (which may be called the base of the bird when in action) had been straight, there would have been more stability in one position, but it would have been only in one, and in that one only when the vertical line of the bark happened to be straight, which is not often the case in those gnarly and decaying trees which afford the fattest pastures for woodpeckers. This, however, would have made the bird work at a disadvantage in excavating a hole to any considerable depth; because, if the position of the centre of action had been immoveably adjusted to any one distance, the action of the bird would have been less effective at every other. But the arched form of the keel enables the bird to keep the centre of action always adjusted for the maximum effect, and that with so slight a motion of the steady or pectoral part of its body that it can hardly be perceived.

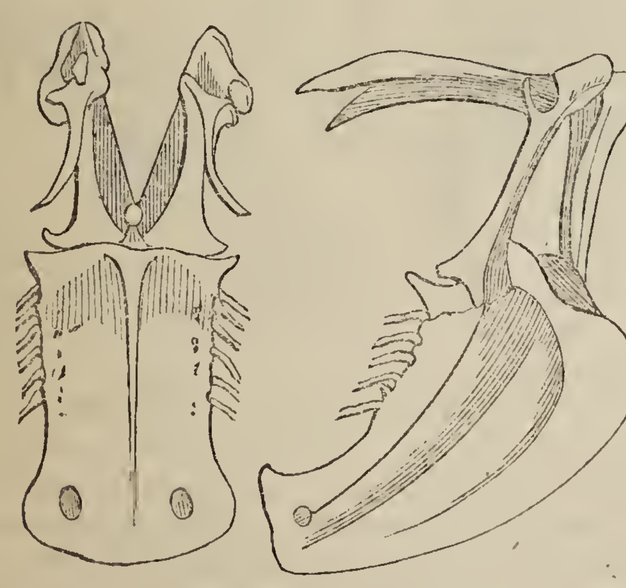
A very little extension of the tarsal joints brings the centre of action more to the tree, and a very little bending of the same joints removes it farther away. Nor is this ready adaptation of the centre to the greatest effect of the stroke the only result of that action of the tarsal joints by which it is produced; for there is the same nice adjustment of the degree of hold taken on the bark to the varying stability of the position. When the centre of action is removed to the greatest distance, the centre of gravity is thrown farthest out, in proportion to the line of the axis, and therefore the weight tends more to pull the bird from the bark; but the very same action of the tarsal joints which produces this, causes the claws to take a firmer hold of the bark, and also the stiff feathers of the tail to bear more against it as a strut. So also, when the centre of action is brought nearer to the tree, and the hold by the foot not so much required, the same extension of the tarsal joint which brings the axis more parallel to the tree eases the clutch of the foot in exactly the same proportion.

Thus, by one of the most beautiful instances of the harmony of parts with each other, the woodpecker is enabled to work with equal stability and effect, while the axis of the body is at all possible angles to the line of the tree, within the range that is necessary for its habit; and yet the different parts of this very curious and apparently complicated organisation are so flexible to other purposes that the woodpecker can at once become a wing bird or a ground bird, when such a habit is necessary.

When on the tree, the woodpecker may be regarded as consisting of three parts, all differently employed; the first of these is the sternum and its apparatus, which acts as the basal or pectoral part, and has no motion except in bringing the centre of action to the tree, or removing it to a greater distance; the second or prehensile part, which consists of the posterior part of the spine and its apparatus, the legs and feet, and the tail; the former of which act as double hooks in holding on, and the latter as a prop or strut; and the third, or immediately acting part, consists of the head and neck, which move with great rapidity without in the least disturbing the other parts. The wings do not come into play, unless when the bird shifts its position laterally, or rises from the tree; but they are, as in the case of all climbing and perching birds, which have much action of the bill when holding on with the feet, always held in readiness, so as to come into action whenever any sudden jerk may require it.

The wryneck, which adheres to the bark of trees something in the same manner as the woodpecker, though its action upon them is different, has the sternum very much of the same structure; only as the wryneck does not hew into the wood of trees, but merely searches the crevices for bark insects, it has a different motion of the head, and the furcal bone differently formed to suit this motion. It cannot strike so forcibly with the bill, or so repeatedly in one place, as the woodpecker; but the wryneck has the joints of that organ remarkably quick and free in their motions, so that when it is searching the crevices, now on the one side now on the other, the well defined mesial line of rich deep brown, which marks the neck and shoulders, appears to be twining up the tree like a little snake.

Zygodactylic birds, which are a very numerous tribe, and the characteristic tree or forest birds of the warmer parts of the world, have many differences of habit, according as they depend more upon flying, walking, or climbing, and according to the nature of their food and the places of the trees, or between them, where they seek it. The sternum is of course modified to suit these differences; and thus no one bird can in that respect be considered as typical of the whole order. That of the woodpecker, which we have given, may be perhaps considered as the one extreme, while the following, which is half the lineal dimensions of nature, may be regarded as the other.



Jacko Parrot.

The posterior part of this sternum bears some resemblance to that of the diurnal birds of prey, but the anterior portion and the attached bones are very different. Its relative length is also nearly the same. But all this similarity of the hinder parts of the two sterna merely shows that parrots and diurnal birds of prey have both a very powerful and firm action in those muscles which move their tarsi or toes, while the different actions depend on the structure of the toes themselves. It is, however, of no inconsiderable importance in facilitating our knowledge of the relation between structure and use in those parts of birds, even those parts which are not immediately connected with each other, to find that the same quantity and power of motion (however different the object) are accompanied by the same general form of the posterior portion of the sternum; and there is still this other relation between the action of the feet in these otherwise dissimilar tribes of birds, that, though they are both powerful clutchers, the one in killing game, and the other in climbing among twigs, they are both very imperfect walkers on the ground.

When we come to examine the anterior part of the sternum—that on which the character of the flight more immediately depends, we find that, though the wing of the parrot must, from both the depth of the keel and the breadth of the sternum, be a ready wing, yet it must be comparatively feeble and unsteady.

The lower ends of the coracoids do not form an angle of about sixty degrees, with these edges attached to the sternum, as is the case in all the falconidæ of powerful wing; neither are their axes directed toward the strongest part of the keel of the sternum, either when viewed in front or on the side, as those of the falcons are when viewed both ways. Their union with the sternum, though not quite a straight line, is upon the whole at right angles to the axis of the body when seen in front, and they are nearly parallel to each other; and though enlarged at the heads, not nearly so robust as those of the falcons, although rather longer in proportion. In their articulation on the sternum, and their position with regard to each other, they have thus very little stiffness in resisting the approach of the shoulder joints toward each other; thus in this respect they are to a great extent the very opposite of those of the falcons. And this flexibility which the coracoids have for bringing the shoulder joints together, is not counteracted by any great strength of the furcal bone; for, though the two extremities of that bone are enlarged, the branches are slender and straight, which renders them as feeble as the coracoids. Even the blade bones are not formed for taking a very firm hold in their embedment.

Thus when we examine the point of articulation to which the wing of the parrot is attached, we find it a very feeble one, and one which could not be used in long flight, without great fatigue to the bird. The coracoids and branches of the furcal bone are placed in that position in which they are the least fitted for resisting that strain on the shoulder joint which is necessarily given when a bird flies rapidly; and they even appear to be loaded with an additional quantity of bone at the joint, for no other apparent purpose than that the joint may be the more unsteady, and the flight of the bird the more feeble and laborious. We would thence, if we reasoned only from the relative structures of the sternal apparatus, be apt to conclude that nature has given to the parrot tribe similar power of foot with the birds of prey, but shorn and crippled them in those characteristic organs of birds, the wings.

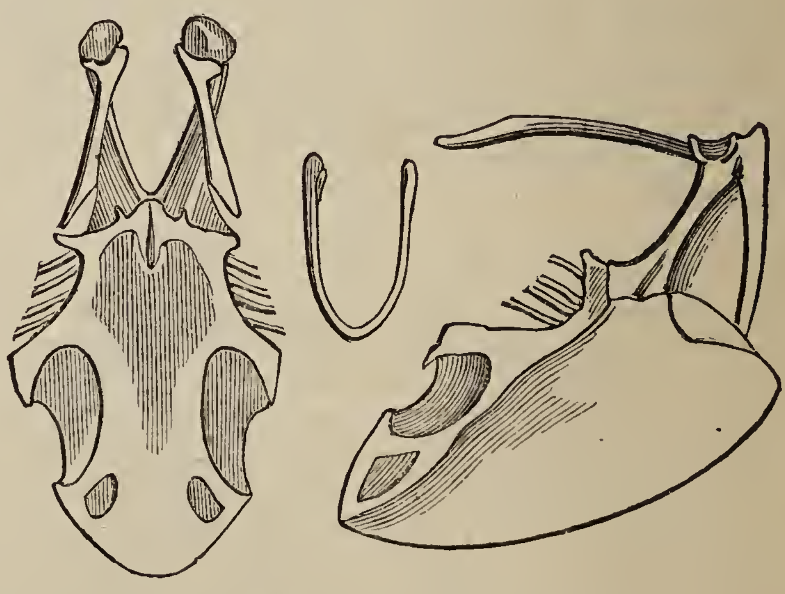
When, however, we take the haunts and the habits of each into consideration, we find that not the jerfalcon herself, in the pride of her finest flight in the free air over the bleak and bushless wild, affords us a better specimen of exquisite mechanical skill, both in the design and the accomplishment, than the parrot among the tangled sprays of a tropical forest. The fine wing of the falcon would avail her nothing in such a place: for it is as unbending as the spirit of the bird; and one stroke of it taking effect on the branches, which in the habitation of the parrots she could not avoid, would fracture the wing, firm as it is, or at all events throw her off her poise, and tumble her to the earth, defeated, helpless, and fit only for food to the snake or the vulture, if even they did not scorn her as a meal.

But the wings of the parrot are, from the looseness of their articulation, proof against any such casualty; so that, though the bird move and flutter them ever so much among the thick sprays, or have to use them in the most awkward situations, in making way from perch to perch, when the distance is too great for the reach of the foot or the bill, they do not sustain the slightest injury. From the flexibility of the wings of these birds in the joints of their bones, the bones are not only saved from danger of fracture to which more firmly-jointed ones would be constantly exposed, but the feathers are also less liable to be ruffled or injured by striking against the twigs and branches than the feathers of those stiff wings which are adapted for more forward and rapid flight are by the contact of the air, when they deliver their strokes from their comparatively immoveable points of articulation on the firmly-knit shoulders.

All forest birds, which have to make their way among twigs and leaves, and all birds generally which are liable to come in contact with obstacles in the stretching out or in the subsequent use of their wings, have them more or less of this yielding structure, according to the necessity which they have for it, so that, whatever may be the difference of the place of resort, or of the hazards to which any creature may be exposed on account of these, the creature which is native, or in its natural and accustomed element, in them, is just as much at home and as safe in the one as in the other.

It is this universal perfection of adaptation which renders the study of nature, the more extended and liberal the scale on which it is conducted, the more gratifying to the best feelings, and the more cheering to the best hopes of man. When we study the different parts of the world, in their climatal differences and in their productions, we find that they are dependent upon the structure and form of the earth's surface, the motions of the earth around the sun, and the reciprocal actions of earth, water, and air, with those of the relative positions of the sun and moon upon both; but that, in all the varieties of climate, and all the differences of surface and vegetation which are produced by those numerous and complicated causes, the animal, to what class soever of animated nature it may belong, is so true to all the rest of the system, that they must be all parts of one design—the workmanship of One Almighty and All-seeing Architect, who required to proceed by no such experience of steps or induction of particulars as that which hems in the widest flights of our invention; and that, ere one particle of the whole system was in existence, every possible part of the complicated whole, and every variety of which any one is susceptible (even those which, to our confined perception of the matter, appear anomalies or imperfections) must have been far more clear and simple than is to us the simplest work which we can perform, after we have performed it the greatest possible number of times. If we attend only to the single organ, we cannot but admire the perfection of workmanship which it displays; but when we, to so humble an extent as our limited powers enable us, endeavour to think of the whole, our admiration changes to the most complete astonishment, because the utmost effort of our powers can no more fathom the depth of design, which is apparent in whatsoever portion of nature we study, than the span of our fingers can measure the extension of the universe.

Sterna of the Columbadæ. Though these birds are not climbers, and the greater number of them seek their food upon the ground, chiefly vegetable, though some of them also eat insects, yet they retain in the sternal apparatus some of the characters of the climbing birds; and there are, among the species found in warm countries, some which have the colours of the plumage as brilliant as any of the climbing or zygodactylic birds. They in general perch in trees, or in the holes and on the ledges of rocks; but there are some species which reside chiefly on the ground. There are also some which, in their general appearance, and partially also in the form of the sternum and its apparatus, have some resemblance to the gallinaceous or poultry birds; and of these, as is the case in that order, there are some which nestle in trees and some on the ground. The race are indeed considerably diversified; but still the more typical ones, in many particulars of their sterna, preserve a resemblance to the climbing birds. The sternum of the rock-dove, which is usually considered as the parent stock out of which the numerous varieties of domestic pigeons have been bred, may be selected as about the average.



Rock-dove, half the lineal dimensions.

In the development of its keel, this sternum bears some resemblance to that of the parrot; but it is better formed for flight, as the keel is more advanced in front, and the angle, though rounded off, is not so much so as in the other. The central portion backwards is much more produced, and it is rendered stiff by the continuation of the keel; but the angles are cut off, which gives the entire bone a sort of lozenge form; and the sides are weakened by the two holes and two notches which appear in the figure. The coracoids, though not very strong, are much better set at their junction with the sternum than those of the parrot. They have not that direct bearing toward the centre of the sternum which we find in the more typical wing birds; but their axes do form an angle with each other as seen in front, and the position of the lines of their union tends also to throw the pressure on their heads toward the middle of the sternum. The clavicle, though by no means of the strongest form, is much firmer, in comparison with the quantity of matter that it contains, than the clavicle of the parrot. It is an arch, though an elongated elliptical one, and therefore comparatively weak against lateral pressure on the extremities, though not so much so as a fir with the branches nearly straight, and its process at the middle bearing on the head of the sternum. Thus the sternal apparatus of this order, though far from being so firm as that of those birds of which the air is the principal element, is not so flexible as that of those birds whose chief action is walking upon legs so articulated as to support the axis of the body in a horizontal posture. The pigeons are thus, in their structure, intermediate between air and ground birds; and they are, on the average, the same in their habits, though, according to this habit, they might perhaps admit of division into four groups. First, those which feed, habitually or occasionally, upon seeds and berries, while these are yet on the plant, the tree, or the bush. Of these the migrant pigeons of the south-east, which are gay in their plumage, and which, though they have perching rather than climbing feet, yet have some resemblance to the parroquets, are the most typical. Secondly, those which, though they feed more on the ground, yet perch and nestle habitually on trees, of which we have British examples in the common ringdove, and in the rarer stock-dove and turtle. Thirdly, those which feed on the ground, and roost and nestle in rocks, of which the rock-dove may be regarded as the type, and all the varieties of pigeon-house and domesticated pigeons as instances. Fourthly, those which bear so much resemblance to the gallinidæ that they are popularly called gallinaceous pigeons. Of these one species is as large as the common turkey, or larger. Some of them nestle in trees, and some on the ground, but they are all lower fliers and less discursive in their range than the true pigeon; they are also much more omnivorous, and on this, as well as on other accounts, they ought in a perfectly natural system to stand as a separate family, if not as a distinct sub-order.

Before proceeding to notice the sternal apparatus of the gallinaceous tribe, it may not be improper to remark that the flexibility of the lateral parts of sterna produced by notches of the bone, or cartilaginous continuations, are intimately connected with the power of walking straight forward upon two legs, in birds which have the use of their wings in flight, and which consequently have furcal or clavicular bones, though the form and strength of these vary with the powers of flight.

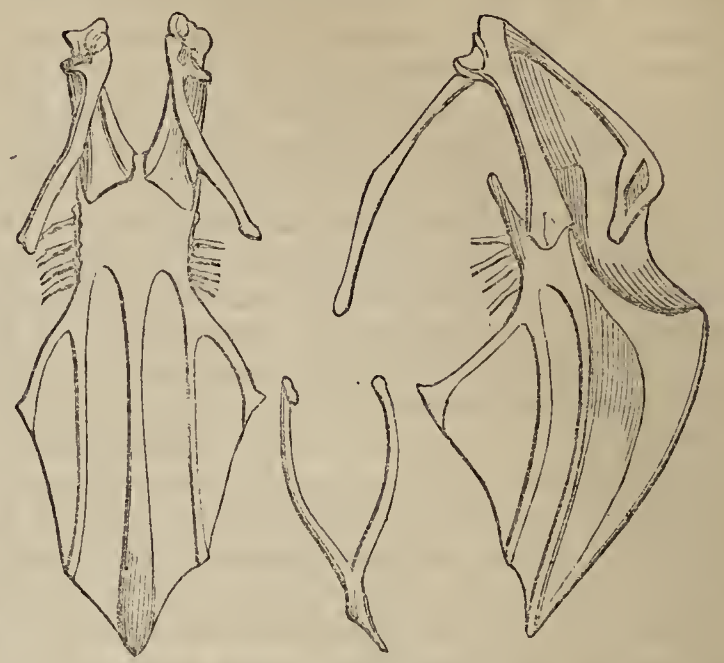
It will be readily understood that the clavicle ties the shoulder-joints together, and the coracoids at the same time keep them both at equal distances from the anterior angles of the sternum, so that the line joining the shoulder-joints is immoveable in position with reference to the sternum, except in so far as the different articulations are loose and admit of play, and the change of position produced in this way is very limited. Consequently, if the sternum were inflexible (as it is in birds of powerful wing) in clavicled birds which walk by striding with the alternate foot, and not by hopping with both feet at once, the line of the bird's body would twine about like a cork-screw as it marched along, as the advance of each foot would necessarily throw the anterior part of the axis to the opposite side, and give the bird a swinging motion upon its centre of gravity, which would considerably increase the fatigue of walking, and thus be a violation of that general law according to which all the natural actions of animals are performed with the smallest possible waste of their energy. We see instances of this swinging of the axis in several flying birds when they walk by steps; and it is more conspicuous in proportion as the tarsi are longer, and the tibiæ more moved in performing the step. But such birds have generally the tarsi rather short, so that on their quick marches upon the ground they take short trundling steps, or they hop, as is the case with most of those *passeres* which are habitually or occasionally ground feeders. In order that the progress may be by steps of considerable length, it becomes necessary that, if the shoulders require a stiffening clavicle to fit them for flight, the posterior part of the sternum and also the ribs, but especially the former, should be flexible, in order that the one side may contract and the other expand on the advance of the leg, as much as shall keep the axis of the body steady to the line of motion. We have a perfect confirmation of this in the sterna of gallinaceous birds, all of which are straight-forward runners, and runners without hopping. Many of the long-legged birds also run fast and steadily forward, and never use any action of the feet for that purpose, except the alternate one; but the particular structure of the bones, by which this is accomplished in them, can be more advantageously explained afterwards.

Sterna of the Gallinidæ. The sternum of these birds has, in its general outline, the lozenge form which characterises that of the pigeon tribe, only it is more elongated in proportion to its breadth. As in these, the anterior part of it is the firmer, but the posterior part is much more flexible, consisting of five processes of bone, all narrow and slender, with the notches next the middle by far the deepest, extending, in fact, fully more than three-fourths of the entire length of the sternum; and the two lateral processes, though united by cartilaginous membranes to each other and to the central bone, having more the appearance of a forked sternal rib than of portions of the sternum as a continuous bone. The keel is considerably developed, especially in the anterior part, but lower toward the rear, though there it still affords some stiffness to the middle portion of the sternum. The anterior part of the sternum terminates in a triangular process, which is notched at the edges to receive the coracoid bones, and the lateral processes extend forwards nearly as far as the triangular one in the centre. The coracoids are rather strong, flattened on their anterior edges, and with an angular ridge backwards. The clavicle is a semi-ellipse, more elongated, and with the branches much more straight, feeble, and flexible, than in the pigeons. It has always a process at the union of the two branches, often of considerable size, and directed toward the anterior part of the keel to which it is united. The shoulder bones are rather large, broader in the middle than toward the extremities, and a little bent.

The whole structure of this sternal apparatus shows that its strength lies much more in the vertical plane than in the horizontal, and consequently that it is better adapted for supporting the body of the bird, while walking or running, than for giving steadiness to the wing in flight. The coracoid and the clavicle stand upon the sternum like two sides of a triangle, of which the anterior parts of that bone and its keel form the third side or base, and thus the shoulder-joint is kept at the same vertical distance from the sternum. The enlargement of the blade-bone, too, gives that joint a firm suspension in the muscles of the back, and this, with the other structure of the bones which have been mentioned, causes the sternum, and the viscera which it supports, to hang, in a great measure, upon the upper part of the back, from which the support is continued through the bones, and furnishing a larger supply of muscles for the support of the legs than in air birds. But this very arrangement, which makes these bones steady, or comparatively stiff, in the vertical direction, and connects them with the legs as the grand organs of motion, renders them more flexible, or less able to resist a strain in the cross direction. This is a general principle in mechanics, that when any arrangement of pieces, framed by carpentry, as one would say, have the greatest possible strength in any one plane, they have always the least possible in the plane at right angles to that one. A truss which supports the most extensive roof, as, for instance, one of those beautifully scientific ones which support the roof of Westminster Hall, would break in pieces by its own weight, if an attempt were made to support it horizontally by the ends of the rafters; and even if it were laid on its side, with the ends of these and the vertex on two walls of equal height, all the framing, which makes it so stiff and strong, when it stands upright, would be just so much of a load upon the rafters, by which they would be weakened to its full weight, from the strength which they would have if laid single at their full length upon two walls, to the general lines at which they were at right angles.

This structure, which throws the strength of the sternal apparatus into the plane in which the legs are moved in walking, is the grand characteristic of a ground bird, and the very opposite of that of a bird of powerful wing, which has the plane of greatest strength in its sternal apparatus nearly at right angles to the plane of walking; and therefore the power of walking in the latter bird is the smallest possible in proportion to the articulation and muscles of its legs, just as the flying power of the gallinaceous, or ground birds, is the smallest possible in proportion to the articulation and muscles of their wings.

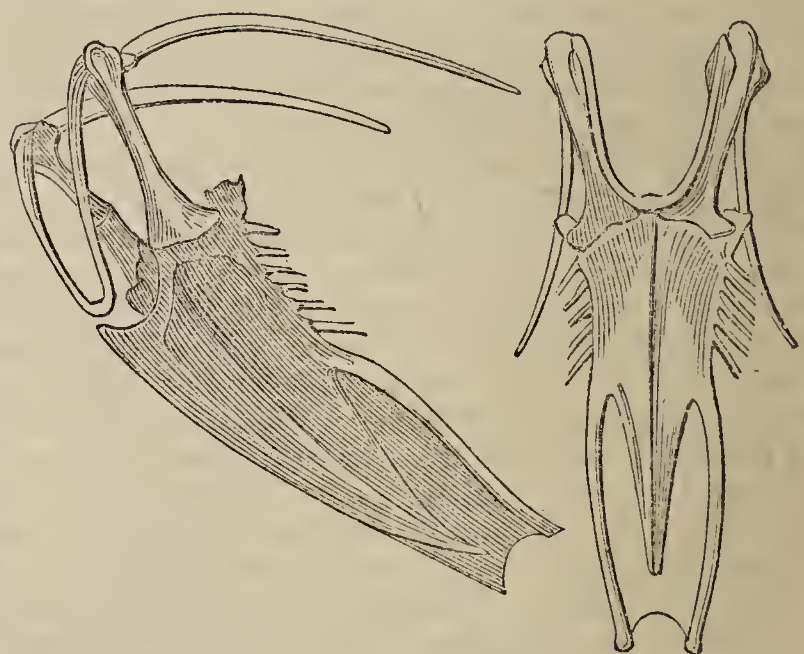
Birds of this order are numerous; and, though there is perhaps fully as much similarity of habit among them as among the different species of any other order equally numerous, yet there are slight differences. The common partridge, as one which is among the fleetest runners, runs almost the instant it is out of the shell, always rests or squats as well as nestles on the ground, and seldom takes the wing, may be considered as one of the most typical; and it has the farther advantage of being almost the only one which, in a state of nature, may be seen and studied alive in every habitable district of the British islands. The following figures represent its sternal apparatus, half the lineal dimensions of nature.



Common Partridge.

Sterna of the Gallinules. Birds of this tribe may be considered as in their habits forming a connecting link between the gallinidæ and those swimming or diving birds which have the feet lobed or webbed, and they may be taken as an average type of the *Long-toed birds* of Cuvier's arrangement.

The following figures represent the sternal apparatus of the common gallinule, half the lineal dimensions of nature.



Gallinule.

This sternum, as may be seen from the figures, is very long and narrow, broader toward the ends than at the middle, divided posteriorly into three processes, by means of two deep and wide notches, which are filled by cartilaginous membrane. The middle process is rather longer than the solid portion of the sternum, and terminates in a blunt point. The lateral ones are more than one and a half times as long, and are a little broadened at the points, and the edge of the membrane between them is concave. These lateral processes are flexible, and may be regarded as oblique sternal ribs for supporting the planks of the bird, rather than as portions of the sternum in supporting the organs of flight. The middle process is rendered stiffer by the keel, which, although not high as compared with that of many other birds, is high in proportion to the width of the sternum. This keel is convex on the under side and concave on the front, the angle pointed, and surmounted by a small bony process outside. The lateral processes are inclined forward and upward, and there are six ribs between them and the posterior lateral ones. Coracoids short, but well formed, and moderately well set for giving firmness to the shoulder joint. The clavicle is a long semi-oval, rather slender, but without any process on the under side at the union of the two branches; but there is a small tubercular process on the upper side. The scapulars are very long, and a little bent downwards, and thin.

This sternal apparatus indicates considerable power of flight, though, from its narrowness, the stroke of the wing must be quick and rather feeble. The central posterior process gives a firm support to the middle of the under part of the body; and the lateral ones, from their great length and flexibility, support the flanks, and at the same time enable the body to accommodate itself to those obstacles among which, from their habits, the birds have to find their way. The narrowness of the sternum in proportion to its length, and the accordant general shape of the bird, also conduce to the same purpose, and the straightness of the sternum enables it better to resist pressure in the direction of its length than the curved sterna of other birds, though these support much more powerfully the flying motion of the wing.

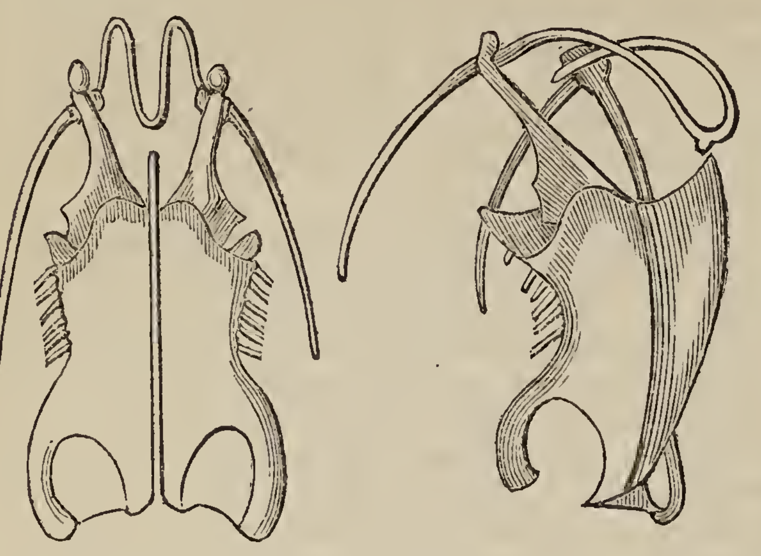
Many of the birds which have the sternum of this form are swift and smooth runners, and all, or at least most of them, run with the head advanced nearly in a line with the axis of the body, which is carried horizontally. The head, too, is small and pointed, and the shoulders are narrow and tapering. This form of the body enables the birds to make their way among the tall herbage of humid places, and especially the banks of brooks and streams, and the reedy margins of pools and shallow lakes in rich and flat countries, where they seek the greater part of their food. Many, if not all of them, can at times enter the water, and, when they are immersed to a sufficient depth, they use their wings for motion in that element. The narrow sternum, and the consequently short and rapid motion of the wings, are much better adapted for action in the water than wings which take longer strokes, and are more powerful and efficient in the air. This can be readily understood when it is borne in mind that the raising or recovering of the wing is a much more laborious operation in water than in air, and that the power requisite for working long wings, almost to the full circle, as is done by air birds, would in water be greater than any ordinary structure of a bird could be supposed to possess. Besides, when wings are used under water, they must keep time with the feet, and hence they are never moved far from the horizontal plane of the body, but strike short and quick, and move most forcibly downwards or upwards, according as the course is ascending or descending.

The natural transition here is not to the running and wading birds, which resort, at least in most of the species, to the banks, shores, and other humid places, which are not so tangled and rank with vegetation as the haunts of the tribe now considered. These carry the type in the general form of the body and the sternal apparatus, though modified by the habit and haunt, from the grebes, which unite considerable powers of flight with swimming and diving, through the divers properly so called, to the penguins, which are incapable of flight; but those species which use the wings chiefly in the water as a sort of fins have the sternal apparatus, of course, different from those that use them in the air.

Sterna of the Divers. There is so much diversity of habit, as well as of sternal structure, among these, that it is impossible to select any single species as an average type. We shall, therefore, give three instances which correspond in some measure to the two extremes and the mean—the grebes, the true divers, and the penguins.

1. *Sterna of the Grebes.* The sternum of these birds is intermediate, in its general form, between that of the coots, as the aquatic extreme of the preceding group, and that of some of the diving ducks, or rather those of the eiders and scoters, which are intermediate between the swimmers and divers of the duck tribe. The sternum is short and broad, and much broader in the rear than the front; but the breadth in that part does not consist so much of continuous bone as of two posterior lateral processes, which are divided from the central part of the bone by notches of considerable depth. These processes are much stronger, as well as shorter, than those of the birds in the preceding family. They are arched, rising upward at their divisions, and recurving again toward the middle portion, though not joining it. The keel is well developed, though its height is not equal to the breadth of one side of the sternum. It is convex on the under side, and concave in front, with the angle sharp, but without any production of bone. The margin is triangular and cartilaginous. The coracoids are of moderate length, rounded on their anterior sides, and flattened and much enlarged in the rear. They are strong, and well set for giving firmness to the shoulder-joint, as they form a considerable angle with each other, and also with the general line of the sternum; so that the strain which they exert when the wings are moved is directed toward the point of greatest resistance in that bone, which is, of course, also the mean centre of the surfaces to which the muscles which move the wings are attached. The clavicle is long, forming a regular semi-ellipse, attached by a small tubercle at the middle to the angle of the keel, flattened laterally, and forming, from the head of the coracoid to the keel, a perfect arch, with its convex side to the front, and the terminations of its branches bear against the heads of the scapulars, the greater part of which is slender, and slightly bent downwards. The general shape may be seen in the following two figures of the sternal apparatus of the eared grebe half the size of nature.

The breadth of this sternum, the convexity of its under side, the form and size of its keel, the strength and setting of the coracoids, and the opening and curved form of the clavicle, all indicate considerable action of the wings. Its stoutness and firmness in the posterior part also indicate considerable action of the legs, not of the tarsi merely, but also of the tibiæ, and not in the vertical plane, as in the common operation of walking, but in a direction contrary, or at all events oblique, to that plane. A sternum which best suits for a walking motion is that which has the posterior angles taken off, so that the whole has a lozenge shape, as in poultry and pigeons; and one which answers best for the alternate foot motion of swimming on the surface of the water is of a punt or boat shape, which bears up the body equally. But the sternum of the grebe does not answer to any of these characters: it is shortened, as in the birds of prey, to admit a free motion of the legs, and the lateral processes backward are formed into a sort of strong, yet partially flexible arches, for defending the sides of the bird.



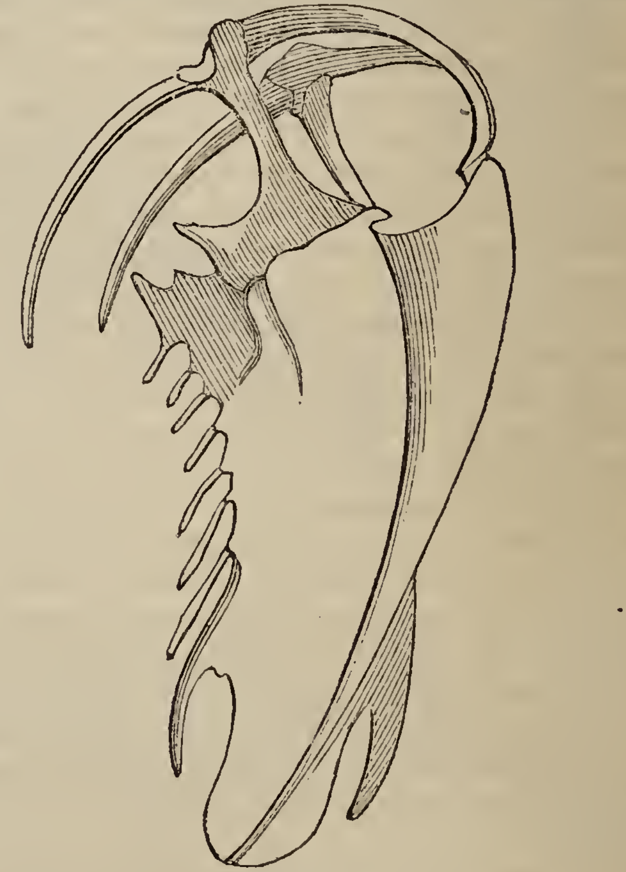
Eared Grebe.

The structure of the shoulder is also well worthy of attention. The form of the clavicle resembles that of birds of prey, both in its curvature of opening and its curvature downwards. The strength arising from these curves is, however, reversed to that of the predatory birds. In them the curve of the opening is the more perfect arch, and the bone is flattened in the direction of that arch; whereas, in the grebes, the lateral arch, which extends from the angle of the sternal keel to the head of the scapular, is the better formed, and the bone is flattened laterally to give additional stiffness to that. The head of the clavicle also bears against that of the scapular something in the same manner that the arch of a bridge bears against its abutment; and the scapular, by becoming narrow toward its termination, resists a thrust on the head much better than it resists a pull.

From this formation of the shoulder, it will be seen that though it forms not an unsteady fulcrum for the action of the wing in flight, it is also well calculated for resisting a strain or pressure from the front; and from the posterior portion it may be seen that provision is made there for a peculiar action of the feet. The sternal apparatus of the grebe is thus a very typical one; and when the small and elongated head and neck, and the lobed toes, with the flattened tarsi, turned outwards on their articulations, are taken into consideration, one might almost arrive at a knowledge of the habit of the bird without further investigation. No air-bird, not even the most typical of the falcons, presents the most powerful arch of its clavicle to the air against which it flies, neither has it the extremities of this arch resting on the angle of the keel and the head of the scapula as abutments, as is the case in this bird. Thus it is evident, from the structure of the shoulder alone, and independently of that of the foot, that the grebe is formed for making its way through the water, and not merely along the surface, though the resemblance of the sternum to that of some of the ducks shows that it is also in part a surface swimmer; and this inference is rendered the more certain by that resemblance being to the ducks of the intermediate division, which have the swimming habit and the diving one in nearly equal perfection.

2. *Sterna of the true Divers.* In these birds, the duck-like character which is traceable in the sterna of the grebes disappears; and while the sternal apparatus presents a still more powerful arch in front, the posterior part of it is continued so as to support more completely the under part of the bird.

The sternum is long and narrow, a little concave on the upper side, and convex on the under; the keel well developed, higher in front than the breadth of the side of the sternum, concave in front, and much advanced at the angle; the under side convex, but less so than that of the sternum, and gradually diminished to the rear, having the middle process, which is broad and rounded, a little flexible. The sides are concave, and have seven or eight ribs on each; and the lateral processes, which are rather slender, and have their terminations curved toward the central one, have the appearance of two short sternal ribs in addition. The anterior lateral processes are large, and have their points directed upwards; and the coracoids, which are strong and short, have their bases very much enlarged to the rear, and with large processes projecting in the same direction as the lateral ones. The clavicle is very much curved downwards, with a tubercle at the middle, bearing on the angle of the keel (which is more rounded than in the grebes), but not articulated to it. The branches of the clavicle are flattened laterally, rather slender at the middle point, but much enlarged at their union with the coracoids and the scapulars. They abut against the latter bones by a head consisting of two processes, and the coracoid has its enlarged head applied over the junction of the two, and a process underneath, which bears up the head of the clavicle. The scapulars are rather slender, bent into a regular curve, and tapering a little toward their points. The following figure of the sternal apparatus of the red-throated diver (*Colymbus septentrionalis*), in the proportion of half the lineal dimensions of nature, and shown obliquely, half on the under side, half on the profile, will afford a better idea of these energetic careerers through the water than could be obtained from two separate views.



Diver.

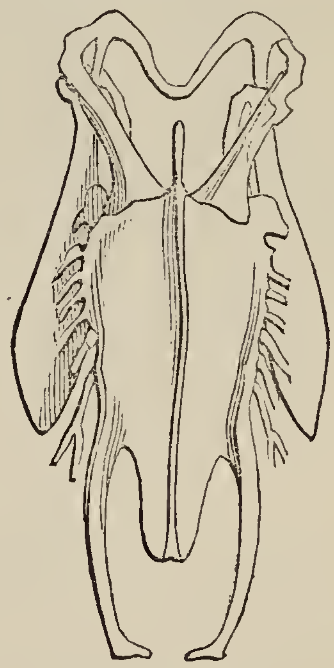
On examining this figure, it will be seen that the keel of the sternum, the clavicle, and the scapular of this apparatus, form nearly one continued curve, which does not bear so much on the angle of the keel, and therefore does not press so much upon the sternum, and the viscera which it supports, as in the grebes; while the sternum, from its greater length, gives more firmness to the under part of the body. The great strain of the shoulder, as the bird moves through the water, is upon the coracoid, chiefly to turn that bone backwards; and this is resisted by the great enlargement backward at the base, and the embedment of the process of the coracoid and that of the anterior angle of the sternum among the flesh of the shoulder. So that, while the resistance is very powerful, it is at the same time elastic, and not a direct thrust of bone against bone, which would occasion a direct prolongation of the strain through all the bony connexion, instead of an extinguishment of it among the neighbouring parts, as is the case in the mode of articulation here presented. Those direct or jarring strains, propagated all in one direction, are never found in the mechanical structure of animals; but, on the contrary, the greater the strain upon any one part, the more speedily and widely is it distributed over a number of other parts.

The form of the clavicle is also a very beautiful part of this structure: the enlargement at the shoulder-joint, the gradual diminution in weight as the bone becomes more curved in approaching the keel, and the way in which the head of the clavicle is united to that of the scapular, so as to bend that bone more firmly against the ribs near the inflexible part of the spine, when the pressure of the water tends to bend the clavicle itself toward the angle of the sternal keel, are all well worthy of close observation: the more so that the natural action of the bird in the water cannot be so easily seen as that of a land bird in the air. Even the point of articulation of the wing is worthy of notice, as having the line of its principal action more in the direction of the general axis of the body than that of wings which are used exclusively in flying. Taken altogether, the divers afford one of the finest and most instructive instances of mechanical perfection which is to be met with in the whole feathered race. Not that their structure is better adapted to their habits than that of any other tribe, for in this all birds, and indeed all animals, may be said to be alike; but their action is particularly energetic; and the energetic action strikes us with admiration, while in the case of that which is less conspicuous we must examine before we can admire. Those striking cases are of course the ones which it is best to present to those entering upon the study, whether the object be to produce love for the productions of nature, or the inseparable adjunct of that love when grounded aright—veneration for nature's Almighty Author.

3. *Sterna of the penguins.* In these birds the wings,—which in the divers, and also in some of the intermediate genera of auks, are capable of tolerably rapid and prolonged flight, so that the birds can not only range over the surfaces of the bays and landward parts of the sea, but migrate from one latitude to another as circumstances may require,—are incapable of every thing which can with propriety be called flight, though they assist some of the species in a peculiar kind of leaping motion by which they can clear any obstacle with which they meet, by leaping three or four feet clear of the water. English sailors call those which have this habit by the not very inappropriate name of "Jumping Jacks."

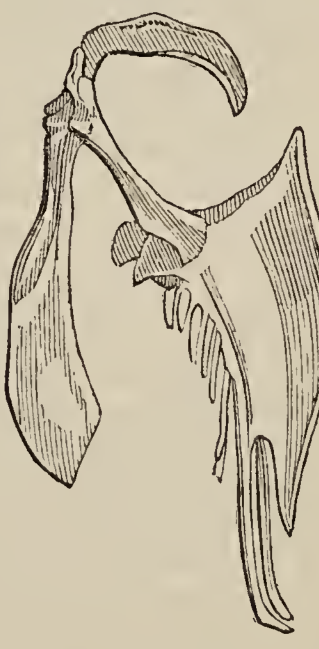
These have the sternum clongated, with the keel well developed, pointed at its angle, and extending considerably in advance of the sternum. The anterior edge of the sternum with two large furrows, terminating in a depression in some of the species, and in a perforation in others. The sides of the sternum concave in the anterior part, and convex in the posterior. The concave portion having six ribs attached, the last one double; and the convex consisting of a slender process, extending backward to a considerable distance beyond the termination of the middle portion of the sternum, bearing in this respect a very considerable resemblance to that of the gallinidæ.

The coracoids are long, strong, flattened, having the inner edge formed into a lamina, which is perforated, and bears at its upper extremity a process of the clavicle. The clavicle has a very peculiar shape, which will be better understood from the following half-size plan of the sternum of the Cape penguin than from any verbal description.



Cape Penguin.

The scapulars are very large, much broader than in any other species of bird, and bearing a trace of resemblance to the same bones in the mammalia. Their form will be better seen in the following profile



Profile of the Cape Penguin.

of the sternal apparatus of the same bird, represented on the same scale.

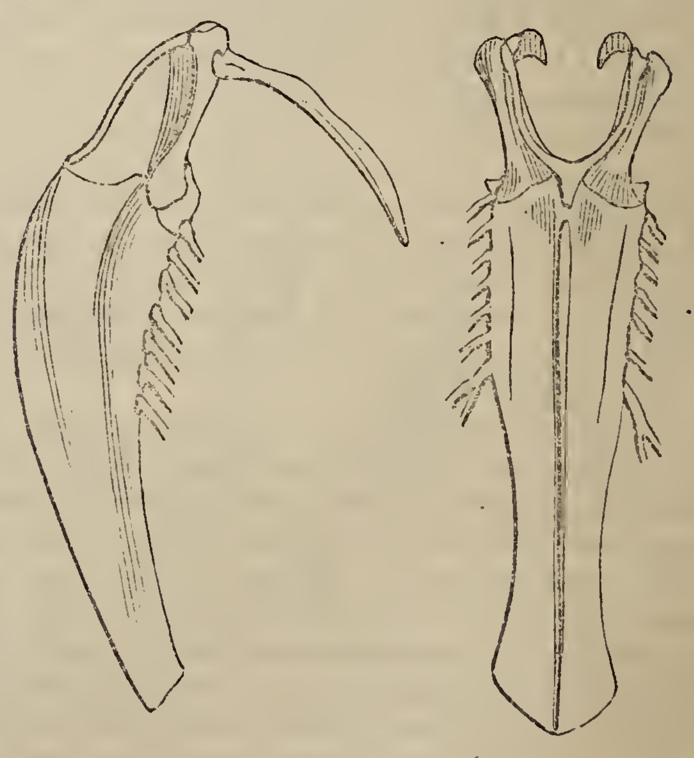
It will be perceived that, in those birds, there is a considerable deviation from the usual means of supporting the shoulder. The coracoids are strong, they are well set as far as direction is concerned; but the smallness of the bases by which they are articulated gives them little stability in the vertical plane. They are, however, strongly tied to the shoulders by means of the large blade bones; and thus the support of the wing, or rather of the swimming flap, is thrown as much upon the muscles of the back, and through these as an elastic medium upon the spine, as upon the sternum.

As these birds use their imperfectly produced wings only in swimming, or in the leaping motion, in which there is no second effort of the wings in the air, and indeed little or no effort of them there at all, the body is never borne up by those appendages, and thus the organisation of greatest ease to the bird is that in which the upper and the under sides contribute equally to its support. In its ordinary habit of being in the water, indeed, it is pressed pretty equally by that fluid upon all sides; and therefore the greatest stability of the clavicle, which is the bone which resists the compressing force in the motion forward, is more stable by having its hold on the back by means of the large scapular. The clavicle is flattened, and placed with the edge forward, so that it presents to the water through which the bird moves the greatest stiffness which could be obtained from the same portion of bone; and its articulation at the shoulder is such that, when there is a strain on the middle part of it, it tends to pull the scapular forwards. This the broad scapular resists, and it is aided in its resistance by the anterior lateral processes of the sternum, while the equal supports which the flap of wing has from above and from below, enable it to act with equal force in its upward and its downward stroke, and thus perform with more efficiency its fin-like function. The birds of this group are slow and unwieldy, with little capacity of motion either in the air or upon land; but their organisation is as admirably fitted to their habit as that of any other birds; and they are curious, as forming the last link between the birds which, as a class, are more typically inhabitants of the air, and those vertebrated animals which are permanently dwellers in the waters, and cannot carry on the process of respiration in the pure air.

Among the long-legged or long-winged birds which find their food near the waters, in fresh water or in the sea, there is a resemblance in the sternum, but there is also a gradation which may be traced, from the agami, which may be considered as among the least aquatic of the whole, to the cormorants and gannets, and perhaps even to the gulls and terns. This sternal structure does not of course, in birds of such varied forms and habits, accord with the classification which is usually made of them on the structure of their bills and feet; but they all agree in being, to a very considerable extent, air-birds; though none of them, the genus lestris excepted, find their food in the air on the wing; and these do not find their own prey in that element, but live upon the food of other birds, which they make these disgorge from their stomachs, and catch it ere it falls. Gulls and terns are the races which are chiefly robbed in this manner, and so prone are they to offer this sort of boon or bribe to real or supposed enemies, that, even in a state of confinement, they will disgorge the contents of their stomachs at the sight of an eagle, or any other formidable rapacious bird. Even the petrels, whose habits are too much seaward for encountering predatory or even plundering birds, have this disposition; for when they are compelled, as they often are during severe weather, to alight on the decks or rigging of ships, they instantly make a votive offering of the quantity of oil with which their stomachs are loaded.

The habits of long-legged birds are so diversified—they are so much on the land in certain cases, and on the waters or by the sides of them in others—that it is not easy to select any species as a fair average of the whole; but they follow the general law in having the sternum short in proportion as they are more on the wing, having that bone more elongated, and narrower in proportion, as they are more of walking birds in open places which have not water, and in having the posterior part more divided by notches, in proportion as they are more aquatic.

Sternum of the agami. In their general characters these birds are certainly not a little anomalous; and though they are usually classed with the cranes, to which they have scarcely any other point of resemblance than a long neck, which after all is not a crane neck, but one fully as like those of the ostrich family, they partake of the characters and some of the habits of gallinaceous birds,—or rather they partake so equally of the characters of many races, and so little of those of any one, that in nature they stand alone and distinct, whatever may be the place assigned to them in any system. It is also not a little remarkable, that the sternum of these birds is as unique as their character; and this very clearly shows that no classification of birds can be either natural or valuable as an index to their history, of which the sternal apparatus does not form a considerable and even the leading part. This is what we might expect; because when we carry our analysis as far as it can rationally be carried, that is to the bones which give the entire structure its form and its leading characters, we find that it is by the sternum, and those attached bones the coracoids, which are never wanting in a bird, be its habit what it may, and never present in any other animal, that we determine a bird to be a bird and nothing else. The following figures represent the sternal apparatus of the agami.



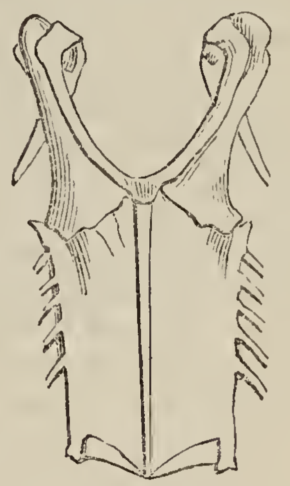
Agami.

Upon examining these representations, it will be found that the bird to which they have the greatest resemblance is the gallinule; that the general form of the sternum is nearly the same; but that as the gallinule is a much more aquatic bird than the agami, its sternum possesses two very elongated lateral processes, while that of the agami is entire. The ribs are also more numerous in the agami, and occupy a greater portion of the length of the sternum, and though the scapular is not so long, it is broader, has a slight approximation in form to that of the penguin, and is strongly articulated to the head of the coracoid, while that bone, though well set as to the resisting of cross strains, is rather loose in its articulation with the sternum as seen laterally. The furcal bone is much more slender than in the gallinule, and it has a process at the junction of its branches directed toward the keel of the sternum as in the gallinidæ, whereas that of the gallinule has only a small tubercle on the upper side at that point. The whole line of the furcal bone of the gallinule, when viewed laterally, presents an arch, though a flattened one, to the front; while that of the agami, though slightly convex near the articulation with the other bones at the shoulder, is concave to the front in the part next the sternum. Throughout its whole length, this bone is remarkably slender and feeble as compared with the sternum, the coracoids, and the scapulars; and on this account the agami may perhaps be regarded as the feeblest winged of birds which have the clavicles united and can use the wings in flight. The great elongation backwards of the sternum makes a very marked difference between this bird and the ostriches, in which this bone, instead of being long, narrow, and but little curved, as it is in this case, is short, broad, and very convex on the under or external surface. The habit of the bird corresponds; for while the ostrich family, in whatever part of the world they reside, are found on dry if not parched and naked pastures, the agami is found native in richer places, near the perennial waters, but on the verge of the tall aquatic herbage rather than in the middle of it. The agami is thus intermediate in its locality between the ostrich and the gallinules, and other macrodactylic birds; and it is not a little remarkable that its sternal bone partakes of the undivided character of that of the one race, and the elongated one of the other.

Sterna of the crane family. The cranes and the herons are not only found in places bearing considerable resemblance to each other, but some of the species are externally so much alike that they have been very generally considered as forming one tribe and sometimes only one genus.

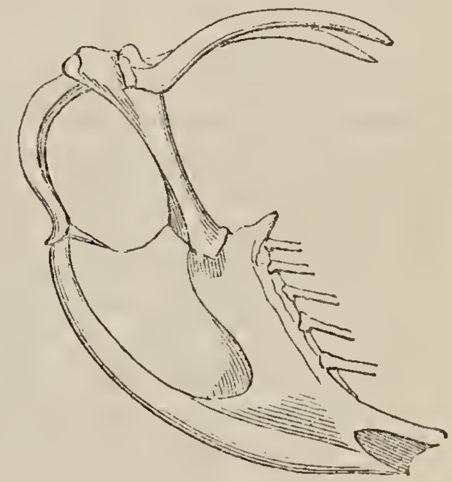
The grand distinction between the cranes and the herons, whether we consider them as distinct groups or merely as genera (and the distinction is perhaps broad enough to amount to the former), is that the cranes have much more of a landward character than the herons, and they are also much more discursive and migratory, though from their habit of fishing or otherwise feeding in the shallows of the waters, herons are also necessarily migrant in those parts of the world which are alternately flooded by water and parched by drought.

The sternum of the cranes is of moderate length, rather narrow, very little hollowed on the upper surface, and of nearly equal breadth throughout its whole extent. The sternal crest is large in proportion to the whole extent of the bone; arched on the under side for the greater part of its length, but slightly concave toward the posterior extremity; and in some of the species it contains a large cavity in which a flexure of the windpipe is lodged, as is also the case in some of those long-necked swimming birds which seek their food with the head immersed in water. The angle of the crest advances considerably in front, is rounded, and, in the true cranes, and some other species, united to the central part of the clavicle. Seen in profile, the sides of the sternum appear concave; and in the rear it is divided by two triangular notches, which form the posterior angles into two processes which extend a little, but not much, beyond the central part. The coracoids are short, strong, and much enlarged on their posterior sides. The clavicle is open, though but slightly arched in the plane of the opening. It is much enlarged toward the shoulder-joints, and much more arched toward the front than laterally. The blade bones are long, flat, and slightly bent, but not so large in proportion as in the agami. The following figures of the sternum of the white stork, on a scale of half the natural size, may be considered as an average specimen.



White Stork.

Profile of the same bone on the same scale.



White Stork.

On examining this sternal apparatus it will be seen that though the keel is well developed, and the shoulder also moderately firm for flight, yet that the extent of the scapular, the arching toward the front of the clavicle, and the union of that bone with the angle of the sternal keel, throw a portion of the support upon the back and thence to the legs, which in all the species are well adapted for walking. Still, though these birds cannot be considered as possessing either very swift or very ready wings, they have all considerable power of continuance on their flight. They are also light birds in proportion to the extent of their wings, and therefore they fly high on their long flights; and, as is the case with the true grallidæ or wading birds, they fly with the feet backwards, and use these in steering their course, in supplement to the tail, which is, generally speaking, short.

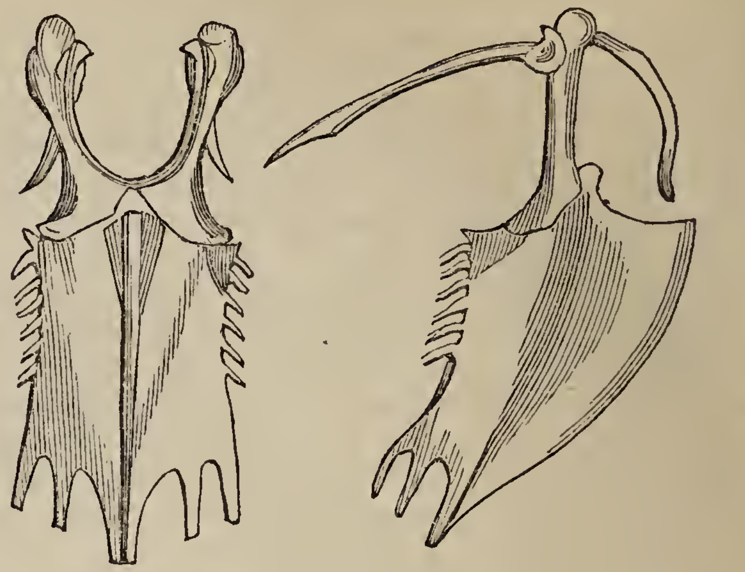
The example above given must be considered not as an average of the crane family, as the storks do not strictly belong either to the cranes or to the herons, though they resemble both; but it is a tolerable average of the sternal apparatus of Cuvier's sub-order cultrirostres.

Intermediate between these and the grallidæ, which include the pressirostres and longirostres of Cuvier, which have much less difference in their haunts and style of flight, and consequently in their sternal apparatus, than in their bills, there are some species or genera, which require distinct notice. These are the ibises and the spoon-bills, which are more discursive than almost any members of the crane or heron families. The birds which may be considered as forming this group do not suit well with the genera with which they are usually classed according to the bill. That of the spoon-bills is not in the coulter or knife-shape, as may be seen by looking back at a sketch of it given on a former page; while that of the ibis, though it resembles in shape the bill of the curlew, and certainly deserves the epithet "long," is not of the same texture with the generality of those bills of which length has been taken as the distinguishing character. The genus tantalus, which resembles ibis in many particulars, has the bill straight; and there are various other genera included in the cultrirostres of Cuvier which have bills so totally different from each other that they cannot properly be brought into one group from the structure of that organ.

With regard to the habits of these birds, and more especially those of the genus ibis, it may not be irrelevant to mention that they have long got credit for being destroyers of poisonous serpents, and according to the story were, on this account, deified by the Egyptians; but this habit is very doubtful, beetles are more likely food for them, and poisonous serpents are not numerous in their haunts.

The general habits of the ibis, tantalus, and spoon-bill so much resemble each other, and they are all so perfectly similar in their sternal apparatus, that they belong perhaps more naturally to the same group than almost any other genera of birds. Their sternum is short, broad, and deep, with the keel much produced, and altogether indicating a capacity of powerful and continued flight. It is pointed anteriorly so as to afford firm basis to the coracoids. The keel is a little concave anteriorly, but convex on its under side. It is nearly of the same breadth throughout; bears six ribs on each side, the sides being concave when viewed laterally, and the posterior portion is divided by two notches of moderate depth towards each angle, the central process being longer and much stiffer than the lateral ones. The coracoids are short, strong, well-set, much enlarged both at their bases and at their heads; and the clavicle forms a perfect semi-ellipse, thickened at the shoulder-joints, and generally united to the angle of the sternum. The scapular is small-pointed at its extremity, and very slight and curved. The strength of this apparatus is obviously directed towards, or concentrated on, the shoulder-joint; while the comparative shortness of the sternum, and the flexibility of its posterior angles in consequence of the notches, give free scope for the motion of the legs, which are in all the species long and well adapted for walking.

The following half-sized figures of the sternal apparatus of the glossy ibis (*falcinellus*), which sometimes, though rarely, makes a dash into this country on its migrations, will serve as an example of those very singular birds.



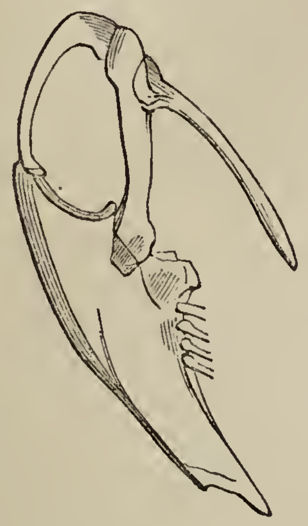
Glossy Ibis.

Sterna of the Totipalmæ. These birds, which may perhaps be considered as, in habit, taking up the system after the herons, have considerable diversity in their haunts and modes of life. Some, as the albatross, are almost habitually on the wing over the sea, while others, as the cormorants, are less discursive, resort sometimes to the fresh waters, and occasionally perch upon trees; but they all agree in finding the greater part, if not the whole, of their food in the waters, and descending upon it on the wing, instead of getting it by wading or by walking, as is the case with the groups last mentioned. Hence, in all the varieties, they have a sternum well adapted for flight; but it also combines another character, which will be better understood after examining the following figures of the sternal apparatus of the common cormorant, which are given of half the lineal dimensions of nature.

Cormorant.

It is however in the next figure, which is the profile on the same scale, that the peculiar modification of the sternum of these birds is best seen.

Upon examining the following profile figure, it will be found that this bone presents a still more powerfully-resisting arch to the front than that formerly alluded to in the divers. The anterior edge of the keel, the coracoid, and the clavicle, form a complete egg-shaped structure, with its narrow end in the head of the last bone, where it is greatly increased in breadth, and consequently in firmness of resistance; while, from the manner in which the head of this bone is formed, any strain given upon the more advanced part of it is divided among the coracoids, the scapulars, and the keel of the sternum, though the greater part of it goes in the direction of the first of these. They are well adapted, both from their form and the mode of their attachment to the sternum, for resisting the strain of a pressure from the front. The basal parts are very large, and so are the heads, with which the branches of the clavicle are in all cases firmly united, and in some they are soldered into one continuous bone.



Profile of Cormorant.

And there is no waste of strength in the firmness against a pressure from the front which is thus given to the shoulders of these birds; nor is the advancement of the clavicle in front of the shoulder-joint, or the strength which it receives there from its increased curvature and breadth, and its intimate union with the head of the coracoid, without an object and use in the economy of the bird.

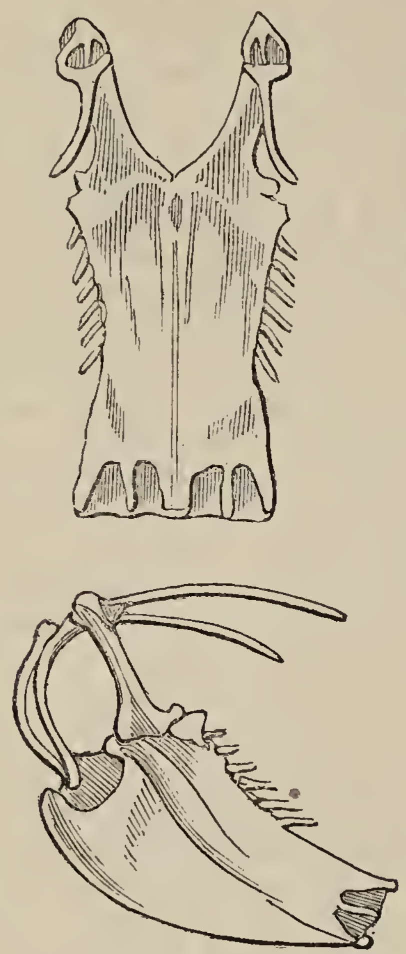
These birds do not make way with their whole body in the water, as is the habit of the divers; but they take the water with much more force, and therefore with a greater shock upon their bodies. Almost all of them plunge headlong on their prey in the water, and some of them do so from a great height—a height from which if even the strongest of the mammalia were to fall on their feet upon the water, they would be in danger of dislocating their joints, or even breaking their bones. All who are in any way familiar with the water must be aware how dangerous it is to descend into that liquid, even from an inconsiderable height, in any other way than head foremost, and especially how very hazardous it is to jump into it from a greater height with the legs apart from each other. Many of the birds of this tribe descend from heights and with velocities which, notwithstanding their feathery covering and the yielding nature of the fluid on which they descend, would, if its effect came as a cross strain, break the stoutest bone in their bodies. The bird from its form penetrates the water easily, and the articulations of the neck are so many, and so free in their motions, that any shock which the head may receive by the plunge is so divided among them as not to occasion the least concussion of the contents of the skull. Thus the parts which come into the severest contact with the water are the shoulders: and this is met by the strong and comparatively narrow parts of the arches in the direction of the vertical plane. And, upon examining the front view of the sternum, it will be found that, besides the hold which the scapulars have on the back and the stiffness given by the clavicle, the great breadth of the coracoids at their bases, and the form of the lines of their union with the sternum, afford a very firm base in the cross direction.

The more typical of these birds are not very rapid fliers, but many of them are much on the wing; and they fly by powerful strokes rather than quickly-repeated ones. Hence they have the sternum broad, and the fibres of the pectoral muscles long, so that, on the principle formerly explained while noticing the wings of the anisodactyli, these wings sweep over large arches and with much power, though slowly as compared with birds that have the sternum narrower and the muscular fibres shorter.

There is another advantage which this large sweep but slow motion of the wing has over a shorter and quicker one: the wind has much less effect either in fatiguing the bird or in drifting it to leeward; and hence we find that most sea birds have this long and swinging flight, whether they belong to this family or not. Those of this family are of course not the best fliers among sea birds, as their sternal apparatus is not formed wholly for flight, but for that and resisting the plunge jointly; and as each of these requires a different structure, each of them must, to some extent at least, weaken the other.

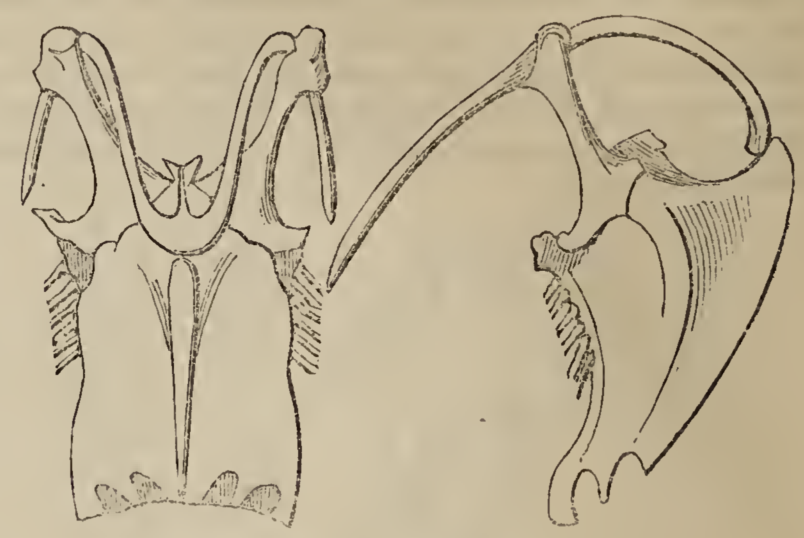
Sterna of the Longipennes. These have some resemblance to those of the former tribe, and also to those of the grallidæ, as might be expected from the birds partaking in part of the habits of both; but they have also habits which are more peculiarly their own, and the sternal apparatus is modified to accord with these. Not only this, but as there is a gradation from the gulls, which feed on the wing, and also, in walking on the shore, to the petrels, which are more exclusively seaward, and walk little: but there are so many modifications of the sternal apparatus, that no single bird can be selected as an average type of the whole. We shall therefore select two specimens: the laughing gull as nearly an average of the more landward subdivision, and the puffin petrel as nearly an average of the more seaward.

The sterna of the skuas, gulls, and terns, are in their general form intermediate between those of the entire footed birds and of the waders. They are rather longer and not quite so broad in proportion as those of the former; but broader and less elongated than those of the latter. The keel also, though well developed, is not so high in proportion to the width of the sternum. From this structure it follows that the motion of their wings, though more powerful, must be slower than that of the waders; and the wing itself is longer in its bones and its feathers, as well as in those muscles which put it in motion. This structure accords with the general habit, which is that of skimming about with smooth and moderately swift wing, and culling their food from the crests of the waves, or from substances cast up by the waters and left upon the strand. The keel of the sternum is deeply concave in front, with the angle much rounded; and the posterior part, which is nearly square at the end, is divided more or less deeply by four notches, the two middle ones of which are larger in some of the species, and the two lateral in some of the others. The posterior, or carrying part, of the sternum is rather broader than the middle part to which the ribs, which are six or seven, are attached; and the lateral processes extend on the flanks without any bending inwards. The coracoids are strong and well set, the clavicle wide, convex anteriorly on the upper parts of its branches, but recurved at their junction, and always united to the keel of the sternum. The scapulars are scithe-shaped, rather long, and of moderate breadth. From its structure, this sternal apparatus indicates considerable power of flight, and also strength for resisting pressure on the anterior part, though in this last respect it is much inferior to that of the entire footed birds; and in both it is very inferior to that of the petrels. The following figures of the sternum of the laughing gull, and more especially the lower one which represents the profile, will illustrate this structure.



Laughing Gull.

The sternal apparatus of the petrels is much better formed both for flight and for resistance of pressure against the front. It is short and broad, rather narrower in the middle than towards the extremities, very concave on the upper surface, and consequently convex on the under. The keel much produced, extending with some elevation to the posterior extremity of the sternum, but much more elevated in front, convex in its under outline, and concave in the front one; the angle much produced, rounded, and supporting the clavicle, which is enlarged at the junction of its branches. The lateral processes of the sternum are well produced, the grooves deep, and the coracoids firmly attached by large bases. The sides concave upwards, carrying six ribs. The posterior edges differing in different genera, being entire in the storm-petrels, having a large notch on each side in the albatross, and two small ones on each side in most of the others. The coracoids are strong in their whole length, but remarkable for the extent of their bases and the largeness of their heads, from the first of which structures they form a perfect arch in the lateral directions, even without the assistance of the clavicle. But the clavicle is also strong, and capable from its curvature of offering a powerful resistance to any strain, whether lateral or from the front. The scapular is slender, very slightly curved downwards, and continued in the same curve with the upper part of the clavicle. This is indeed one of the firmest shoulders which occurs in the whole class; and, as will be seen from the profile in the following figure, the keel of the sternum, the coracoid, and the scapular form a very perfect ellipse, extending to about three-fourths of an entire circumference.



Puffin Petrel, half the size of nature.

Though the sternal apparatus of all these birds possesses great power, that power does not indicate an equal capacity of flight in the whole. The differences as connected with flying are chiefly found in the posterior edge; and as we have them in birds which have the rest of their sternal apparatus very much alike, and have the habit of flying connected with each, we are thereby better enabled to judge of the difference between entire and partially divided sternums than if we had the means of comparing these only in birds which less resembled each other in other respects. The different species of storm petrels which have the sternum entire, and consequently the firmest origin for their pectoral muscles, are among the most continued and excursive fliers of which we have any knowledge. The wide sea is their pasture, and, be its extent what it may, they range from shore to shore; now rushing at a moderate height through the air, with light wing and with great velocity; again skimming close to the surface, so that the points of their wings tip the water at every stroke; and yet again running along the water, with expanded wings, which, though they seldom move, float them so buoyantly that they just touch the water with the points of their webs, and thus paddle swiftly along, collecting on the feathers of their breasts that floating pellicle of oil which forms no inconsiderable portion of their food, and which, when they have wearied themselves in skimming, they lean on the wave, and remove with the bill at their leisure.

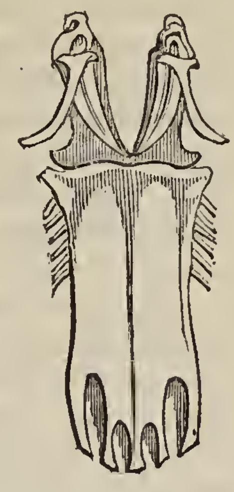
The albatross, which, though a very long-winged bird, has a more heavy and gull-like flight than the storm petrels, has, as already noticed, one notch in each posterior angle of the sternum, by means of which those parts of the bone are rendered feebler. These birds are scavengers for larger matters rather than skimmers of the oil of the sea, like the preceding genus, but they are wide ranging scavengers, and, when they are once on the wing, miles of ocean are of little consequence to them in their range.

The common petrels, and other birds which have four notches in the posterior part of the sternum, are inferior to the others both in the style and the rapidity of their flight, and a connexion may be traced perhaps as naturally from them through the puffins and auks to the wingless birds, as that which is traceable from the divers. The whole of this family may, however, be considered as the most pelagic of all birds, because, though there are others which are much more in the water, or on its surface, there are none which have equal power of wing, or are capable of extending their excursions so far from the land.

Sternum of the Grallidæ. Though the birds which form this order, even when restricted by leaving out those groups which have been already mentioned in the course of these observations, differ very much in the structure of their bills, yet there is far less diversity in their sternal apparatus than the consideration of the bills, as their chief character, would lead us to suppose. But, when we consider that none of them are habitual fliers, that they fly only for change of place, and that their flight is generally taken by rather short and swiftly-moving wings, we might be prepared to find that agreement which there is in the sternal apparatus.

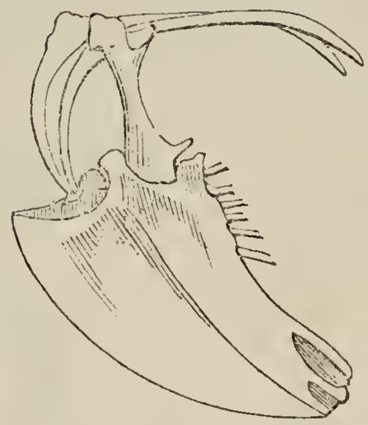
It suits the walking and the wading habits of those birds, and also the tangled herbage through which many of them have to make their way, to have the body narrow in proportion to its depth. The sternum is in consequence long, and rather narrow, a little enlarged towards the posterior portion, and divided there by four notches of considerable depth, the lateral ones generally the deepest; the processes between the notches feeble, but generally enlarged at their extremities, so as to form the posterior outline of the sternum into a convex curve. The crest is generally large, convex below, concave in front, with the angle terminating in a process; lateral processes not nearly so much developed as in the petrel family; the basis of the coracoids not nearly so large, and their attachment to the sternum not so firm; the coracoids are, however, short, stout, and considerably enlarged at the heads, but their position is too parallel to each other, and too much in the general line of the sternum, for giving that stability to the shoulder-joint which is essential to long-continued and rapid flight. The clavicle is elongated, curved forward at the middle of its branches, and directed at their junction throughout the middle part of the anterior edge of the keel, and they are enlarged in breadth toward their junction with the coracoids. The scapulars are rather large, flat, straight for great part of their length, but bent downwards toward the points, so as to have a firm embedment on the back.

In this latter part of the structure it will be perceived that those birds have much more the character of walking or ground birds, than those of the preceding group, or indeed than any of the water birds which are much in the habit of using the wing, even though not so good fliers for a short time as some of the wading birds are. The enlargement of the clavicle toward the shoulder-joints, the large heads of the coracoids, and especially the increased size and peculiar form of the scapular, together with the comparatively loose attachment of the coracoids to the sternum, show that the strength of the shoulder in those birds is not wholly, or even chiefly, based upon the sternum, but that great part of it is connected with the back through the produced shoulder-bone, and being connected with the back, it is, by means of that, referred to the legs for support. This is not the case so exclusively as in the wingless birds, because all the grallidæ can fly occasionally, most of them can fly well, though their flights are rather short, and the wings of them all are ready in turning and wheeling; but still a careful examination of their sternal apparatus, as combining the elements of walking and the elements of flight, would probably be found a much better ground of classification than any to which systematists have hitherto resorted. We shall give the sternal apparatus of the lapwing, which is a tolerably good runner, and also a ready flier, as nearly an average specimen of the whole.



Lapwing.

The following cut represents the sternal apparatus of the same bird in profile, and both cuts are of the natural size:



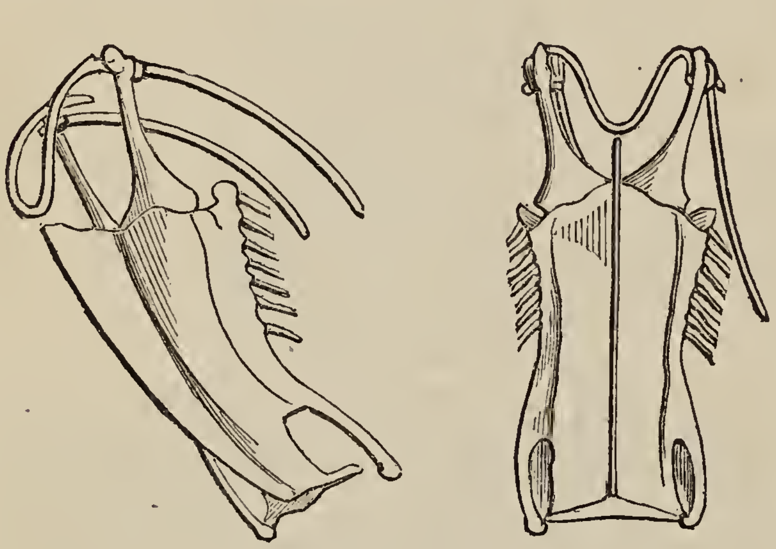
Profile of the Lapwing.

Sterna of the Lamellirostres. As in so far as their aquatic habit is concerned, the sternal apparatus of all these birds is adapted for the bearing up of their bodies while they float upon the water, there is, independently of their different degrees of adaptation for flight, a general character which runs through the whole order. The largest diameter of the body is reversed as compared with that of the grallidæ. These have it vertical, so that they may the more easily make their way among the herbage, and also present the least resistance to the air, and give the greatest scope to the legs in walking, wading, or running. But the flat-billed birds have the body more or less flattened horizontally, as well as the bill, by which means they present to the water a large base in proportion to their weight, and thus swim more lightly. The sternum is elongated, and also increased in width, so as to accommodate itself to this form of the body, and upon the average it is so placed that the centre of gravity of the bird is very nearly over its centre of resistance, so that all parts of it are pressed upon with nearly equal force as the bird floats along.

The habit of floating along the water is, however, in the different genera and species of these birds, combined with so many modifications of other habits, that it is subject to numerous though slight variations. Those habits are greater or less degrees of flying, walking, and diving; and, from what has been already said respecting birds of which each of these is the principal habit, it will readily be understood, without repetition, how far each must modify the swimming or floating character, which is the principal one of this class.

They have the sternum elongated, varying in breadth, narrower in the middle than at the extremities. The sternal keel is well developed, but usually lower than the width of half the sternum. The lower edge of the keel is sometimes convex, sometimes straight, and the anterior one generally concave, and in some of the species there is a cavity at the base of the crest, in which a duplicature of the trachea is lodged. The coracoids are never very long; they are large at their bases, and rather firmly attached to the sternum.

There are seven or eight ribs (in some cases nine) on each side of the sternum, and the posterior part of that bone is generally divided by notches, though the heads of the processes are so much produced as nearly to meet each other. The clavicle is of moderate length, and well arched, and the shoulder bones rather slender, and arched through the whole extent. The general character is that of having the bones of the shoulder much more exclusively supported from the sternum than is the case in the wading birds. The following figures of the sternal apparatus of the nyroca pochard, or white-eyed duck, may be taken as a specimen.



White-eyed Pochard.

In these sections we have taken a rapid glance at the general structure of birds, and those characters which distinguish them from the other classes of vertebrated animals; and we have entered rather more minutely into those peculiarities of their three grand structures, the bill, the feet, and the wings, upon which, singly or jointly, the leading differences of their habits in a great measure depend. It would now remain to investigate their relations to the rest of nature in locality and in season; but as this part of the subject involves the knowledge also of the natural history of localities and of seasons, it is of too general a nature for being made a specific portion of the natural history of birds, though they cannot be known to the full extent without a knowledge of it, neither can it be understood to the full extent without a knowledge of them. Nature is one workmanship of one Author, and he who wishes to know any single part well, must lay the foundation in some general knowledge of the whole.

BIRDS OF PARADISE (*Paradisea*). A genus of birds belonging to the sub-order or group *Conirostres*, of Cuvier's order *Passerus;* and, from the manner of their feeding, to the natural order *Omnivora.* Their generic characters are: The bill of moderate size, four-sided, straight in its general line, but arched in the culmen, and slightly hooked at the tip of the upper mandible, in which there is either no notch, or a mere rudiment; lower mandible straight, and the tomia closing for the whole length of the bill; the nostrils basal and lateral, open, but concealed among the feathers at the base of the bill, which is without any naked skin. The tarsi and toes are stout; the latter, three to the front and one behind; the middle toe shorter than the tarsus, the outer united to it at its base, and the inner joined half the length of the first phalanx, the hind toe larger and stronger than the others. The first five quills of the wings are nearly of equal length, and the sixth or seventh usually the longest.

As the skins of these birds, deprived of the feet, the wings, and the tail, have long formed an article of export from those countries in which they are found, they were known in Europe in that mutilated state long before any of them had been seen alive, or their manners were at all known. In this state they do not bear much resemblance to an ordinary bird, at least in any part except the bill, head, neck, and shoulders, for the rest of the body is hidden by supplemental feathers issuing from the flanks, the shoulders, or both, which are so loose, light, and airy toward their points, that they bear (in as far as that which is *solid* matter, however finely divided, can have a resemblance to *light*) some resemblance to the tails of comets. The feathers, which are not thus produced, especially those about the insertion of the upper mandible, are remarkable for their velvety texture, and the beauty of their metallic reflections; and with this fineness of gloss, and richness of tint and texture in the part which was like a bird, and the substitution of these curiously produced feathers, in place of all the ordinary organs of locomotion, either on the ground or in the air, it was perhaps not much to be wondered at, in those early days, when foreign lands were new and little known, and romance and marvel were the order of the time, that these birds should have been supposed to whisk about like meteors in the bright beams of the equinoctial sun, without the usual attributes of wings, or that they should have been supposed to dwell in the air, and live upon the nectar of those flowers, which, in the climates where the birds are native, twine their beautiful garlands and festoons to the very tops of the trees.

It was from this supposed aerial habitation, and all but etherial food, that these creatures obtained their somewhat inappropriate name of birds of paradise; and their elevation above the dull earth, and abstinence from all the more gross ways of life which its more humble tenants require, have been the subject of many an eloquent and elaborate descant.

But it is provoking to the inventors of those fancy-wrought marvels of nature, who, like the eye of the sleepless, people the dark with phantoms of their own creation, and are enabled to do so, just because it is the dark, that truth comes with her torch, and they vanish; and it is sometimes still more provoking, that the torch is not sufficient to reveal those real wonders of nature which were concealed by the darkness which admitted the fictitious ones; and thus we are reduced to that vexatious twilight, which is too light for fancy, and too dark for fact. This is that "little learning" which, on all subjects, but especially in natural history, is truly a "dangerous thing." It resembles, in the progress of knowledge, that stage in the life of man, in which the toy of the child has ceased to please, and the mind is yet all too inexperienced for "standing up against the wind of the world's temptation:" it is the time of peril—that at which knowledge stands most in jeopardy of error, and character and happiness of ruin.

The false charm of these birds has been dispelled: they have feet and wings, just as the most humble and despised of our common birds have; and so far from feeding upon nectar, they feed on the pulpy and farinaceous parts of fruits, upon worms and insects, and the carrion of larger animals; and it is probable that they rob the nests of the smaller birds, and even strike the birds themselves on the head, and eat their flesh; at least, all this would accord with their analogies as omnivorous birds, and birds of bold and pugnacious character; and these facts have, in part, been established by observation. The truth is, that they more nearly resemble, in their habits, our magpies and jays than they do any other of our resident birds; and it will be borne in mind, that these are among the gayest of our birds both in the tints and the metallic glosses of their plumage.

Still, though these birds have lost all the ethereal and fairy-land part of their character, their real interest has not been thereby diminished. In human exhibitions, we despise the puppet when we discover the string; and the picture, which appeared fine at a distance, becomes a daub when we examine it too closely. But so different is it with nature, that we never can see enough of the moving power, or approach sufficiently near for finding out all the beauty. Hence, whatever may be the case in human character and conduct, the romance of nature is always tame and tiring as compared with the reality.

It is so in the case of the birds of paradise, and we cannot be too thankful to the naturalists, who have delivered those children of the sun from the bondage of fable, and brought them to the light and the freedom of science. They are singularly formed; they inhabit a very peculiar portion of the globe; and we may rest assured, that when once we have fully found it out, they have a singular tale to tell.

New Guinea may be considered as the head-quarters of the genus, and they range seasonally between it and the smaller isles which lie in its vicinity. Their feet (which, by the way, require to be more carefully examined as to the articulation of the toes) are not ground feet, but perching ones; and though they live in the depth of the forests, they do not, in fine weather at least, hide themselves in the covert of the twigs and leaves, but perch on the summits of the loftiest trees, being thus the highest dwellers in the forest. Their flight is that of the tribe with which their habits more immediately connect them. It is undulating and jerky, and not smooth and continuous. Their wings are short and broad, and probably their curiously produced feathers act in some sort as a parachute to render their settlement on their elevated perch more easy. It is obviously, however, not a plumage for entering into the tangled parts of the trees, and contending with the twigs and other interruptions, as may be seen from the four species represented on the plate "Birds of Paradise;" to the two of which that are represented on the wing Landseer has contrived to give more buoyancy, and even appearance of upward motion, than perhaps the burin alone ever previously imparted to the representation of a bird. They put one in mind of the floating figures in the *chefs-d'œuvre* of Raffaelle, which, all wingless as they are, ride more lightly by the magic of the master's hand than the compositions which less skilful and scientific artists endeavour to bear up upon those incongruous, and therefore unseemly appendages. These two birds are quite a study; but they probably may not strike the unpractised eye so much as inferior productions, which first attract the attention because they are out of nature, and then please mechanical taste by that handling of the tool which is feeble and lifeless in proportion as it labours to be fine. We seldom need to invite attention to what comes from this artist, and such would be a work of supererogation; but, in the present case, we must appeal to the picture to help us out: the flight of a bird of paradise is, from the peculiar form and lightness of those produced supplemental feathers, so unlike that of any bird with which we are familiar in Britain, that to give a verbal description of it would be no successful matter; and we feel satisfaction in being saved from the chance of failure, by bidding the reader turn to the plate, and see the birds on the wing.

We know not enough of the habits of these birds to be enabled to say what specific purpose their very singular plumage answers in their economy; but we know that those herons which have feathers somewhat similarly produced, migrate with the seasons, and follow the line of the waters, leaving those districts in which the brooks and pools seasonally become dry, and the rivers low. We know also that the islands in which birds of paradise have hitherto been found, are subject to alternations of rain and drought, though not so violent nor of so long continuance as in the more extended lands within the tropics. Farther, we know that in the tropical countries the fervent heat of the rainless period, comes at last to have all the effects of a winter, in the suspension of animal and vegetable action. The depth of the tangled forest is, indeed, in some measure, proof against the heat, and the creatures which inhabit and feed lower down and more in the shade than the birds of paradise, can still obtain their subsistence. But though the smooth leaf reflects off much of the heat, and does not fall or wither, the vegetable action of the tree, at least in the exposed part of it, is suspended; and when the vegetable action of trees is suspended, the feeding of insects upon them is suspended also. In our gardens and groves, it is the young and growing leaf on which the caterpillar feeds; and when the hardened leaves of autumn are consumed, they are consumed not by animals of any kind, but by the smaller fungi. We are not to suppose that the leaves of tropical trees are, in the dry season, consumed in the same way, for humidity is as necessary to the growth of this smaller vegetation as it is to that of the larger; but if the leaves are less fit for the production of fungi than with us, much more must they be less fit for the food of leaf insects; and though there are tropical insects which are wholesale consumers of decayed or decaying trees, they attack them from the ground, consume the wood rather than the bark, are not found on those parts of the trees where the birds of paradise reside, and therefore they cannot be considered as forming even a part of the food of these birds.

Thus, as one part of those countries in which they have their haunts becomes parched, the birds of paradise must remove to another, just in the same manner as the lighter herons which have similarly produced feathers, must flit along the courses of the streams as the drought invades their dwellings at particular parts of them; and we shall see presently that the produced feathers, besides enabling the birds to ride more easily and descend more softly on their shorter excursions, in consequence of the hold which their countless flocculi take of the air, assist the birds in finding their way to those other places where there is food for them.

At those places where the earth and the upper part of the forest are parched, and the ardour of the unclouded sun continues to beat, there is a constant rarefaction and consequent ascent of the whole mass of the atmosphere; and in consequence of this the winds from the more humid surfaces must blow toward those parched places with velocities proportional to the differences between the one and the other. It is this which produces the seasonal winds of the tropical countries; and it is this, acted on by the changing declination of the sun which produces the changing monsoons or alternations of the tropical seasons: and here we have an instance of that beautiful arrangement in nature in which, from the motion of a planet in its orbit, to the action of an insect or a microscopic fungus upon a leaf, what seem to us to be the aberrations of nature, all contain in themselves the means of their own correction and reversal when they have reached their limit, which proves so clearly that the wisdom of design which is in nature is infinite.

This, when it arises naturally from the immediate subject of our contemplation, as it unquestionably does in the present instance, is always worthy of something more than a mere passing expression of wonder. For, as is the case with the Creator himself, space and time are so small impediments in the way of those laws which he has given to his works, that we may fetch from the most distant point of observable space, or the remotest one of known history, an illustration of that which is before us at the moment. As the earth rolls along from its perihelium or point nearest to the sun, its motion along the elliptic path contains the element, by means of which it shall again approach nearer to that luminary; and in like manner its approach as it rolls onward from the point of aphelion, contains in it the element by means of which it shall again recede. It is so with the different seasons in all regions of the globe, and it is so with all those creatures which the seasons put into motion, whether the motion of life or that of migration. But to return to the birds of paradise.

When the forest which is their haunt at any particular time becomes parched, their food lessens, and they are compelled to be more on the wing in their search after it. But on which side soever there then happens to be a place more humid and more abounding in those creatures on which they feed, and which on this account is better suited to them for the time, there is a wind which blows from that side toward the place which is parched and heated; and as the action of that wind upon their flocculent feathers, turns them round on their centres of gravity like weathercocks, their heads are, as they fly, turned to the wind, and their progress is, of course, against its current. Their feathers must thus in so far assist the birds in finding out the direction of those places where they can feed; and though this is more remarkable in the case of birds of paradise than any other species, it is probable that many of the softer-feathered birds are also assisted in their tropical migrations by the set of the wind.

We must not suppose that this is too mechanical; and that the whole is performed by that to which we give the name of instinct; for of instinct we know, and can know nothing further than that it is a name which we give to those movements and actions of animals of which we can give no explanation. The word instinct, though we can hardly avoid using it, is never anything else than a subterfuge for our ignorance of the means by which any action of an animal is brought about; and we may rest assured that natural actions are no more performed without means in the unexplained cases than in the explained ones.

If we analyse the matter downward to the primary impulse of life in the creature, the mere fact of flying at all is just as much an instinct (that is, a matter of which we are ignorant) as the impulse of life which originates its flight in a particular direction at a particular season. The act of flying cannot be performed by the instinct alone, and indeed in all that part of the act which can be made matter of science, the instinct has no concern; we invariably find wings as the motive organs, and those wings are always fitted to the average style of flight which the habit of the bird renders necessary, with such perfect unity, that we would at first sight suppose that the one were the cause of the other. When, however, we examine them, we find that they both answer so equally either for the cause or the effect, that we are unable to select either of them without feeling that we are in error and have done injustice to the other; and therefore we either fall into absurdity and nonsense which bitterly, though secretly, reproves ourselves, as well as tends to mislead others, or we at once and frankly refer both to the same source, and confess that Maker who thus stands demonstrated in his works.

In the countries which these birds inhabit there are some races of insects which migrate on the wing *en masse*, but they float before the light winds and not against them; and the produced feathers by means of which the birds move slowly to windward, may thus enable them to meet their food, and seize it with the bill. Too little is, however, known relative to their manners for enabling us to speak with precision on this point; but those feathers which do not serve for clothing, or answer any of the ordinary purposes of flight, are well worthy of further investigation, as among the most curious parts in the structure of birds.

Night feeders, in all the races of birds with which we are well acquainted, are remarkable for having their feathers more soft and downy at the margins, and more loose in their whole texture and application, than day feeders. This holds good of many of the soft-plumaged birds, such as some genera of gallinidæ, which, though they find their food by the eye, and thus cannot find it in the dark, or even in the dim twilight, yet feed early in the morning and late in the evening, and squat and repose during the greater part of the day. Birds which have feathers thus formed are unable to contend with strong winds, and they are equally liable to injury from rain. This must apply in an especial manner to the birds of paradise. They are unable to contend with the blasts or endure the heavy rains which occur about the changes of the monsoons in those seas; and indeed these are often so violent that no bird can keep the air or remain on an exposed perch. Birds of paradise do not of course remain in the air at those times; but how or where they then find shelter has not been ascertained,—probably it is beneath the leaves of the palm family, some of which are so large that a single one suffices for a tent; and they are more tough and firm than many kinds of our ordinary timber. Palm trees are altogether admirably fitted for resisting the violence of the tropical storms, and for affording hold and shelter to any creatures that can cling to the thick tufts of leaves with which their tough but flexible stems are crowned. A palm trunk is, indeed, a realisation of the fable of "the bundle of rods." The longitudinal fibres, which extend from the root of the tree to its crown without any interruption from branches, or even any flexure, are so hard, firm, and elastic, that they have almost as much resemblance to wires of elastic metal as to the timber of any tree of temperate climates; and while they all have equal tension, they are embedded in a cellular tissue, which keeps them from pressing upon each other; and so renders the fracture of a very tall and slender stem, and therefore one which, according to our ordinary notions seems very feeble. next to impossible. The palm family are so numerous, and form so general and characteristic a feature in the scenery of tropical countries, that the knowledge of them is necessary to the proper understanding of tropical forest animals, whether mammalia or birds. But though closely connected with the history of birds of paradise, an account of those highly interesting trees would be out of place here. See the article Palms.

Notwithstanding that the old fable of the birds of paradise being footless, inhabiting the air only, feeding upon nectar and dew and even odours, and never coming to the ground, or resting upon any other support than the air until exhausted, incapable of the mysterious wingless flight, and at the point of death, has been exploded, there still hangs a good deal of mystery about their mode of flying; and they do fall, both on the earth and in the narrow seas across which their periodical migrations are taken, more frequently than any ordinary air-birds. They fly, as has has been stated, only with their heads to the wind, and as the produced feathers of the flanks entirely cover the closed wing when the bird is in a state of repose, the same feathers would keep down and entangle both wings if the bird were taken by the wind in the rear; and even when it attempts to come obliquely, or fly upon a wind as one would say, the windward wing gets entangled in these feathers and down the bird drops. If it falls in the water, it of course speedily perishes; and when it falls on the land, though its produced and flocculent feathers prevent it from receiving any injury, yet it has considerable difficulty in righting itself, and it cannot take the air again without getting upon a stone, a clod, or some other little eminence. In consequence of this it becomes an easy prey to the natives, in the same manner as the parrot tribe are easily taken when they miss their hold and tumble from their perches.

So far as is known, birds of paradise are the only species which are subject to lose their poise and command of themselves in the free air, and tumble down without any injury or exhaustion; and it is possible, and even likely, that this habit, which must have struck the first observers of them very forcibly, gave rise to that part of the fabulous account which represents them as tumbling to the earth in order to die there, but keeping the air at all other times. Here it may be proper to remark, that it behoves us to pause before we altogether discard as fabulous any of those accounts of natural productions, however ridiculous they may appear, and however they may involve contradictions or impossibilities, which have been made by persons actually visiting the places alluded to. Those fables are seldom if ever substantially inventions of the original narrators. In nine cases out of every ten it will be found that how much soever they may have blundered in the representation of it, there was a real foundation for the story; and thus the fable has its use as the means of guiding us to the reality; and the business of true science consists in setting these matters to rights, while that which would explode them altogether is the mere arrogance of ignorance. We have proofs of this in many instances; and among others in the giraffe and the unicorn; though the former animal is now well known; and not a doubt remains that the animal which has so long flourished in heraldic and other fanciful story, is the oryx or straight-horned antelope of Central Africa, of which there are profile representations in the ancient monuments of Upper Nubia and Abyssinia, which are intermediate in their form between this antelope and our fabled unicorn.

In like manner the perpetual dwelling in the air attributed to the birds of paradise was the way which the folks of the olden time had of expressing a style of flight, and the use of feathers, which they did not very well understand. It is worthy of remark too that it is not the early visiters of the distant climes where these birds are found to which the fabulous accounts of them are owing, so much as to the hasty conclusions formed by the learned at home, from the imperfect data which the narratives of those travellers afforded. Pigafetta was scolded by Aldrovand, and even by Scaliger, as a most audacious heretic in science for daring to say that the birds of paradise had feet, although he had actually seen them using these organs in perching; and as, in the earlier stages of discovery especially, we did not get the information direct from the original observer, but through the medium of some learned rédacteur, or the combined speculation of some learned body, and therefore the truth of the narrative was trimmed to the fashionable theory of the day, be that what it might. One of the greatest improvements which has resulted from the general diffusion of knowledge as preparatory for observing and recording observations, is the perfect fidelity with which all that is new in nature is now rendered to the world by travellers of almost every class in their own words, unencumbered by anybody's speculation; and the advances which have in consequence been made, more especially in zoological science, are unprecedented in the whole annals of human knowledge.

That birds of paradise are incapable of taking flight in any way but against the wind is proved by their migrations, as well as apparent from their feathers, and the general form of the anterior part of their bodies. They shift with the monsoons, to which the turn of the seasons in those seas is chiefly owing. The principal range of the birds is nearly under the equator, though more on the south of it than the north, and while it does not, so far as has been discovered, any where exceed 10° in latitude, or about 700 miles, and is generally much less, it ranges 25° in longitude, or 1750 miles, that is from about 125° to about 150° east longitude.

This space, though (with the exception of New Guinea, the geography of which is imperfectly known) it consists only of small islands, which if they are long are always narrow, as if it were the mere ridge of a chain of mountains rising above the water, is, on this account, the garden of the world in respect of the beauty, the richness, and also the peculiarity of its vegetable productions. The vicinity of the sea to all parts of the land of these small isles, and the general set of the wind from the wide Pacific, prevent these places from being visited by those severe droughts which parch more extended lands in tropical climates; but still there are shifting monsoons, and varying seasons even there; and though the birds of paradise never have been known to range beyond the limits that have been stated, that is beyond the isle of Ternate on the north-west, and New Guinea on the south-east, yet they have their seasonal motions answering to the monsoons within their own limits.

The monsoons are distinguished as the dry and the wet, the first blowing from the west, and the second from the east; but it is to be understood of all those regular seasonal winds, which are occasioned by the ordinary action of the sun upon the surface of the earth, that the monsoon, whether wet or dry, has its cause in the place toward which the wind sets. Thus, although the dry monsoon blows from the west, it begins in New Guinea, and proceeds gradually westward. It is the drying and heating of the surface of New Guinea which rarefies the air, makes it ascend, and thus puts the monsoon in motion. And when the heat and drought have become sufficient to produce these effects, the woods of that island are in that state in which they furnish the least possible supply of food for these dwellers on their tops. Consequently the birds are compelled to seek better pastures; and their very structure, whenever they get on the wing, turns their heads and preserves their courses in that direction in which food is to be found. This dry monsoon from the west does not extend very far to the westward of the limit which has been mentioned; because, further west, the larger lands which lie on opposite sides of the equator (Asia on the north, and Australia and Africa on the south), give another direction to the seasonal currents; and by the way it is where the sets of these different monsoons, meet or cross each other, that the tiffoons or gusts of variable wind are so violent and so dangerous to navigation.

The drying effect of this west wind is of course in proportion to the time of its continuance; and thus the drought and the progress of the birds both proceed westward, the one turning the east wind to a west wind, and the other following up to that wind's commencement. When the western part of the range becomes dry and the monsoon shifts, the birds again return upon the east wind, and reach the different places as the rain has brought abundance. Thus they are not in any one locality either during the rigour of the drought or the violence of the rain, but rather during that season of plenty which follows the latter.

The species of birds of paradise are differently stated by different describers, and they have been confounded with some other genera, or rather perhaps the genus *Epimachus* has been confounded with them. Indeed there is a portion of ornithology, including a number of very beautiful birds of warm countries, and ranging from the birds of Paradise to the bee-eaters, or at all events to the hoopoe, which is not very clearly defined, and will perhaps, when the structures of the different species are a little better known, require some modification in the arrangement.

There are, however, seven or eight species of birds of paradise, of which the characters are tolerably made out: and to these we shall restrict the details of this article.

They have all produced feathers with flocculent webs on the flanks, the scapulars, or both; they have in general long thread-like feathers in the tail, which end in little discs or pallettes; and the plumage of the rest of their bodies is in a great measure peculiar. All their feathers are better formed for taking hold on the wind than for making way against it; for they are all remarkable for their loose and velvet-like texture. This is remarkable in the feathers of the head, and in those of the neck, more especially in the species which have a ruff of produced feathers upon that part; but it is not confined to these, for the whole plumage of the body, and even the flying feathers of the wings, have a more loose and velvety texture than those of most other birds.

In this respect, the birds of paradise, which are dwellers on the tops of trees, or hoverers over them in the air, bear a considerable resemblance to the humming-birds, which are hoverers over flowers; and along with the same velvety texture of plumage, they have the same richness of metallic reflections, more especially in bronze colour and golden green. No contrast of plumage can be greater than that of these birds with the parrot tribe, which often inhabit among the sprays and twigs of the same trees on the tops of which the birds of paradise roost. The tints of the parrots are rich; but they are generally tints of entire colour, without gloss, and without any reflection or change of shade from the different directions in which the light falls upon them. The feathers on the parrots are also in general firm, hard, and well made out, as if suited for enduring the contact of those branches among which they have to make their way, while those of the birds of paradise appear to be fit for contact with the air only. The plumage of the one set of birds bears, in fact, some resemblance to a coat of mail, while that of the other is soft and flocculent all over. The texture of feathers, as varying with the haunts and habits of different birds, has not been investigated with that attention which it deserves; but it certainly forms a very marked and therefore a very useful character; and the contrast is no where more striking than between the parrots and the birds of paradise,—the one having to find their way among the thickly ramified branches, the other only in the free air. We shall now very shortly notice the species.

1. Great (or common) Bird of Paradise. (*Paradisea major*). The trivial name apoda, which has been given to this species is inaccurate, as the bird, instead of being "footless," as that name implies, has very stout feet, though short in the tarsi, and otherwise not well adapted for walking on the ground. They are, however, very efficient perching feet; and from the peculiar way in which the toes are united, and the great length of the hinder toe, they are well adapted for resting, not merely by perching on a twig, but on the top of the leaves, as, though differently constructed and differently used, they still bear a resemblance to those feet with the produced hind toe and claw which fit their owners for walking upon tall and elastic herbage on the ground.

This species is the one which is best known and most generally used as an ornament. The use of it in this way in the East is not confined to the head dresses of females, as it is in Europe; for the chiefs use it in the adorning of their horses. It has thus been in request from the earliest times of which we have any knowledge in those eastern climes; and the natives of New Guinea, from whose country it is obtained in the greatest numbers, as it is more abundant there, and found for a longer time of the year than in the Moluccas, endeavour to kill or otherwise procure it without any wound to the skin, or if possible any ruffling of the plumage. These islanders are very expert bowmen, and the bows which they use in their wars are of such power that they can send a pointed arrow to the depth of two or three inches into the planking of a ship. But when they shoot these birds they do it with blunted arrows, or even with arrows which have their heads padded, so that they only partially stun the birds, and neither penetrate the skin nor injure the feathers. They also sometimes use birdlime for snaring or entangling the birds; but, as they roost high that method of capture is attended with very considerable labour, so that the favourite mode is that of shooting with the blunted or padded arrows; and the wings get so easily entangled in the produced feathers of the flanks that the birds are brought to the ground very readily, and when they are there, they are helpless and easily taken. The feet and wings are then removed, the body drawn, extended on a stick inserted by the bill, and then dried in smoke to such a degree that it is not liable to be destroyed by insects.

The general appearance of this, which is the handsomest bird of the genus, may be seen by examining the first figure on the plate "Birds of Paradise." It is about one foot in length, from the point of the bill to the extremity of the tail; but the produced feathers of the flanks, which are exceedingly light and beautiful in their form, extend about a foot more. The general colour is a rich cinnamon brown, but it varies considerably on the different parts. Over the nostrils and on the forehead there are very thick, soft and velvety black feathers, with green reflections. The crown and nape are pale yellow; the throat golden green, the hind part of the neck purple brown, the rest of the upper part, and also the breast and belly, maroon brown; the bill yellowish black, and the feet black. The colours are subject to considerable variation in different specimens, as for instance, the throat is of every shade from golden green to a rich golden yellow; and when this part is more inclined to yellow, all the rest of the bird is of a paler tint; but whether these variations are the result of difference of age or season, or whether they are permanent for the life of the birds, has not been ascertained.

The produced feathers on the flanks, and in the tails of these birds are among their most remarkable external characters. Those which originate in the flanks are of a pale yellow or straw colour for the greater part of their lengths; but they are marked with purplish red toward their origin. It is difficult to imagine any structure more beautiful. The shafts are finely tapering, and the fibres of the webs, which are quite detached from each other, have secondary ramifications; and, the whole are fined off toward the extremities, so that they really more resemble the tail of a comet than they do any more solid matter; but unsubstantial as they seem toward their extremities, the shaft and web are so well proportioned to each other that the whole feather floats far and gracefully; and with the very maximum of tenuity it has no appearance of weakness. Besides those, there are two very peculiar filaments of feather, covered with velvety down, interspersed with short stiff hairs, which have however nearly the same lustre as the down, which originate one on each side of the rump, and both extend to nearly the length of two feet. These are yellowish at their bases; but for the greater part of their length they are nearly black, and show a very peculiar mixture of greenish lustre, which can hardly be called a reflection, for the hue of it is velvety rather than metallic, and it is a very intense and rich colour; though there is so small a portion of this green that it is only visible in certain positions of the light with regard to the feather, yet when the eye can catch it, it is of the most intensely rich shade that can possibly be imagined. It is said, however, that the skins, whether prepared by the usual methods of the natives or not, which are brought to this country, have the green shade less rich, and the whole colour inclining more to yellow, than in the living and healthy bird; and especially that the smoke-drying, which is found necessary in order to preserve the skins from the ravages of insects, imparts a brown and muddy tone to all the richer tints of colour.

These produced feathers, whether they originate from the flanks or the sides of the rump, are wholly unconnected with the flying feathers of the birds, which both in the wings and tail are short. The wings are hollow as well as short, or rather they have a peculiar curvature, in consequence of which alone, one would be led to infer that they have not the same kind of action as ordinary flying feathers, by means of which birds make their way in the air; and though the body of the bird is not a very heavy one, the wings are so small that they seem incapable of floating it freely without these produced feathers. We are still, however, too ignorant of its economy to be able to speak with confidence on the subject of its very peculiar mechanical action in the air.

2. Royal, or King, Bird of Paradise. (*Paradisea regia*). The species of these curious birds have been as unfortunate in their names as in their history. There is no attribute of royalty in this one, any more than there is a particular reason for applying the epithet superb or magnificent to two other species which remain yet to be noticed. The species which has been already described, to which the equally humble and faulty name of "footless" has been given, is unquestionably the finest bird of the genus, and therefore the one to whom superlative epithets are the most applicable. Those superlative epithets are generally rather awkward in science; for in all cases where *magnificus*, or *splendens*, or *gloriosa*, has been applied either to a bird or a flower, it has generally turned out that some other species, which had to be called by a humbler name in consequence of the appropriation of the superlative one, put not only the species with the lofty name, but the party by whom that name was given, completely to shame. To this, the lofty names of some of the birds of paradise do not form an exception.

The species in question which is No. 2 on the plate, is a much smaller bird than the former; and, so far as its habits are known, it is not nearly so much "a thing of the air." Its produced feathers, although peculiar, have none of the airy beauty which is so conspicuous in the larger bird; and it does not appear to be so capable of migration. It has not often been found out of New Guinea, while the other ranges with the monsoons not only to the Moluccas, but to some of the isles further to the east.

The king-bird is not one eighth of the volume of the common one, being only from five inches to five inches and a half in length. It is also less royal in its habits; for while the other is found chiefly in the air, or on the tops of lofty trees, and on its migrations sails majestically in company with its associates, this species is a bark bird, seldom found on a very elevated perch, and solitary and shy in its habits. That it does migrate is understood, because the food of such birds is seasonal in the places which they frequent, and this species feeds principally on berries; but it is seldom seen on its migrations; and as its produced feathers are not of the same floating character, its style of flight cannot be so peculiar.

The upper part of this species is reddish brown, of velvety texture and gloss, the pouch and part of the head rich orange of the same, with a small black spot at the inner angle of the eye. The chin is of a rich nut brown, forming a large spot upon the upper part of the throat, and passing into a margin of pale and yellowish brown; and that again passes into a gorget of very intense golden green, with metallic reflections. The rest of the under part is leaden grey. The feathers of the flanks, though not long and flocculent like those of the former species, are considerably produced, but they incline downwards, and save the legs more than they do the wings. For the greater part of their length these produced feathers are of nearly the same subdued tint of leaden grey as the common clothing feathers of the under part, but toward their extremities they become more brilliant. There they have, first, a narrow line of white, then one of the same rich nut-colour, as appears on the skin, and after these there is a broader band of exquisitely rich emerald green. The flying feathers, both of the wings and the tail, are dark nut colour, or reddish brown; and two of the tail feathers, or rather two feathers from the rump (for it is thence, and not in the true tail, that the produced caudal feathers of most birds have their origin), are produced beyond the rest to a distance about equal to the whole length of the bird, and they are very peculiar in their shape. For the greater part of their length they continue nearly parallel or very little divergent from each other. Toward their terminations they curve outwards, or apart from each other, and at the ends they curl into a sort of spiral discs, consisting of nearly two convolutions, but with an opening in the centre. The webs which form these discs are all upon one side of the shaft, which, for the greater part of its length, is covered with velvety filaments, as in the former species, and interspersed with small barbs of stiffer texture. The discs in which these two feathers terminate are of a very rich golden green, with metallic reflections. The naked skin on the feet of this species is of the same soft leaden grey as the under part of the body, and the bill and claws are yellow.

3. Red Bird of Paradise (*Paradisea rubra*). This, which is a very elegant, as well as a very beautiful species, is figured on the wing, as number 3, on the plate. It is much more a floating bird than *regia*, though perhaps not so much so as *major*. It is between nine and ten inches in length from the extremity of the bill to that of the tail. The upper part, the sides of the neck and the breast, are yellow. The feathers at the base of the bill, which cover the openings of the nostrils, are velvet black; and those on the top of the head, which have the same soft texture, but are much more produced, and parted in the middle so as to form a sort of double crest, are of a fine golden green, and they partially extend over the nape and sides of the neck. The lower part of the breast is brownish, and the flying feathers of the wings and tail brown. The flanks are furnished with numerous produced feathers, which are detached from each other, and bare and flocculent on their neck, in the same manner as those of the species first mentioned; but their direction is much more across the axis of the body, their curve more downwards at their points, and they are very differently coloured. They are of a deep and full red, or the character which may be considered as blood red, or the nominal or primary tint of that very varying colour; but still their tone is subdued, and more inclining to that of venous than of arterial blood. From the sides of the rump there proceed two thread-like feathers, of an intense black, a little flattened, curving on their upper sides, and concave on their under ones, which extend to the length of from twenty inches to two feet in their different specimens. Their feathers are nearly straight and tapering, and without any convoluted discs at their extremities, like those of *regia*. The bill and feet of this species are brown. Its head-quarters are in New Guinea, and it does not appear to be so discursive in its range over this island to the eastward as some of the other species.

4. Magnificent Bird of Paradise (*Paradisea magnifica*). This is the fourth and last species figured on the plate, and, like *regia*, it is a small species, though considerably larger than that, being at least half an inch longer, and proportionably greater in all its other dimensions. The upper part is of a rich and brilliant brown. The feathers over the nostrils and on the head short, but very thickly set, and of a rich reddish brown. The top of the head green, with metallic reflections. Around the neck there is a double ruff of produced feathers. The first, or nearest the head, and shortest one, is composed of straight feathers, of a reddish colour, and with black spots on their extremities. The second, and larger one, is straw yellow, with the colour darker towards the extremities of the feathers. The ends of the feathers of both are squared and abrupt, as if they were trimmed by a pair of scissors; but the webs of that part have the same velvety texture which characterises all the produced feathers upon birds of this genus. The primary quills of the wings are of a fine crimson colour; the coverts yellow on the upper sides, and brown on the under. The secondary and tertiary quills brown. The throat and breast are clouded with green and blue on the middle, passing into brownish green on the sides of the breast, and the belly is bluish green. The feet and bill are yellow on the principal part, but the tomia of the latter are margined with black. With the exception of the double ruff, which gives a very singular appearance to the neck, there are fewer produced feathers upon this bird than on most of the others, but there are two very beautiful ones arising from the sides of the rump, extending to some distance nearly parallel

to each other, and then forming two wide circular loops outwards. The colours of this bird are exceedingly rich, without being gaudy, and they harmonise remarkably well with each other. It is found principally in New Guinea, and as it wants the floating feathers on the flanks, it is like the species mentioned second in order, more of a land bird than of a tree and air one.

5. Six-threaded Bird of Paradise (*Paradisea esxsetacea*). Some notion of the general form of this species may be obtained from the annexed representation. It is a native of New Guinea, and measures ten or eleven inches in length. The prevailing colour of the upper part is rich velvet black. The front and top of the head are thickly set with slender feathers, a little produced, and mottled black and white, so that they have something of the appearance of a grey crest. Each side of this bird is furnished with three produced and thread-like feathers, about six inches long, of a black colour, and having a small oval disc at the termination of each. The feathers of the neck have reflections of golden green, and on the flanks there are produced feathers of a black colour, and with large and flocculent webs, which cover the wings when the bird is in a state of repose. The head and breast of this species are of a very rich and brilliant golden green; they are somewhat long on the breast, and it is the margins of the feathers only which are green, the central part of the feathers being black. The feet and bill are brown. In addition to the six filament-like feathers on the sides, from which the name *sexsetacea* is derived, and the produced feathers on the flanks, some

Six-threaded Bird of Paradise.

of the coverts have their shafts ending in produced filaments. Altogether, this is one of the most gorgeous birds of the genus, though its colours are five in number. The black, which is the prevailing colour, is, from its velvety texture, of the most intense depth, not returning a single particle of light, while the blue and yellow of which the green is formed show every tint, according as they are turned to the sun, from the finest gold to the very verge of blackness, and in all the varieties there is a very rich lustre. Thir species is not so common as some of the others.

6. Superb Bird of Paradise (*P. superba*). This species is smaller than the above-mentioned one, being only between eight and nine inches in length, and altogether it is not so gorgeous in appearance, although its colours are more varied and showy. The clothing feathers on the upper part are black, glossed with reflections of green and purple; the forehead has two small crests of black silky feathers; the fore part of the neck is black, with blue and purple reflections, of which the lower feathers are considerably larger than the rest, and form two points, which hang down the sides of the breast, something in the form of a forked tail. The back of the neck and breast are of a rich golden green; the belly, and also the feet and bill, are black. From the scapulars there arise long feathers of loose texture and of an intense velvet black, which curve backwards and outwards, and in part cover the wings. This species is found throughout the whole range of the migration from Ternate to New Guinea. The following figure will give some general idea of its form.

P. superba.

7. Small Green Bird of Paradise (*Paradisea minor*). This bears so near a resemblance to *P. magia*, the species first described, that it may be only a coloured variety, arising from age, or some other circumstance. It has been found only, or chiefly, in New Guinea. It is about nine or ten inches in length from the point of the bill to the end of the tail. The upper part is bright maroon; the sides of the head, the back of the neck, and upper part of the back, pale yellow; the feathers at the base of the bill soft and velvety, and black, with purple reflections; the throat and upper part of the breast bright green: the rest of the under part rich brown; some of the coverts of the wings bright yellow; the feet yellowish, and the bill yellow, with a black margin on the tomia. The flank feathers are very much produced and flocculent; they are yellow and white, and the filamentous feathers of the tail have a very considerable resemblance to those of *major*.

The following figure is a representation of this species.

P. minor.

Such are the principal species of these curious birds, and indeed the only ones which can be satisfactorily proved to belong to the genus; but there have been, as was already stated, some species, principally of the genus *Epimachus* of Cuvier, though those last are by him classed among the tenuirostres, and are, from the structure of their feet, anisodactylic birds. But the foot of the birds of paradise is also a peculiar one, and, in a strictly natural arrangement, would prevent the classing of them with the common omnivorous birds, which have all the toes free, and the feet equally fitted for perching across a twig and for walking on the ground. Their foot is not anisodactylic, with the two outer toes united together, and acting against the inner and the hind one; neither is it syndactylic, having the external front toe and the middle one of nearly equal length, and so united together as to have partly the firmness of one broad toe. But the foot of the birds of paradise partakes something of both characters, though it is the inner and the middle front toe which are united, and the union does not extend so far as in the syndactylic foot. The outer and middle toes are united and soldered at their basis, and the hind toe is very long in proportion to the rest.

This foot does not thus come within any of the descriptions of feet to which characteristic names are given, and the habits of the genus are also different from any of those with which we are familiar; and as the genus *epimachus* and the genus *paradisea* inhabit not only the same country, but the same forests, and are both perchers, and have produced feathers on the flanks, we must consider them as naturally belonging not only to the same order, but to the same group. They resemble each other even to the velvety feathers on the head; and it is a very common law among birds, that where there is a similarity in texture of feathers (how much soever the colours may differ), there is a similarity in feeding and in the general habits.

So closely do some of the species of these two genera resemble each other, that it is highly probable, that when Cuvier changed the *Paradisea alba* of former writers to *Epimachus alba*, he was misled (as continental naturalists have been on former occasions), by a mutilated specimen. He says:—"*Les pennes primaires de ses ailes sont courtes, et beaucoup membreuses qu' aux oiseaux ordinaires.*" That this must have been the case with the specimen (a skin, in all probability, upon which Cuvier founded his description), is true; for of the subject before him Cuvier was an accurate observer and a faithful describer. But it really appears that this specimen must have had the wings mutilated by the abstraction of the whole, or the greater part of the primary quills; for though the primaries are not very long, as they never are in any of the tree birds which have produced feathers, they are as long as in the ordinary birds of paradise. This species, if coincidence in all the leading characters is to be considered as the foundation of every arrangement, should make an eighth species of the bird of paradise.

8. White Bird of Paradise (*P. alba*). This species inhabits the same places, and has the same habits, as the others. Its length is about nine inches and a half. The feathers of the flank, which are produced in the same manner as the others, are white, with some markings of yellow. The filaments, which are twelve in number, or six on each side of the bird, issue not from the rump, but from the produced feathers of the flanks, and these filamentous productions are about the thickness of a horse-hair, ten inches in length, and twisted or curled in different directions. The wings are of exactly the same form as in the rest of the genus. This species is certainly much less gay in its plumage than most of the order; but if general form and habit are to be the foundations of arrangement, it is much more entitled to be considered a species of this genus than *P. micra* is to be a separate species from *major*.

We must expect some time to elapse before the natural history of these long and deservedly-celebrated birds is any thing like perfect. They are not easily observed in their native climes, because, when in a state of repose, they are on the tops of the very highest trees. Their countries, New Guinea especially, is very unsafe to visit for scientific or any other purposes; the natives are watchful of their birds, as they constitute no inconsiderable branch of their rude commerce; and the skins which can be purchased of them, whether of the true birds of paradise, or of any of their gay brethren of the spicy groves, can hardly be obtained in any other state than mutilated and prepared for the market.

They seem also to be as delicate, and difficult to be transported, reared, or kept alive out of their own very peculiar locality, as the mangosteens and durias, and other choice fruits of that oriental archipelago. There has, we believe, been instances of their arrival in this country not absolutely dead, but they were barely alive, all those fine and peculiar feathers fallen off, all the beauty of their colours gone, and they themselves were landed only to pass a few days in pain and misery. We might infer this from their habit of perching and basking under the ardour of the tropical sun, as well as from their proneness to migrate even in that part of the world, where the weather makes the nearest approach to perpetual summer.

BISMUTH. A mineral but little employed in the useful arts. It is found in the native state somewhat alloyed by arsenic or cobalt, either massive, dendritical, or in the form of a regular octohedron. The ores of bismuth are but few; in that called sulphuret of bismuth, it is combined with sulphur; in another, called bismuth ochre, it is mineralised by oxygen, and includes a small portion of oxide of iron. It also occurs mineralised by the carbonic acid. Native bismuth is rare, as well as its ores; these are found in veins, mostly in primitive mountains, accompanied by the ores of cobalt, of iron, of zinc, and sometimes of silver; and by quartz, calcareous spar, and barytes, in Bohemia, Transylvania, France, and Sweden. The sulphuret of bismuth has occurred in Cornwall, as well as the oxide.

Bismuth unites with most metallic bodies, and renders them in general more fusible. When calcined with the imperfect metals, it produces the same effect as lead in cupellation; combined with the latter body, it produces a fine coloured alloy.

BISON. The name of one of the subgenera or groups, into which, for the sake of brevity and perspicuity of description and consistency of geographical distribution, modern naturalists have divided the great genus Bos (the ox), the most useful to man of all the ruminant mammalia. For the general characters of the genus, and the number and distribution of the several groups, we refer to the article Bos; and for the structural character of the order, which is a very well marked and natural one, to the article Ruminantia; so that we may in this article confine our observations more exclusively to the group of which the name stands as title.

We may, however, remark that the domestic ox, with whose appearance and uses every one must be familiar, though broken into varieties almost innumerable by the effects of climate and domestication, possesses nearly the mean or average characters of the whole genus; and may therefore, in all cases of reference, be considered as the type, by their differences from which all the groups in their several species may be most clearly and briefly described.

There is not a better general means of distinguishing the different groups of animals of the same genus, that is which possess the same general type of organisation, in the number, form, and arrangement of those parts of which their bodies are made up, than the shape of the bones of the head and face. Even in the human race, who we are taught to believe are, in all their tribes and varieties, descended from a single pair, we find that the general shape of these bones is one of the best means of distinguishing tribe from tribe; and though attempts have been made to carry this means of judging too far, and to draw conclusions from it which not only it does not warrant and will not bear, but which cannot in the very nature of things be drawn from any structural form or arrangement whatever; yet within proper limits this mode of judging is among the best analogical ones which we have.

Even in the case of man, though as applied to man himself the terms of the analogy have often been reversed, and the mere frame, which is the passive part of man's compound nature, has been considered the active one, much in the same way as we would allege that the tool employs or uses the hand in working, instead of the hand using the tool;—even in his case, though the form of the head, in the opinion of the writer of this article, cannot possibly throw any more light upon the physiology of the mind, than can be thrown by the form of the limb, or any other part of the structure, yet a knowledge of the effects which are produced upon the form of the human body by external circumstances is of much use to us in studying the general history of animated nature, and especially that very interesting and useful part of it, the adaptation of animals to the several climates over which they are locally distributed. This subject bears so closely upon the group of animals which we are about to examine, that a few words on it will facilitate instead of retarding our knowledge of that group, at least if this knowledge is to extend any farther than mere names and external appearances, which can hardly be said to deserve the name.

This is the first instance which has occurred in the alphabetical arrangement of this work of any portion of a genus of mammalia, generally distributed in its different sections over the cold, the intermediate, and the warm latitudes, and which neither hybernates nor is capable of migrating, except for short distances within the same country; it is therefore the first opportunity which we have had of alluding to the adaptation of different sections of the same genus to very marked differences of climate; and consequently it is the one in which we can most valuably and profitably introduce some allusion to the general principle of such adaptations; and we shall find the case of man of no little use for illustration; and the more so that man is not, in strict propriety, part of the system.

The general principle stated briefly is this: it agrees with the unity and perfection which, wherever observation has been extended, belongs to the whole system of nature, and follows almost as an immediate consequence of these being there, that the plants and the animals which are found native in any climate or locality, whatever it may be, are the best adapted to it in all its average circumstances; and the worse adapted for any other climate or locality, in proportion as the circumstances of that locality differ more from those of the native region of the plant or animal.

But if this mutual adaptation of place and native inhabitant be general, as it certainly is, we are unable to say that either of the two is adapted for the other, because the position admits just as readily of being inverted; the hill-top, for instance, is adapted to the ptarmigan, and the ptarmigan to the hill-top; and in all cases, as well as in this one, the natural adaptation is mutual and reciprocal. They are not *different* things adapted the one to the other, by the act of a third agent, in whose hands they are both passive; they are self-adapting, and accommodated to each other by that law which their Maker has implanted in them, and in virtue of which they are what they are found to be, and not something different. When the plant or the animal is of such a nature as that it can give way, and in so far accommodate itself to a place originally not quite natural to it, it always approaches to the natural type of that place, if there be any native creature there which has the same general organisation.

Further, it is found that races which are natives of regions where the natural circumstances are the most variable can most readily accommodate themselves to new places; a native of the mean latitudes can accommodate itself much better either to the tropical or the polar ones than a native of any of these can accommodate itself to the middle latitudes. The horse, which is supposed to be a native of Central Asia, can live and preserve his spirit in Lapland or Java; but no art could keep the white bear of Lapland permanently on our shores, or the ape of Java in our woods. Thus, though circumstances can produce a considerable degree of modification, there is a natural limit which they cannot pass, a natural adaptation of creature to situation which they cannot bring about, even with all the assistance of art, in attempting to accommodate the place to the creature.

In all these cases of limit, and the limit is never a very wide one, unless the time allowed for the change is great, the animal cannot make what we call a *voluntary* effort to pass the limit; it cannot anticipate by reasoning what is to take place, and meet it by expedient, as man does. Thus when the circumstances of the locality in which it was at first native and at home, as it were, change either more extensively or more rapidly than the power of its nature to yield to circumstances can bear, the animal can subsist no longer, and so becomes extinct; and the only memorial of it that is left is its bones, in the debris and rubbish, or the impressions of them in the more consolidated strata.

It is to the mammalia chiefly, among vertebrated animals, that these observations apply; and therefore it is chiefly their bones which are found in the apparently more recent deposits. We do not find the bones of birds, because they can gradually retire as the changes occur, or take to the wing and escape from more hasty contingencies.

The judgment of the future which man is enabled to make from the experience of the past serves him even in better stead than the wings and power of aerial motion do the bird; and therefore, though there are accumulations of human bones, the result sometimes of sudden natural catastrophes, but much more frequently of the wars of mankind with each other, we never find the remains of an extinct nation preserved in the soil, as we do those of various species of mammalia, some of which have perished from those regions in which their bones are found, and others altogether from the face of the earth as living creatures.

But the power which the use of experience and reason gives man, both of enduring differences of climate, which no other animal can endure, and of maintaining his possession during changes which no other animal can undergo, is of itself perfectly capable of enabling the circumstances of climate and time to have produced in him, out of one, all the varieties which we now find—out of one original race—one original pair. With this resource, man might see race after race perishing around him, and the character of the country and the successive generations of men so changing with the lapse of long periods of time, that were it possible for the men of remote antiquity to visit the places of their former habitation, they would not know their former abode, and would reject their lineal descendants as a new and a strange people. This almost unlimited power in man to accommodate himself to the differences of climate and situation, if they come on him with sufficient slowness for enabling him to make use of the resources of his reason, release him from that bondage to climate which attaches to all the mammalia which have not the power of migration with the seasons. There is thus no natural necessity for a separate typical man of each different climate, as there is for a typical species of the mammalia where the genus is generally distributed, and the individuals incapable of migration; for if man moves slowly enough towards any climate, and takes the due precaution, he can be just as much the man peculiarly adapted for any one climate as for any other.

Those mammalia which man has long held in a state of domestication hold, in respect of this adaptation to climate, a sort of intermediate place between man and the species, even of the same genus, which are left to the contingencies of circumstances in free nature. The domesticated animal partakes in the protecting contrivances of his master, and therefore is enabled to live and become more and more adapted to the climate in each succeeding generation. So much is this the case that in climates which are much inferior to those out of which the animals are originally brought, no small part of the cultivator's art consists in preventing too much accommodation to the climate.

These circumstances bring us very naturally both to the original characters and the progressive history of the bisons. They are naturally the arctic tribe of the genus bos; and unless it be about the longitude of the Himalaya Mountains, where not only the chain of being but almost the very same race appears to extend from Siberia to India, the bisons appear to have been in all ages inhabitants of the northern latitudes only. There is no vestige of them in South America, where ruminantia appear never to have existed as inhabitants of the plains; there is no vestige of them in Australia, and so far as is known there are no ruminantia there; there is no vestige of them in Africa, though ruminant animals of other genera, and of the more tropical groups of the same genus, are by no means rare; and the species of Southern Asia, which have been referred to the group, are of somewhat doubtful admission into it, or if they are of the same stock they are wonderfully altered by climate, for animals which have never been in a state of domestication, and thus have derived no assistance from the protecting care of man.

As natives of less fertile and more inhospitable places than the rest of the genus, the bisons are endowed with greater courage, proportional strength, and relative power of locomotion. They have a daring and even a ferocious aspect; and they are as savage as they look. The beasts of prey can take or master them only by stratagem; and the wild hunters of the places in which they are still to be met with, who are equally bold and skilful in the hunting of animals, as they depend chiefly on them for their food, consider the bisons as their most dangerous game.

In consequence of this boldness and ferocity of character, the bison has never been domesticated, but left to the contingencies of wild nature, and those changes which its haunts have in the lapse of ages undergone, without any advantage from the arts of man; but rather the reverse, as both his personal safety and that desire of fame by conquering powerful animals which is so characteristic of man in a state of semibarbarism, by what name soever that state may be called, have induced him to thin, by every act in his power, the numbers of those animals.

And here, contrary to what we would expect on a first and superficial view of the subject, the course of natural circumstances co-operates with this disposition in man. The most powerful and formidable animal, the one which we would have imagined to be so sinewed and so spirited that it could overcome all contingencies and hold its ground against time itself, is the very first to give way. The northern elephant was, in all probability, the most powerful animal that tenanted the arctic lands; and of it there are no memorials save its bones in the accumulations of rubbish, or a few specimens preserved in the ice, just to let the curious know what a giant creature it had been. The same is the case with the giant bear and the giant stag; and while there are bones of bisons of nearly the same dimensions as those of which a living remnant is yet left, in places where no live one has been found within the limits of historic record, there are embedded at still greater depths bones of bisons of much larger and even gigantic size. These, from the situations in which they are found, do not, as is the case with the more ancient races, which show greater structural differences from those which exist at the present time, give any evidence of having perished by any disturbance of the strata—anything that can be considered as geologic revolution, but in consequence of the ordinary surface changes, which take place in the common course of time by the common action of the weather. Thus they tend further to prove (if further proof were necessary) that those animals which are in their own nature the most powerful and stubborn, are the first to yield to those general agencies which, in a placid though constant and successful manner, alter the state of things on the surface of the globe.

Those gigantic bones must have been more common nearer the surface, and therefore more familiar to common observation, in times long gone by, than they are now; and it is not improbable that in them we have types of those fabled men of giant dimensions, of which there are traditions in most countries. In those times the structures of organised bodies were but very imperfectly known, and it is no very great stretch of fancy to suppose that these giants, to whom was given the credit of erecting some of those ponderous structures which have no real history, and which have something the appearance of works of human art, whether they are so in reality or not, were fabricated out of the bones of these lost animals. Our proper business is, however, with the living species rather than with the fossil remains, and therefore we proceed to notice those bisons which are still to be met with, though the rapidity with which their numbers are obviously diminishing, renders the allusion to them as a race in progress towards extinction, a very rational part of their prospective history.

The characters of the bisons, which appear chiefly in the head are: the forehead arched or convex, instead of being nearly flat, as in the domestic ox; the breadth, measured between the orbits of the eyes, greater than the height; the bases of the horns before the ridge of the occiput; the whole outlines of the cranial bones more curved or convex; and the occiput being rounded instead of quadrangular, and passing into the line of the forehead by an obtuse and rounded angle, instead of an acute one. This form gives much greater strength to the skull, and more firmness to the bases of the horns; so that the bison can dash the head with much more impetus than the ox can, either against an enemy or against an obstacle, without the danger of equal injury either from fracture of the skull or concussion of its contents.

The legs of bisons are also longer, more clean in the make, and altogether better fitted for fleet motion than those of the common oxen, or any other division of the genus. The body is also more compact, and the strength more concentrated upon the fore part, so that in its attacks the animal advances with a powerful spring, and delivers the whole impetus of its body upon the horn, much in the same way that a lion does upon the paws; and if the rush of the bison takes effect, it is more immediately fatal than the spring even of the lion.

The produced hair on the neck and head gives it also more of a lion-like appearance, than one who had been accustomed only to the sober bearing and placid manners of common oxen in a meadow would be prepared to meet with in any animal of the same genus. This mane or shaggy hair on the sides of the neck, on the part of the head, and forming a sort of beard on the chin, appears chiefly on the males, as is the case with the lion; but there are upon both sexes two sets of hairy covering, which indicate their capability of resisting the rains and snows which occur in the northern parts. The one of those sets of covering is woolly and soft, partaking in some measure of the nature of fur, and calculated for protecting the animal against the cold; the other has the hairs individually thicker, straighter, and of more inflexible consistency, so that they are better adapted for throwing off the rain and snow.

One other remarkable difference of appearance between these animals and ordinary oxen, and indeed the greater part of the tribe, is, that the abdomen is much smaller and more firm and compact, and the whole of the hinder parts cleaner and lighter in their formation. The compactness of the abdomen is, in part, owing to an additional rib on each side: this group having in all fourteen pairs of ribs, while the other species of the genus have only thirteen pairs. Even the tongue of the bison is different; it is blue, while the tongue of the common ox is flesh coloured. The tail is not very long, but the brush of hair upon it is very full. Though the hair on the anterior part of the male is more forward, and resembles the mane of a lion much more than that of any other of the genus, the hair on the hinder part is comparatively short, especially in summer after the old coat is cast, but it gets more shaggy, and also fades in colour during the winter. One other remarkable characteristic of the animal is the thickness of the hide, which is more than double that of any other ruminant animal of the same dimensions. These animals are very indiscriminate in their attacks, and evince as much hostility to the other species of their own genus, which are incapable of doing any harm, as they do to the carnivorous or mammalia.

There still exist two northern species of those very powerful, and on account of their daring energy, very interesting animals, one in the northern part of the eastern continent, and the other in America.

The common Bison (*Bos Bison*). Is a forest animal, better able, from the texture of its covering, especially that of the anterior part of the body, to endure cold than heat. In ancient times it appears to have been very plentiful in what was then considered as northern, but which is now central Europe. At that period the whole line of country from the Rhine, indeed from the shores of the British seas, along the north side of the Alps, and all the way to the confluence of the Don with the Black Sea, and probably in continuation to the centre of Asia, appear to have been one vast forest, consisting of an admixture of the pine family with deciduous trees, according to the different qualities of the soil. It appears to have been a forest bearing no inconsiderable resemblance to those which covered great part of North America, when that country was first made known to the Europeans; and of which the remains are still met with in the unsettled places. This forest, as is the case with that of America, was a great source of cold, in consequence of the evaporation caused by the surfaces of so many leaves, and the shade of the trees not allowing the rays of the sun to act upon the ground. This forest was the abode of many wild animals, and of the bison among the rest.

Common Bison.

The bison was thus, though abundant, only occasionally seen by those of the ancients who have left their observations or their annals on record; and therefore we need not be surprised that the accounts which they have left of it are both vague and contradictory, or that both they and the writers of the middle ages, and also some of the readers, following their example, should have confounded it with the *urus* another species of the genus, which is supposed to be the original stock of the domestic ox. Both animals appear to have inhabited nearly the same localities, or if, as is probable, the bison was the more northerly dweller of the two, both met on the confines of their wild pastures, the bison more in the depth of the forest, and the urus more in the glades and openings. As a forest animal, the bison of course subsisted in great part upon leaves, but on the leaves of deciduous trees only; for the quantity of turpentine in the leaves of pines causes them to be rejected by all the genus. Hence, in those countries to the south-east of the Baltic, which are still covered with pine forests, continuously or in patches, there are no bisons; the few which yet remain in Europe, being found near the north-east of the Carpathian Mountains, or in the more thinly inhabited parts of Russia, which are rich enough, and far enough to the south to be covered with deciduous trees. In western Asia, between the northern plains and the central straits, they are said to be more numerous; but they are not found on the steppes of Siberia, or in the pine forests toward the north of that country. The same appears to be the case with the American species, though there are differences of habit, and even differences of structure between that and the bison of the old continent. The bison then is not found in the pine forests of the north, nor in the dreary country which extends from the great lakes to the polar sea. There, as in the northern extremity of the eastern continent, the only ruminant animals are deer, which being fleeter-footed, are better able to range these wild places than even bisons; and capable of supporting themselves upon lichens, which may be considered as the verge of the food of herbivorous mammalia.

As the bison was seen only occasionally, and as it is a shy and wary animal when it can escape, as well as a bold and daring one when it cannot, it has received many names; and the accounts of it have always been, and in part continue, mixtures of fact and fable, mixed up so intimately that it is not easy to separate the one from the other.

This animal is called *Tseber* by the natives of that part of Poland (now territorially of Russia) where it is found, and it is styled *Aurach* and *Wizend* by the Germans. The radical part of the word *Aurach*, though differing a little in the terminal part—there being a tendency in the vernacular use of imported words to naturalise them, as it were, by affixing a native termination, appears to be very common in all the northern tongues—seems to mean a shaggy creature, may even mean a creature of the imagination, and has been indiscriminately applied at different times to the bear, the lion, the bison, and the wild bull; so that etymology, generally a very unsafe guide, is not to be depended on in endeavouring to trace the progressive history of the bison.

As now found, it is certainly the largest, not only of the native ruminantia of Europe, but of all the land mammalia. The height of full grown specimens at the shoulder is at least six feet; but it is lower at the crupper; the height at the shoulder is in part made up of the very much produced processes of the interscapular part of the spine. These are so much elevated that when the animal is lean they are prominent, and their ends have a sort of pectinated appearance; but when it is in better condition the parts get full and rounded, and these bones are concealed. This production of the shoulder cannot be considered as a hump; but there is no doubt that it in part answers the same purpose; namely, that of a magazine against the season of severity, a season which from the nature of their haunts and their food, must have been severe upon the bisons, as the time which the deciduous forests were leafless must, in consequence of the greater cold, have been longer there than it is now.

These accumulations of matter for the supply of the animal, at those times when there is little of the ordinary external food to be obtained by the mouth, are a very beautiful provision of nature, for preserving the herbivorous mammalia of seasonal climates, during that portion of the year when, but for this provision, many of them must perish. In southern latitudes this provision, which appears on some of the ox tribe as well as the camels, in the form of a hump, is as a provision against the season of drought. Among the oxen of the middle latitudes, where the grass or other herbage is more perennial than at either extremity of the quadrant, and which feed more on the open meadows, and therefore can range to greater distances as the seasons render it necessary, the accumulation is less; and the portion of it which is localised is principally in the dewlap under the sternum.

But for the bison which is a forest animal, and has its natural pasture bare, or nearly so, during the winter, (although at that season these animals gnaw the twigs and buds,) a winter store is necessary, and yet in the march of the animal among the branches and underwood, a loose hump or large dewlap would be inconvenient and liable to injury. The accumulation in it is, accordingly, embedded on the produced processes of this part of the spine, by which means it has a firm hold, and neither loads the animal as a weight, nor is so liable to injury as if it were an attached accumulation.

This provision not only adds to the height of the shoulder, but gives the animal a greater appearance of strength in that part than it possesses in reality. Still the bison is both a tall and a powerful animal. Its length in full-grown specimens is upwards of ten feet; but as its spine is much more elastic than that of the common ox, and it stands with the spine a little curved and the feet nearer each other, it does not appear to be so large as it really is.

The head is broad; the forehead rounded; the horns far apart from each other, short, stout and slightly bent upwards. Their form, and the manner of their attachment to the head, give them much greater firmness and power than the horns of the ordinary ox. These in the wild animal in a state of nature, and without any regard to the endless varieties of form that have been produced by domestication, are nearer to each other at their bases, spread wider at the tips, and inserted behind the arch of the top of the head. On this account, the horns of a common ox never can act with their greatest strength, and be at the same time urged on by the force and momentum of the arch of the body. It is rather in the forehead than in the horn that the weapon of the common ox lies for this sort of combat; and the horn, which can be used with its greatest effect only when the head is oblique and the neck twisted, a position in which, if the whole body were to be impinged and meet an obstacle, dislocation or other serious injury to the neck would be the result. On the other hand, from the set of the horn, if the common ox were to spring and deliver the weight of the body upon that with the neck in a safe position the horn would be subject to a cross strain, and as likely to be broken as the neck would be to be injured in the former case.

It is different with the bison. When its neck is brought into that position which has its greatest strength, namely, when the line in which the centre of gravity of the body is situated, nearly coincides with the axis of it, the horn is placed on the anterior and lateral part of the convex skull as on the crown of an arch; and in this case, the axis of the whole body passes between the two horns, and parallel to the direction of them, so that the animal can deliver its whole momentum from a rush or a bound either upon both horns, or upon one of them, with full effect, and without injury to itself. This structure renders the bison a very formidable animal, and one which no beast of prey inhabiting the same regions would venture singly to attack, unless with the advantage of an ambuscade; while the length and fleetness of its limbs enable it to range much more freely in interrupted pastures than the shorter legged and heavier members of the genus.

The forehead, from the horns is, in this species, covered with short hair only, all of nearly equal length and texture; but the rest of the anterior half of the body is furnished with two coats, the one consisting of long, hard, highly polished, and rather stiff hairs, such as are found upon other animals which from the nature of their places of resort, have to shake off the rain or snow, especially the latter, from their covering. The under, or warm clothing, is more of a woolly texture; and it is greyish or whitish, while the points of the longer hair is blackish-brown, but fades into a rusty tinge in the course of the winter. The produced hair is very abundant on the chin, throat, and breast, forming a sort of beard upon the first. In the male, it is about a foot in length; and as it is very thick and matted, and partially connects the base of the horns and shades the eye, which is otherwise very dark as well as full and clear, it adds considerably to the formidable appearance of the animal. The hinder part of the body, as well as the fore legs from the knees downward, are covered with smooth hair, all of one consistency, like that on the face. The tail is rather short, containing a few ragged hairs throughout its length, and having a little brush at the end. This, as well as the short hair on the posterior half of the body and the legs, is of a blackish-brown colour.

This single coat where it is found has the texture of the produced hair on the forepart of the body, and not that of the woolly hair, so that the wool is to be considered as the peculiar additional clothing which adapts the animal to the cold climates. This agrees with the analogy of other animals, whether mammalia or birds. In the latter the clothing for arctic climates is not so much an additional production of down. Pigs, in cold climates, have the bristles produced something in this manner; and they have an under and woolly coat among the roots of these; and even the dogs which ventured on the arctic shore of America along with our adventurers, got in the course of the winter, not only a much longer upper coat than is natural to the species in Britain, but also wool among the roots in supplement.

The case of the dogs undergoing this change in so short a time must not, however, be considered as wholly the result of natural causes, for the animals were not so well tempered to the weather as their coats were. Notwithstanding their increased hair and their fur, they lay so closely and habitually by the fire, that their coats were burned into holes, extending more than half way to the skin, without their being at all sensible of it.

This fact proves two things; first, that those coats of animals which are thus formed are very perfect non-conductors of heat, because the natural heat of the animal must have as little tendency to pass off to the cold air as the heat of the fire had to pass inward through the coat to the body; secondly, this addition to his coat was not a natural production of the dog; that is, not one which he would have acquired in the same short time, if he had been carried to the same region and turned adrift to his own resources. He had the protection of the ship, and the warmth of the fire, and he was fed. Thus it was in consequence of human protection that he was kept alive to have this produced coat; without that protection he would have perished before the coat was obtained; and as it was not what we may call a *natural* protection, he did not, as is done by the arctic foxes and the arctic wolves, go forth armed in it, and hunt for and find his food in defiance of the cold; he cowered spiritless, and almost in a state of torpor, close by the fire, and lay there till the coat, which should, had it been the production of his own unassisted nature, have completely protected him without fire at all, was burnt half through by the heat.

It is not upon the hair immediately and directly that the cold acts; it is upon the more sentient parts of the animal, not merely upon the glands, which immediately secrete, or otherwise produce the hair or wool, but upon the general system of the animal. The hair or wool is an ulterior production, and we know not how many parts of the animal may have to be changed before the production of it is begun. There must be an apparatus formed, or, at all events, developed, capable of elaborating the new substance out of the general disposable mass of the animal, and this, which is a new action, cannot be supposed to take place in a diminished state of the general action of the system. Upon the same principle we must suppose, that such an adaptation as the double coat upon the anterior part of the bison is not a mere climatal one, produced in the course of time, but original, and, as such, specifically characteristic of the animal. It is true, that the stiff hair on the fore part of the female is not so long as that on the male, but still the female has the two distinct kinds on that part of her body; and there are physiological reasons, as well as practical instances, which lead us to conclude, that every additional production of the skin, whether of feathers or otherwise, which appears as a natural character of any species of animal, though it usually appears on the male only, and that merely at certain seasons, as, for instance, at puberty in the mammalia, and at pairing time in birds, is, notwithstanding, actually existent, either in the rudiment of the production, or of that by which it is produced, in all perfect animals of the race, whether male or female, and from the very moment of their organisation. Nor is it difficult to see why, physiologically, those apparent additions, which are thus in reality only developments, should appear more frequently and conspicuously in the male than in the female. The female system has a heavier duty to perform, in the gestation and suckling of the young; and to these grand purposes, upon which depends the stability of the race, the whole energy and working of the female system must be previously directed. But still there is not merely a similarity, but an absolute sameness of species in the two, and be it bison, or any other species, both male and female must coincide in being perfect to the *one* species, as each is perfect to its own sex.

Thus male or female, and whether this double coat be more or less developed, we are to consider it as a primary and inseparable character of this group of animals, and as it is a character which none of the arctic mammalia, which range and are exposed to the rivers, are without; for the extinct northern elephant, as was proved by the Siberian specimen, which was thawed out of a mass of drift ice toward the close of the eighteenth century, had it on still more conspicuously than the bison. According to the accounts, the accuracy of which there is no reason to doubt, the bristles of this elephant's mane were of sufficient power to break the fall of an avalanche of snow, at least such an avalanche as could be shaken from the leaves of the giant trees, which, from the remains, appear to have then existed, while this giant animal was tugging at them at its food; and, if we are to judge from the deposits, those giant elephants were contemporaries, or at least the immediate predecessors, of the gigantic bisons and stags which are now found only in similar graves, though, as none of these latter have been cast on the shores embalmed in ice, it is probable that they have belonged to a less aquatic period of that portion of the globe.

Thus, though the bison is not only a mere remnant in the existing zoology of Europe, and one which appears to be fast dying out, as not being in accordance with the present state of the country, or its surface, its climates, and its other productions, yet it is an animal of much and somewhat melancholy interest. It is, as it were, a voice from times which have gone by, the shadow of a system of things which is now no more in those parts of the world, and which, from the progress which has been made since notice began to be taken of it, appears to have no sign, in the present state of things, from which its return can be predicted, or even hoped for. Where it is now found, is not in the extreme of the bleak cold, where vegetation is stunted, but rather where, while the earth is rich and the summer warm, the winter sets in quickly with heavy falls of snow. Therefore, it does not follow, that when the bison was a general inhabitant of central Europe, the whole year, or even the average temperature of the year, was colder than it is now, but merely that the summer and the winter were much more strongly contrasted, and that the transition from the one to the other was much more sudden. Nor is it at all improbable, that, for the natural and indigenous productions of the country, whether animal or vegetable, that may have been a much more favourable state of the seasons than we have at present. This is rendered probable by many evidences which we find in this country: the bogs are full of the boles and branches of oaks and pines in very many places of the country, where even the heath itself is languishing and giving place to mosses and lichens; and we find the bones of large animals in the soil, in situations where, for miles round, not even a field-mouse can find food and cover for its nest on the surface. But though the bison is one of the few remaining animals which would enable us to embark on this tempting ocean of the past, the chart is imperfect, and we have neither star nor compass should we quit the shore.

American Bison (*Bos Americanus*). This species, though in some places it now appears to be wearing out faster than the arrow of the red man and the plough of the white are piercing its flanks and invading its territory, is still far more numerous than the former species is in any part of the eastern continent, and in many places as numerous as we can well imagine a ruminating animal of large size to be. In general the two species have a great resemblance to each other in shape, in colour, and in size, but there are some structural differences, and also some differences of habit. The specific difference, which is most to be depended upon, is the same as that which distinguishes the eastern bison as a species, from any possible variety of the stock of the common ox.

We have stated above, that even those external appendages, which appear chiefly on one of the sexes, and then only occasionally, and as it were for ornament, are all parts originally appertaining to and characteristic of the species, and, as such, may be developed in either sex, if the circumstances which prevent these developments be removed. We are, farther, to consider those developments as the perfect model of the species, beyond which nothing can vary, and that all deviations from it are stoppings short, and their causes hindrances.

Now, if such be the case with appendages which grow from the skin, much more must it be the case with the essential parts of the body, and especially with the spine and its immediate productions, for the spine may be considered as the foundation upon which all mammalia are in a pre-eminent manner organised. Now, as the spine of the common bison has fourteen ribs on each side, while that of all the varieties of the ox has only thirteen, the American bison has fifteen pairs. Farther, as the interscapular vertebræ of the bison have their spinous processes much more produced than those of the ox, so their processes are, in the American bison, much more produced than in the other. There are no such differences in the skeleton of any two more varieties of animals of the same species, and therefore we must conclude that the difference of these bisons is specific: that though they have a considerable likeness, each is an original race, and not a branch of the other.

Size is, in the genus bos especially, not a specific character, as may be seen by placing the Shetland and a Lincolnshire ox in juxtaposition. But the American bison is usually described as being, in all its dimensions, a foot less than that of the east, namely, about five feet high at the shoulder, four at the crupper, and between eight and nine feet in length. As the spinous processes over the shoulders are larger in proportion, the hump, or accumulation there, is larger, and extends farther down the back.

The forehead is very broad in proportion to its height, as in the other species, and the face is rather shorter in proportion. As is the case in the other, the face is covered with short hair only, but the short hair upon all parts of the American one has, in the cold season, a tendency to meet or curl slightly. The mane and produced hair upon the fore part generally is longer and thicker than in the other species, but it does not contain the same quantity of woolly under covering. The old coat on the short-haired part of the body comes off when the new is just beginning to make its appearance, so that, for a portion of the summer, the skin of that part, which is black, rough, and furrowed, and very strong, is easily seen. This difference of covering would of itself indicate some difference of habit in the two species.

The horns are set wide apart from each other, as in the former species, but they are shorter, not quite so robust, and bent more, first laterally, and then forwards. The eye is of the same dark colour, but smaller. The tail is larger, and the brush of hair in which it ends longer. The colour is of the same general character. but darker; and when in the perfection of its growth, the long hair on the anterior part of the body is nearly black. When this part of the skin is prepared with the hair on, it is proof against the weather.

This species is popularly known in the United States as the *buffalo*, but it has none of the characters of the buffaloes of the eastern world, farther than belonging to the same genus. So far as we can judge from the common bison, as known by the small existing remnant, the American species is much more gregarious, and as such, it is much less a woodland animal, being found in the open savannahs rather than the forests, and living more by browsing grass than by eating the leaves of trees. In accordance with their habits, it is much more migratory, and it does not appear to be either so spirited or so formidable as report makes the other species.

All these characters indicate an animal which is not so tied to its locality, but which can migrate more from place to place according to the season and supply of food; for forest animals are always more resident and less social than those which keep the open plains. This is the case with very many of the antelopes (see ANTELOPE); and it is so with all the ruminantia, in so far as they can be distinguished as animals of the wood and the open field. The causes, so far as they are known, will be found hinted at in the article ANTELOPE, so that there is no necessity for repeating them here. This species of bison or buffalo, or bonassus, as it has been called by showmen of animals when they wished to make it new and wonderful, extends over a very considerable range of the American continent. It is not met with in the extreme north, nor much higher than from the 55° to the 60° of latitude, neither has it been found farther to the south than about the parallel of 30°. That, however, is a range equal in distance to that of Europe from the Baltic to Gibraltar; and the range in climate, taking the winter at the one extremity and the summer at the other, is greater than from Lapland to Spain; for though the severity of winter extends farther south in the valley of the Mississippi than it does in Europe generally, the vegetation, and even the animals of the lower part of that valley, have a more tropical character than those of the south of Spain.

In the breadth of this latitudinal range, there are at present but few of these animals to the east of the Apalachian chain of mountains, which divide the valley of the Mississippi from the Atlantic states; and little is known of the numbers of these or of any other animals on the western side of the Stony Mountains which divide the valley from the countries sloping towards the Pacific. The western side of the great valley, the extensive meadows or savannahs which are formed along the banks of the river itself, and of all the branches which come in from the west, are their chief haunts. These savannahs are in many places liable to be inundated by the rivers, which in these cases leave large stagnant expanses of back water, as the streams have thrown up banks higher than the neighbouring surface. These floodings occasion a very rich herbage, which continues far into the dry season, and then the bisons collect in vast herds, herds which are quite unprecedented in the genus. Their tracks from pasture to pasture, and from the pasture to the pool, are as well beaten as the pathways in a thickly inhabited country. The grass on their pastures is rather rank and coarse, for there are no specimens of the velvety turf of islands which have mild winters, and frequent showers in the summer, in such countries as the centre of America. These tall, coarse, and semiaquatic grasses, which are characteristic of plains flooded by great rivers, which would prevent the more kindly grasses from "tillering," even if the germs of them were there, are in their texture and probably also in their nutritive qualities intermediate between the leaves of trees and the finer grasses; if indeed they can be considered as nutritive as the former are in the young and juicy state. Animals which feed upon such grasses generally do so in the morning and evening, when the dews are upon them; and in such places the formation of dew is often in proportion to the heat of the weather. The bisons follow this course, and during the heat of the day they retreat in great numbers to the pools of water, and stand and enjoy themselves there.

About the middle latitude of their range, that is about where the Missouri comes in from the west, they appear to be most numerous; and it is there that they have been described as assembling in such vast herds, sometimes to the estimated number of not less than 20,000 at one time. It is also there that they are said to attain the largest size, and to be of the most bold and determined character.

In these their most appropriate pastures, and accompanied as they are by rivers like seas, and single plains like counties or even kingdoms, a herd of them must be a splendid sight, especially when thrown into a state of agitation by a thunder-storm or any other cause of alarm. They are by no means so fleet footed as the more slender-bodied ruminantia; but the enlargement of their bodies forwards, the compactness behind, the flowing of the shaggy mane, and the sound which they utter, which is something between bellowing and groaning, their dark colour, and above all their numbers, must have a splendid effect.

American Bison.

In their most southerly latitudes they are migrant, and probably they are so also in their most northerly ones; but there is no reason to suppose that any of them migrate through the extremes of their distribution, which are about 2000 miles asunder, or even over the tenth part of that long distance. The very instinct or tendency, whatever it may be, which renders animals social or gregarious keeps them as a matter of fact and of course to their own herd; and they never quit that but when the others expel them by force, and the reception with which the exiled beasts are greeted by new herds, which they attempt to join, are not of the most courteous nature. Thus it is probable that where the savannah is so large as to admit of the assembly of thousands, they shift only from the one part to the other, as the seasons may require, approaching the waters in the droughts, and retiring from them during the rains.

In their more southerly localities, where the character of the seasons is more tropical, and the plains are entirely destitute of herbage, saving only aloes and other esculent plants, they are much more migratory; and have some analogy in their motion to the herds in the plains of Asia. Though even in those places the migration appears to be as much to the hill as to the northward in the summer; though they collect in the more temperate forests in winter. In the north they are of much smaller size, and shaggy in their coats, and not so spirited as in those latitudes which are the most congenial to their habits.

They are said not to be naturally vicious, but they are easily excited, and then their activity often makes them mischievous. They are capable of a sort of domestication, but they are neither very pleasant nor very profitable on a farm. Their form disqualifies them for animals of draught; and they take their range of the whole, heedless of ordinary fences. The males are rather formidable at all times; and during the rutting season, which is about the month of June, they are dangerous. Against biting animals they make a much better defence than most of the others. They keep their heads resolutely to the enemy, and as the face only is vulnerable to any ordinary bite in that direction, and the hairs are a good protection to the upper part, they stand resolutely; and they are equally dexterous at tossing their foes and trampling them under foot.

In all parts where they are found the Indians hunt them very assiduously, especially in the fall of the year when they are in the best condition. The flesh has a smoky flavour, but is very wholesome; and the skin forms the most desirable mats which the Indians possess. Various accounts of the modes of capture, some more ingenious and some less, have been published; but these belong to the history of the hunters and the hunted.

In a natural history point of view these animals are important as being the only species of the ox genus, the existence of which on the American continent, at any period of its history has been fully authenticated. There have no doubt been reports of individuals of much larger size, and supposed to belong to another species, being seen on the Stony Mountains. But the species which are known differ very much in size; and there is besides some difficulty of judging of the magnitudes of two animals when the one is seen on a mountain, or on an elevation of any kind, and the other on a plain. Deer when seen on a hill-top, projected against the sky, seem giants, and their horns to be the leafless boughs of large trees, but if one follow the very same herd till they are in the hollow and look down upon them, they seem the miniatures of their former appearance. Even the horns of the extinct species seem a little doubtful, for it does not very clearly appear, from any collateral evidence of a peculiar state of vegetation, that North America has undergone any climatal change, which would have rendered the extinction of any species of ruminant animals necessary; at least there is no evidence of any necessity of the kind, unless we are to suppose that some violent catastrophe of nature has intervened; and the possibility of anything which has disturbed the solid strata is precluded by the situations in which the horns are found, which are always such that no catastrophe greater than a mere surface one, such as an inundation arising from the bursting of a lake, or an alteration of the course of a river, can be admitted, indeed can possibly have taken place since those horns formed part of the bodies of living animals.

Besides, when America was first discovered by Europeans, it was completely stocked with the existing species, down to the very shores of the Atlantic, so that it is difficult to imagine a country as being better adapted to its native animals than North America was at that time to its bisons. Even now, notwithstanding the disappearance of these animals from the parts which have been settled and cultivated, the immense herds show that there is no falling off in the fitness of the country in those parts where the animals have not been invaded by civilisation. South America, too, which appears never to have had any ruminant animals save the lamas and alpacas of the more alpine districts, has proved, by the vast extent to which the cattle introduced by Europeans have multiplied in the plains, to be well suited for these animals, while in the greater part of Europe, and also in many places of Asia, the numbers of these animals in the wild state, have certainly been diminishing, in situations where they cannot be supposed to have vanished before the progress of population and culture. The unavoidable inference is that, in Europe and great part of Asia, seasonal changes have taken place, and taken place without any geological catastrophe of which we can find a trace, or even a single circumstance which we can twist so as to render such an occurrence probable, or even possible, to which nothing analogous has taken place in America. The bisons of the two continents are, no doubt, not the same species. But if deviation from the character of the common ox, which has accompanied civilisation and prospered along with it, is to constitute a species, the peculiar characters of the American bison, as deviating farther from those of that animal make it of the two the more characteristic of a different state of the country. The field for speculation in progressive natural history, which the consideration of these animals would open up is both wide and curious; but the data are few, and it comes not within the scope of a popular work in any other way than as a subject to which attention may be profitably directed. We shall, therefore, only further remark here that those species of the genus *bos* which have been sometimes classed and described as bisons, and which are all natives of south eastern Asia, partake more of the characters of one or other of the remaining groups of the genus *bos* than they do of those of the true bisons, whether we consider the eastern species or the American as the most typical.

BISTON (Leach. *Amphidasis*, Treitsehke, Duponch). A genus of lepidopterous insects belonging to the family of the *Geometridæ* or *Loopers*. The body is much more robust than in the generality of the family; indeed this circumstance combined with the strongly feathered antennæ in the males might easily lead the tyro to arrange the insects composing the genus amongst the *bombycidæ*, or feathered full bodies, as they are called; the females, however, have the antennæ quite simple; the palpi are very short and clothed with minute hairs, the spiral organ usually termed the tongue is very short, the thorax is stout and very woolly; the wings, which exist in both sexes, are of small size compared to the robustness of the body. The caterpillars which are decidedly loopers or geometers (moving along with a motion somewhat like that of a pair of compasses alternately opened and shut) have ten legs; they are long, cylindric, and more or less covered with warty excrescences, which give them the appearance, when stretched out at length, of a twig of the trees upon which they feed; the head is flattened and somewhat notched in front, and the chrysalis is not enclosed in a cover. This state is passed under ground. The type of the genus is the oak beauty moth, *B. prodromarius*, a handsome and not uncommon species, measuring nearly two inches in expanse, having the wings of a whitish colour, freckled with dark brown, the upper pair having two irregularly waved bands of reddish chocolate edged with black. It appears early in the spring. The other species included by Stephens and Duponchel are *B. betularius*, the peppered moth, and *B. hirtarius*, the brindled beauty.

BITTACUS (Latreille). A curious genus of neuropterous insects belonging to the family of the *Panorpidæ*, having for its type the *Panorpa tipularia* of Linnæus. The wings are long and narrow, four in number, of an equal size, and carried when at rest horizontally upon the back; three ocelli; antennæ very slender; the abdomen is long and slender, and nearly alike in both sexes; the males not being armed with the remarkable claw which is so peculiarly characteristic of the genus panorpa, and which has suggested the name of scorpion-flies for the insects of that genus. The legs are long, and terminated by a single tarsal claw. The species are very few. In all, however, there is exhibited the same striking resemblance to the dipterous tipulidæ, which is commemorated in the name of the species serving as the type of the genus, and which is an inhabitant of southern Europe. We believe that nothing is known respecting their habits.

BITTERN (*Botaurus*). A genus of birds, usually included in the order *Grallidæ*, yet not much in the habit of wading, though they are frequenters of marshy places, and dwellers and nestlers in tall aquatic herbage.

In the systems of ornithology, these birds have been very generally classed with the herons; but their appearance, their structure, their habits, and their whole characters are so very different from these, and indeed from all other birds, that there are few genera in the class which admit of more distinct definition and description; and their affinities or points of resemblance connect them much more with the rails or gallinules than with any other race.

They are birds of peculiar manners and haunts, and therefore they are characteristic of peculiar states of those districts in which they are found. They shun the abodes of man and the places which he improves by his culture; not merely the corn field and the rich meadow, but the coppice and the wood; and if the habitation of bitterns is surrounded by planting, the birds take their departure: neither are they ever found in the natural forests, unless where these are interspersed with marshy pools margined with tall and close aquatic herbage. There is no music for the bitterns' ear in the songs of the groves; and even if the air is free and fine enough for the sky-lark, the bittern comes not there. Nay, the nightly monotonous cry of the corn-crake: similar as the birds are in their appearance and in many of their habits, the bittern comes not to those moist fields and meadows where it is heard. The wail of the lapwing, the whistle of the plover, the scream of the curlew, and the bleating of the snipe, are the only voices of birds in chorus with which the bittern will join its booming and somewhat dismal sound. And with the exception of the snipe, even these dwell in the neighbourhood of the bittern, and not in its immediate haunts. In the mode of their inhabiting, more especially in the breeding season, which, in the case of all birds, may be regarded as the most characteristic one, there is more resemblance between the bitterns and the snipes, than between them and any other birds. There is also a considerable degree of resemblance in the outline of the body, and in the tints and even the markings of the plumage; though the brown on the bittern is more inclining to red, and comes nearer to the general hue of the corn-crake than that of probably any other bird. The feet also indicate a bird something intermediate in its haunts between the snipes and the corn-crake. The tarsi are long, the tibiæ bare for some distance above the tarsal joints; and the whole structure and articulation of the legs, and the bearing of the axis of the body in nearly a horizontal position, indicate considerable swiftness in running. The toes are not so long as those of the crake, and they are longer than those of the snipes, and more free to their bases; the hind toes in particular are very considerably longer than those of the snipes. The whole foot indeed indicates a walker upon herbage which is elastic, rather than upon the bare ground; and though the anterior side of the tarsus and the upper sides of the toes have their scales of that form and arrangement which are characteristic of a defence against humidity, yet the foot is not so much of a wading foot as that of many birds which have their nesting places much farther from the water than the bitterns.

The generic characters of the bitterns are: the bill to the bottom of the gape about the same length as the head, moderately thick at the base, but compressed or higher than broad; general section four sided, but rounded off in the culmen, nearly straight, and tapering to a very sharp point; nasal grooves very shallow, nostrils near the base, and half shut by membrane; a small portion of naked skin reaches from the gape to the eye; and the whole bill is exceedingly firm and hard in its structure. The legs are long, though not so much so in proportion to the size of the birds as those of the herons, but they are stouter, and altogether better formed for walking, the outer toe is connected with the middle one by a membrane which is merely rudimental. The wings are of moderate length, shorter than those of the herons; and the birds use them much less in their ordinary habits. The tail also is very short, and there are not on the sides of it, or on the lower part of the back, any of those produced and flocculent feathers which are characteristic of most of the herons; neither have the bitterns any flowing crest, though the feathers on the hind part of the head are much produced, and give the line of the crown a very peculiar straightness, which is not observable in almost any other bird.

The neck is long, but it is more robust in proportion to its length; and it looks more robust than it really is from the feathers upon it being much produced and loose, from which circumstance alone one might infer that it does not subsist so much by fishing as the herons. The neck is also borne very differently both on the ground and during flight. When the heron flies, at least on its longer flights, it carries a fold of the neck upon the shoulders; and it does not under any circumstances rear the neck into a straight line, unless when it stands up, raises the general axis of the body into the same position, and stretches the wings. When it is waiting for its prey close by the banks or in the shallows (for it walks little and uses the wing if it has to shift more than a few yards), the heron has the neck bent in contrary flexures. The shoulders are round, and the curvature of the neck continues till the upper part is as low as the under line of the body; then the neck folds back upon itself till it is rather higher than the turn of the wing; and the neck then bends downward till the point of the bill is below the under line of the body, and in a position nearly at right angles to the axis.

It is necessary to attend to this mode of bearing the neck in the heron, and contrast it with that in the bitterns, in order to arrive at an accurate knowledge of the habits of the latter bird. This is the more necessary that the two have been very generally described as different species of the same genus only; and though, in the case of birds of which the habits are especially open to common observation, this is a matter of minor importance, yet in the genera under consideration this is far from being the case. The heron is neither a shy nor a hidling bird. It nestles in trees, and may, when it is perching or rather standing upon the tops of these, be closely approached and attentively observed. Also, though it is rather more shy when it feeds, it is always visible on its feeding ground. It fishes in the shallows, but generally where the beaches are clear, and not where they are rank with herbage; and the constant readiness in which it holds its wings, prepared for flight, would be inconsistent with a footing among tall herbage: and it is to permit of this ready action of the wings, that herons stand on the tops of the trees, or rather rest on them in such a manner that their wings shall be clear of the twigs and leaves when they stand up.

Wherever there are herons, all their actions are thus easily seen; and though they are not so numerous as when there were more undrained pools and marshes, and consequently more brooks and streams, or at all events more water in them, and indeed a moister state of many parts of the country than at present, they are still not rare. But bitterns are not only very rare, but very seldom seen even where they are known to exist; so that there are comparatively few persons in a country so cultivated as Britain (England especially), that can obtain a sight of a living bittern; and still fewer that can obtain any personal knowledge of its habits. Therefore classing and describing the bittern as a species of heron must of necessity lead to very false notions of its character; and as that character is as singular and curious as the knowledge of it from personal observation is difficult, the prevention of mistakes regarding it becomes the more necessary.

Now, the different bearing and action of the neck in the two birds, is sufficient to prove that there must be considerable difference both in their food and in the manner of their obtaining it. The neck of the bittern, measured from its first articulation, is nearly as long in proportion as that of the heron, that is, about as long as the body. But when the bittern flies, the neck is stretched out; when it walks, it is borne upright, with the line of the forehead and bill horizontal; and when the bird reposes, which is always among tall herbage on the ground, and never upon trees, the position of rest is the neck erected, and the bill in the same line with it, or with the tip pointing to the zenith.

Thus, while the bill of the heron is held in readiness to act *below* the plane of the body, that of the bittern is held ready to act in the same plane, or above it; for when it is at rest, the neck is so far bent, that the bird can strike upward with the bill. The observation of the heron is thus also from the position of the head, below it, that of the bittern around and even above. This position, both of the bill and the observation of the heron, agree with its habit as a fisher; but the different position of both in the bittern, cannot agree with the same habit; and therefore, the classification of the bittern with the herons, and the interpretation of its unknown character by means of their known ones, which is inseparable from the classification, must lead to error, and error which, from the difficulty there is in actually observing the bittern, is not easily corrected.

No such conclusion as that the heron feeds chiefly upon fish and the bittern upon insects, mollusca, and aquatic reptiles and their spawn, can be drawn from the qualities of the flesh of the two genera; for though there is a difference, and the flesh of the bittern is described as more resembling that of hare, and the flesh of the heron more that of pheasant, though tougher; yet that of the heron has little of the rank and oily flavour, which, in aquatic birds, is usually denominated *fishy*. It would seem that it is not feeding on fish, but feeding on *sea-fish*, and partly also on water beetles, which gives this peculiar rankness to the flesh of birds; and though this is not a point upon which any certain conclusion can be arrived at without much previous observation and experiment, yet it is not improbable that the rank flavour is, in no small degree, owing to phosphorus and sulphur (especially of the former) in the food. The science of ornithology is still, however, too much in its infancy for admitting of a satisfactory conclusion upon such points; and yet, in so far as the economical use of birds is concerned, they are points of no minor importance.

In so far, however, as bitterns are concerned, the importance in an economical point of view is not great. The flesh of the common bittern is no doubt in request for the tables of the luxurious; and when a bird can be obtained, which is but rarely, it sells for from half-a-guinea to a guinea. This is, no doubt, in part owing to its rarity: but it has a rich and rather an agreeable flavour.

But a "bittern preserve" is amongst the last possessions for which luxury can hope, and it is also among the last which the friend of mankind would desire to see. The cover which man can produce artificially, may answer for the pheasant and the partridge, and also for the hare, as a substitute in flavour for the bittern; because, in proportion as man drains and improves the ground, and shelters it by planting, the food of these animals becomes more abundant. Even the heron may multiply in proportion as man increases the number of his fish ponds and his woods —for these voracious fishers, though they come to such places chiefly in the grey dawn of the morning, and retire by the time that the heat makes the fishes still, will come to the mill-pond, or even to the pleasure-ground near the dwelling-house, if there is a fish-pond there. But the bittern loves the seclusion of wild nature; and no known temptation will bring it upon the cultivated or improved lands as a permanent resident; and when the scarcity of the winter forces it from the upland, it appears to come down reluctant and stealthily; and seeks those streams and banks which are in the rudest and least improved state. The bittern, as already said, does not like trees; and it is never found by those waters which have either pebbly beaches, or a sod of rich grass down to the water's edge. Some of the running birds come to the beaches in the winter, and the goose and swimming duck tribes to the grassy banks; but if the soil is rich enough to bear even flags and reeds, it is shunned by the bittern. The bog-bent and the rush are the favourite plants with this bird; and it is fully more true to them than the cross-bill is to the pine forest. These are plants which very few insects inhabit, and which we do not often find eaten by any creature; and therefore, remaining in them, the bittern cannot be very insectivorous. Horse-leeches and the smaller grey slugs are, however, to be met with in the vicinity of these plants; and both the species which have been mentioned, have those parts of the young roots which are in the humid earth and blanched, very albuminous, and very sweet to the taste. These could easily be dug out by a much less efficient bill than that of the bittern; and as they do not require trituration in a gizzard, as is the case with most seeds, the fact of the bitterns having only membranous stomachs, and very short cæca to their intestinal canals, is no good argument against their feeding on the roots of those plants. Indeed, in those places which appear to be preferred by them, if they do not occasionally feed on these roots in the winter, it is very difficult to imagine on what they can feed. Fishing, by any wading bird, even if we are to suppose the bittern a wader, is out of the question at the season alluded to. There are few fishes in those places at any time of the year; and even the herons quit the upland brooks, and retire to places which are warmer before the intensity of the winter sets in. It is possible that when the bitterns descend the streams, they may eat the spawn of those fishes which deposit it in such places in the end of autumn and the early part of winter; but when they descend they follow the rushes, and other herbage which is firmly rooted; and these are not generally the depositories of the spawn of fishes.

In summer, so far as the observation of the writer of this article has gone (which has, however, been chiefly where the moors were very bleak and bare, with the bittern pools on the very summit, or at all events at the water-shed, where there was only a small pool for the wild goose in the winter, and the aquatic plants equisetums not reeds, with broad margins of hummock and rush, and then hard bent outward to the heather,) the heron never ascended so high as the abode of the bittern; and though one cannot speak with so much certainty of the marchings of the bitterns, as they are both hidling and silent, except during the breeding season, yet they were not observed so far down the streams as the places occasionally frequented by herons, unless when "frozen out" at their native places.

Thus, in whatever point of view we consider them, bitterns are a very singular race of birds,—peculiar in their habits, and characteristic of a very peculiar state of the countries, or at all events the districts, in which they are found. They are, as it were, the children of desolation; and they hide themselves there, and will not be either enticed or driven to better pastures; nor can they be made in any way to accommodate themselves to, or partake in, the improvements which are made by man, or even in those which take place from natural causes.

Improved places of the latter description are found only among the mountains; and even there the course of nature is more frequently the reverse: the transition from grove or copse to peat-bog, and the consumption of heath by moss and lichen. There are, hovever, some instances of natural improvement; a flood of more than ordinary strength and duration, will sometimes break down the natural dam which retains the stagnant water, wash away part of the miry soil, and drain the remainder; and when this takes place, the subsequent rains wash down sand and more kindly particles of earth, and the seeds of the mountain grasses and little trefoils come along with them; till in time the erewhile swamp is changed to a green and wholesome pasture. Nor are there wanting instances in which, from some such natural change as this, though these are far less frequent than changes of man's making, the blithe carol of the skylark succeeds to the dreary boom of the bittern.

There is not, in many of their habits, and especially in their voices, a more striking contrast among our native and resident birds than the skylark and the bittern; and yet, when we come to examine them closely, we find more points of resemblance between them than we would be prepared to expect. They are not, upon the whole, very like either in shape or in size; but the outlines of the heads and the marking of the plumage have some similarity. Their food, though different in species, as being found upon soils very different from each other, yet belongs to the same general class of substances, especially during the nesting time, which is the truly characteristic time of all birds. Skylarks are usually classed among the vegetable feeders; but that applies chiefly to their food during the winter, when the majority of our resident birds which do not either resort to the shores, or feed upon the tops of heath or moss, like the mountain gallinidæ, will then feed on the seeds with which the ground is strewed, or on the berries on the bushes. In summer, the skylarks feed more upon animal matter; and their general feeding brings them more within the division of omnivorous feeders than any other; we have said, and though it is not proved it is probable (and much of the history of bitterns is eked out with guesses), that bitterns must either have long fasts, or live partly upon vegetable food in the winter. It is further worthy of remark, that the skylarks do not flock in the greatest numbers to the places which abound most in annual plants and their seeds, but to those which abound most in the common red earth-worm. Thus, there is a similarity in the seasonal food; only the lark frequents places where the soil is dry, and the vegetation kindly, and the bittern humid places, where the vegetation is harsh.

There is also some similarity in their feet, though the one bird is fitted for running among the dry clods or upon the grassy sod, and the other for the rushy hummock, or the stiff bent, and the stiffness of the bittern's footing does not require the same elongation of the hinder claw.

Even the voices of the two birds, different as they are in the place, the hour, and the sound, have still some resemblance in the way in which they are delivered. Both birds deliver their song only when they are on the wing; both ascend the air in spirals; and both sing loudest at the top of their flight. There is even some resemblance in the time (of the day) at which their very dissimilar notes are begun. The lark begins at grey dawn in the morning, the bittern at grey twilight in the evening; and while the one is never known to sing when the sun is below the horizon, the other is never known to sing when the sun is above it. They both agree in singing only when the air is tranquil, or at least when the wind is very light; and they both agree in singing most blithely (if blitheness can be predicated of both) when the air is in that relenting state, which does not severely dry the surface, and therefore brings out the small earth animals on which they feed. An unusual vehemence in either of their songs is thus an indication of rain, or at all events of what is called "soft growing weather."

But notwithstanding these very curious analogies, it is equally curious to observe how much the strain of each bird's voice is in accordance with the place where, and the time when, it is heard. The song of the skylark, is given over fresh and fragrant fields coming into bloom; for even at the earliest time that it gives its full stave, the daisy has bloomed on the sward and the coltsfoot on the lea; and it is given as the matin song of those places of hope and promise; the awakening call for all nature to arouse to enjoyment. The lively song of the lark, is therefore in admirable keeping with the time and the circumstances, and they and it give reciprocal effect to each other. Nor is that of the bittern less accordant. It is heard only as the evening twilight begins to deepen the gloom of the wilderness, and the few prominent objects which mark its dreary surface put on a spectre-like appearance. Then, though the air is tranquil at the height to which the bittern wheels, there are little winds in motion between the dry moor and the bog, which cause a rustling among the withered stems which have outstood the winter, as if some unseen creatures were moving to the sound of that dismal voice which is shaking the sky, and grating on the ear till the whole body quivers, and the earth feels as if it were unstable and quaking at the sound. The popular name given to this very singular sound is "booming;" but neither that nor "bellowing" like a bull, from which the genus has been called *Botaurus*, nor any other single epithet, is accurately expressive of it. Nay, it is by no means easy to imagine a compound, which can convey anything like an accurate notion of the bittern's voice to those who have not heard it. Think of a full chorus of bulls, horses, asses, turkeys, and geese, driven forcibly from their repose, amid the loud shouts and wild laughter of banditti; and perhaps the approximation might be as near as most others.

Sir Walter Scott, whose extraordinary powers of observation and description were as true to nature generally as to the characters of human beings, has described and discriminated the skylark and the bittern with very graphic effect, in the serenade which Helen sings to Fitzjames on the island:—

> "But, the lark's shrill pipe shall come,
> "At the day-break, from the fallow;
> "And the bittern sound his drum,
> "Booming from the sedgy shallow."

Small critics might, perhaps, take some exception to the juxtaposition of these; but there is no violation of nature in this,—the lark may begin to sing before the bittern gives over.

These general remarks have extended to so great length, that we must shorten considerably our notices of the species; and we do not require to be very detailed with these, as they are all obscure, and all bear considerable resemblance to each other. The species which is best known in Britain, though it probably never was a plentiful bird, and is now a rare one in all places, and unknown in very many, is,

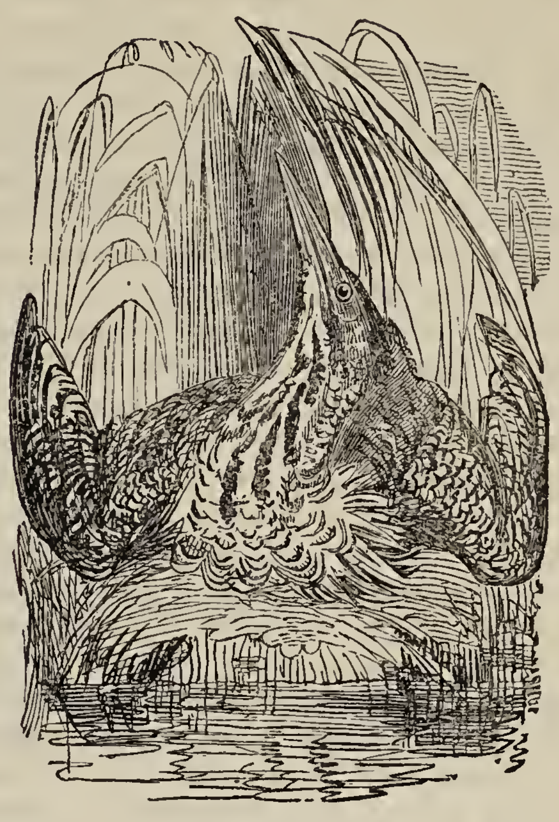
The Common Bittern (*Botaurus stellaris*). This is the species chiefly alluded to in the former part of this article, and the one, indeed, from which almost all the general descriptions of the genus are taken; and then, in most instances, it is, as has been mentioned, considered as a species of heron, under the name of *Ardea stellaris*, and the generic descriptionis confounded with, or merged in, that of the common heron, as the type of the genus *Ardea*.

The length of the full-grown male is sometimes two feet and a half, but generally rather less; and from the length of the legs, and the length and erectness of the neck, the height to the top of the head, when the bird stands up, is nearly equal to the length. When the length is two feet and a half, the stretch of the wings, from tip to tip, is nearly four feet, and the proportion is preserved in full grown specimens of whatever size. The wings thus bear nearly the same proportion to the length of the body as those of the heron, but they are not so well feathered, and both they and the bird altogether are heavier in proportion to the lineal dimensions. It is not, however, so much the want of wings which renders the bittern so much less a wing bird than the heron, but the difference of its food, and especially of the places where that food is found. When it takes its wheeling flights in the manner which has been described, it flies, not very rapidly certainly, but still with firm wing, and it turns very smoothly and gracefully. It is capable of taking pretty long migratory flights, though it flies high and silently, and is seldom observed during them. Indeed, it is probably more of a migrant than is usually supposed; for when cultivation makes it disappear from those places which have been its haunts, we are not to suppose that it perishes, as we do not find the bodies or the bones of dead bitterns in the wilds when we begin to lose the sight and the sound of living ones; and thus the fair inference is, that it is capable of removing to a new haunt, even though at the distance of many miles.

The lofty flight which those birds, which frequent only very peculiar places, take when they are once fairly on the wing, answers other purposes than that of being in a rarer medium, and one in which the currents of the air are much more steady than they are nearer the surface. They are more out of the reach of their natural enemies, which are principally the harriers, buzzards, and other low-flighted hawks, and they command a wider horizon, and find out more readily the places where it is most advantageous for them to alight. When, however, they are settled in a locality, their flights are low and short, and if either the sportsman or their winged foes can succeed in raising them, they become a more easy prey than many birds which are far less powerful. Thus the common snipe costs the peregrine falcon more trouble, and so does the lapwing the jer-falcon, than the bittern costs the moor buzzard, if the buzzard can keep it on the wing.

The wing is not, however, the bittern's means of escape from its enemies, especially where it nestles and inhabits. Its feeding time is in the twilight of the morning and evening, and probably during the whole of the night, when the moon shines clear, or where the place is so far to the northward as that a bright twilight continues all the night. This last circumstance may, indeed must, be one of the reasons why those birds which feed in the twilight have in general a tendency to move polarly in the summer. The more northerly, in our hemisphere, the longer the twilight, and therefore the longer the portion of each day during which they can procure food for themselves and their young at that season when they stand most in need of it.

Even when not upon the nest, the bittern squats among the rushes, or other tall stems, during the greater part of the day. The mode of squatting is rather peculiar, and may be understood from the following figure.



Bittern.

The neck, when the head is in this posture, is raised, and the point of the bill directed upwards, the body and legs being, at the same time, in such a position that a violent thrust may be given by the bill, if necessary; and as the neck is powerful, and at the same time readily moveable in such a manner as to secure the whole body from attack, there are few birds of prey that would venture to descend upon the bittern in this position, even if they should see it; and its form is so unlike that of any bird in a common attitude, and the tints of its plumage so like those of mud and half-withered herbage mixed together, that it is not easily seen; while, from the elevation of the head, and the position of the eye, it readily commands the whole horizon around it. If it is attacked, its first attempt is to transfix the assailant, by receiving it on the sharp point of the bill, or by an upward thrust with that instrument. If it fails in that, it alters its mode of warfare, by throwing itself on its back, and fighting desperately with both bill and claws, and it is so strong, and so ready in the use of these, that it makes a very stout resistance.

The common bittern is widely distributed, being found in Europe and Asia, and also in America; and this general distribution would of itself lead to the conclusion that the birds are capable of migratory flights. In every part of the world, however, they are rarely to be seen, though in all places where they breed they are pretty certain of being heard about the commencement of the breeding time.

The particular characters of this species, besides the dimensions as already stated, are: the bill, from the tip to the hollow of the gape, about four inches, or nearly so, in length (which, from its form and the firmness of its substance, makes it a very formidable weapon), and it is of a dark colour for the greater part of its length, but greenish at the base of the lower mandible. The naked skin at the gape, and the naked parts of the legs, are nearly of the same colour, but the legs have a very slight tinge of a reddish hue along with the green. The feathers on the forehead and crown are black, but the general colour of the clothing feathers is yellow, with more or less of a reddish brown tinge, and very finely spotted and barred with black; and it is from the number and regularity of the spots that it gets the name of *stellaris*, or "starred." The greater coverts of the wings and the quills are more inclining to rust colour, and more thickly and regularly barred with black than the general plumage of the body. The tail is very short, but the closed wings do not reach to the extremity of it. The toes and claws are long, and both rather slender, though the claws are sharp pointed. The claw of the middle front toe is slightly toothed on its inner edge. These are the characters of the male. The female is smaller in size, and the colours of her plumage are not so bright.

The common bitterns feel the influence of the season rather early. The love song of the male begins early in March, and sometimes even in February, but that depends on the season and the locality; and it is sometimes begun and continued for a few days, and then left off for a week or more, in consequence of that short supplemental winter, which is pretty regular, as well as severe, in those wild places which bitterns most frequent, and known by the name of the "Lapwing Storm," as these birds and it very frequently come about the same time. When this storm, which is never of long continuance, and is often unknown in the low and warm places, or is merely a bleak wind there when it is snow upon the bittern's habitation, is over, the harmony of the bittern begins anew. It is hardly necessary to say, that the once popular notion, that this sound is produced by means of the bill thrust into the quagmire, and aided by the vibrations of that in the jarring sound, is without foundation. Of all imaginable places, a quagmire covered with rushes and other rough herbage, such as that which bitterns frequent, is the least sonorous, or capable of producing, or aiding in the production of sound of any kind; and whatever the note of a bird may be, that note is never produced, or even much modified, by the bill, or the upper end of the trachea. The real organ of voice in birds is always at the bronchial end of that canal, and not at the larynx, or upper end, as in the mammalia. In consequence of this structure, the whole of the trachea is converted into a sort of wind instrument, by which the sound, of which the lower end is the more immediately, or originally producing organ, is modulated in the same manner as the voice of the mammalia is modulated by the palate, tongue, and mouth. Of course the sound which birds emit varies with the length and form of the trachea, and, just as is the case in the sound of artificial wind instruments, the sound, whatever may be its original quality, is rendered deep and hollow in proportion to the length and size of the trachea, whether the additional length be produced by convolutions of that organ, or by a greater length of the neck. When there is a shaking sound, there is of course a vibrating membrane in the original organ of voice; but whether that shall produce a sharp and clear trill, as in the warblers, or a grating and hollow sound, as in the bittern, depends partly upon the structure of the membrane, and partly upon that of the trachea. Some further observations on this subject will be found in the article VOICE.

When the male bittern has continued sufficiently long at the exercise of his music, such as it is, for "winning the favour of his dame" (for such is the object of his to us unseemly music), the two, in concert, set about preparing the nest—that is but a homely structure—a rude couch of withered grass or rushes, placed on a hummock, where it is well concealed, or upon the short stump of an aquatic shrub, if there happens to be one in the nuptial demesne of the pair. It is never far from the water, because the birds do not range out of the humid places; but it is always above the "rise" of any ordinary flood which can take place during the time that it is in use, and it is always formed of dry materials. All nests, indeed, are so, though there has been mention made of some aquatic birds taking advantage of the fermentation of green or moist vegetables, and the heat thereby produced, to assist in the hatching of their eggs. But the action of water would, even in this way, destroy the principle of life in the eggs, instead of maturing them; and therefore, even those eggs which are committed directly to the waters, are so defended by their peculiar tunics, that the water has no direct chemical action upon them.

The eggs of the common bittern are generally four, though, as is said, they are sometimes five, and they are of a greenish brown colour. The nest is, however, as rarely seen as the birds, because, though, in the early part of the season, the male is noisy enough in the air during the evening twilight, both birds are remarkably silent during the day, and they are always silent when they are at or near the nest.

The period required for rearing the young is little short of seven weeks, about twenty-four days of which are spent in the hatching of the eggs, and three weeks in feeding the young in the nest. The young differ much from those of the true grallidæ in the length of time which they require before they are able in any way to shift for themselves. The young of the true grallidæ, though covered with down, and not feathers, when they come out of the shell, are very soon able to run, and in this respect they have some resemblance to the gallinidæ; but those of the bittern are callow and almost naked, and at the same time scraggy and skeleton-like in their form.

The common bitterns live at all times solitary, or at most in pairs, and never flock, or even congregate together in families; and as soon as the young are able to shift for themselves, they follow the habit of their parents, and are not seen together till they pair and have families. With the exception of the love-song, which is not long continued, the birds are quiet, and they are quite inoffensive, and never attack or annoy any creature save those small animals which constitute the greater part of their food. In their chosen habitations there are, indeed, few animals with which they can quarrel, even were they so disposed; and as we have already seen, it is not very safe even for birds of prey to quarrel with them. Nor are they powerful in defending themselves against birds of prey only, for they offer formidable resistance to dogs; and if the dog is not all the more staunch, he will hardly go in upon the bittern if he gets a thrust from the bill. Even the sportsman, when he only wings the bird, or lames it so that it cannot escape in the ordinary way, but yet retains the greater part of its strength and spirit, must approach it with caution. It strikes so fiercely with the bill, that it can wound the leg through a thick boot; and if it can strike any part of the body which has not such a protection, the wound which it is capable of inflicting is very severe; and thus, while it never invades the haunts of man, man does not invade it in its haunts with impunity.

The Little Bittern (*Botaurus minutus*). This is a much smaller species than the common bittern; but it appears to be better winged in proportion to its size, and it is much more discursive. It belongs to what may be called the eastern migration, or to that of those birds which range along the line of the Asiatic rivers which empty themselves into the lake of Aral and the Caspian, and the European rivers which empty themselves into the Black Sea. In its structure, especially that of the head and neck, it bears a much closer resemblance to the smaller herons of the eastern migration than the common bittern does; but still its prevailing characters are those of a bittern.

Birds which come into the British islands upon any of the lateral migrations, of which those of the eastern one are most numerous, from the narrowness of these which they have to cross. Most of the aquatic birds which straggle into Britain on this migration from the east, come by the lines of the Danube and the Rhine. As they retire westward from the marshes on the lower Danube, and the other rivers which fall into the Black Sea, whether they merely disperse for nesting places, as is the habit with some birds, or are driven from those places where the water becomes low before the autumnal rains set in, they are divided into two sections by the Carpathian mountains; but as the northern section have their progress arrested by the dry sandy grounds of western Poland and northern Germany, there are comparatively few of that division which reach the shore of the north sea, and consequently fewer that find their way to Britain. Those which come by the lines of the central rivers, have an uninterrupted pasture all the way; and as the countries on the lower part of the Rhine are, from their flatness and humidity, well suited to the habits of such birds, they are plentiful in Holland, and find their way to the marshy portions of the north-west coast of Germany in that direction, and not by the more northerly, and, geographically speaking, more direct route. It is on this account that those wanderers are more frequently found in England than in Scotland; but though generally, they are not always found on the eastern shores. The breadth of the island is not a very serious journey for a migrant, when it is once on the wing, as there is perhaps no bird which, on its high and long flight, makes way at the rate of less than thirty or forty miles an hour. Many of them appear to fly much more slowly than this; but it should be remembered that this is an optical deception produced by the height at which they fly; and if we do not take this into the account we are sure to conclude that their motion is much slower than it is in fact.

It will readily be understood that the apparent motion of a bird flying, or indeed of any other moving object, must be lessened by distance in the very same proportion that its lineal dimensions are diminished; that double the distance, for instance, will reduce both the apparent size and the apparent velocity to one half, and the same in proportion for all other distances. This, though it is seldom noticed in popular works on natural history, is a very important consideration for the observer of nature; and in the case of birds especially, the most erroneous estimates of their rates of flight will be made, if distance is not taken into the account, and the effect which it has in diminishing the apparent rate. The motion of the sun, which though only an apparent motion as regards that luminary, is the exact counterpart and consequently the exact measure of the motion of the earth. Now this apparent motion of the sun appears, in consequence of the vast distance of that luminary, so slow and lagging that we can hardly perceive it; and yet is more than two thousand times faster than the swiftest light carriage that ever steamed along the Liverpool and Manchester railway. If distance can reduce so tremendously rapid a motion as this —a motion which would not only dash into atoms any two masses of any known substance, if they were to come into collision at that rate, but which would instantly kindle and dissipate into their constituent gases two globes of ice; then we can easily understand how distance will deceive us in the flight of birds at different elevations. The swift at steeple height, appears to us to move more slowly than a barn-door fowl; and yet it will make a turn round the churchyard in the time that the fowl takes to flutter across the pathway. Wild geese too, seem to get on very slowly; but they very soon clear the horizon, or pass along that space over which they are visible, which to a good eye is at least two or three miles. We are of course liable to fall into the same error when we look at any birds on their elevated migratory flights; and by not making allowance for the optical deception stated above, we are apt to wonder at the effort made by such a bird as the little bittern when we are told of its alighting in those places of the British islands which are remote from its native localities; whereas, in truth, the stretch across such an island as ours, is no more fatigue to the bird than those walks which we take, absolutely for the purpose of refreshing (that is, *resting*) our limbs, are to us.

The little bittern is about fifteen inches in length, and two feet in the extent of the wings. Its bill is about two inches long, brownish-horn colour at the tip, and partly along the ridge, but greenish yellow at the sides and the base. In form and colour it is a more aquatic bill than that of the common bittern; and the neck is more borne in flexures. The feet are dull green, and the feathers on the tibiæ reach down to the tarsal joints, which shows that it is not much of a wader; and also that though it may find more of its food in the water than the common bittern does, it does not frequent such moist and tangled places during its walks. The feet are otherwise formed like those of the common bittern, and, as in that, the inner margin of the middle claw is slightly serrated. It is a much more beautiful bird than the common bittern. In the male, the head, upper part of the neck, back, and tail are glossy black with green reflections; the chin, throat, and breast are buff colour, and the rest of the under part is white. The scapulars are relieved by a chesnut-coloured spot; the lesser coverts are buff; the larger whitish, and the quills black without any gloss of colour. The female is smaller than the male, and so differently coloured that it has sometimes been described as a distinct species. Where the upper part of the male is black with reflections, that of the female is brown with rust-coloured margins to the feathers; and the buff on the under part is much paler, and appears chiefly on the margins of the feathers.

Of the few specimens which have been observed in this country, some have been found perching on the stumps of trees by the margins of rivers, and others in places where there are no trees, or even stumps upon which a bird can perch. It does not appear however that the birds builds on trees, or that it even rests on their tops like the heron. The nest is said to be in the cover of a bush or tuft, and rudely formed of the dry leaves of the aquatic plants. The eggs of the same number as in the common bittern, but nearly white in the colour.

The American Bittern (*Botaurus lentiginosus*). This species is a native of America, over the northern part of which continent it is pretty generally distributed. In form and in the general tint of its plumage, it bears no inconsiderable resemblance to the common bittern; but the spots and markings of dark colour are much more minute and thickly spread, on which account it gets the epithet "*lentiginosus*" or "freckled." This species is said not to ascend and boom in the pairing season, in the same manner as the common bittern; but it makes a hollow drumming noise when it is disturbed.

On the continent of America, this species is very migratory. Indeed, from the intense cold of the winter, even in latitudes which are not very high, the great range of country, the abundance of water, and the warmth of those countries which border on the Gulf of Mexico, and which are at the same time very humid, abundant in cover, and in the food of all sorts of birds, but more especially aquatic and forest ones, and which are even at this time very partially cleared and very thinly inhabited, birds are far more migratory, and far more numerous on their migrations, than on any part of the eastern continent. From the moors of north-eastern Russia to Egypt is the only portion of the eastern continent, in which there is a migratory range from the one extreme to the other, without being actually interrupted by mountains; and even there, the path lies for great part of the way upon the sea, and the mountains approach so near on each side as to leave only a comparatively narrow gorge, while Egypt, as a water bird's country, though rich for its extent, is only a broad stripe seaming the desert. In America there is no such interruption; but from the swamps of Florida and Lower Louisiana, northward to the utmost extreme where a bird can find food, there is free range, abundant food, and congenial resting place for every way-farer on the wing. This ample scope, by means of which the seasonal action of nature plays freely from the polar to the tropical sea, is one of the causes of that great diversity of seasons, which renders it necessary that birds which live on the margins of the waters, and yet are inland and not shore birds, should move to the southward in the winter. But the very same structure of the surface which imposes this necessity upon the birds, finds them accommodation, and nearly equal accommodation, at every latitude of this wide range, so that they can shorten their journeys if the season is mild, or lengthen them if it is severe. On their northward journeys there is little chance of these birds ranging across the Atlantic to Britain; because at that time the southern part of the great central valley of America is warm, and the northern part cold, and the high flying birds get above the southward current of air, which sets near the surface of the ground, and float easily upon the upper or return one from the south, which at some elevation is the prevailing wind in the valley of the Mississippi, just as the south-west wind is, from the same cause and at the same season and height, the prevailing wind with us, even when the surface wind blows steady from the north-east.

It is not probable that the same individual birds, of the freckled bitterns or any other species, range the whole length of this vast district, which from the Gulf to about the middle latitude of Hudson's Bay is about two thousand miles. We must suppose that the water birds at all times inhabit a very considerable portion of the length, more especially the bitterns, which are at all times solitary birds, and do not flock even upon their migrations, as is the case with many species which dwell apart when they take up their seasonal abode. The species under consideration appears on the swamps near Hudson's Bay in the beginning of summer, and breeds there; but as it is a retiring bird, and as those swamps are not very accessible till they are frozen, before which time the birds have of course removed to the southward, comparatively little is known either of their numbers or their habits.

Besides the three species of which some notice has been given, there are others that have been described either as bitterns, or confounded with them in the melange of the old genus *Ardea*. The three which have been mentioned are, however, the only ones of which the history is sufficiently made out for popular purposes. As bitterns their story is soon told, being in all the three little else than a repetition of that of our native one. But as they are very pre-eminently birds of wild nature, the study of them in all the different habits of the species, is important, as they are in some sort keys, not only to the ornithology, but to the general state of nature in those places where they are found. We find the common one migrating but little, dwelling pretty generally over the globe, but only in very peculiar spots, and incapable of bearing much change in their physical character, by whatever cause that change may be brought about. We have the second much more discursive, not so resolute a feeder in the rough herbage, or so determined a dweller in the wild and lonely marshes only. It has a seasonal migration from east to west and back again, along the central part of the old continent; though to the eastward of the Caspian, it is probable that its motions are reversed in time as compared with those to the westward. In the last mentioned species again we have a migration nearly upon the meridian, in a bird which resembles more the first, or least migratory species, in its habits. But we have also seen that the country in which this last one takes its seasonal flights, is one remarkably well adapted for the support of birds of this tribe; and that, with the exception of being stationary in the same place from the time that the nest is begun till the young are able to shift for themselves, which takes place at the most northerly part of the annual movement, or when the twilights are longest and the food most abounds, and is more easily obtained,—the movement for the rest of the year is a gradual shifting from day to day, without any necessity for those long and laborious flights which the migrant birds that in general visit our shores are obliged to take across the sea. Many inferences from the hints which have been thrown out in the course of this article will suggest themselves to the reader: among others, that the migration of birds is not that mysterious matter which some have asserted, but that it is varied as much by natural circumstances, and therefore depends as much upon natural causes, as any other occurrence.

BITTER VETCH is the *Orobus* of Tournefort, a numerous family of the tare kind, mostly indigenous to Europe. The orobus belongs to the *Diadelphia* class and *Decandria* order of Linnæus, and to the natural order *Leguminosæ*. Generic character: calyx of five teeth, the upper ones shorter and deeply divided; style round at top, and downy; pod roundish. There are above thirty species of this genus divided into three sections according to the composition of their pinnated leaves—as one-paired, many-paired, &c. They are all pretty flowering plants: the *O. vernus* in gardens, and the *O. tuberosus* on our heaths, are universally admired.

BITUMEN. This term includes a considerable range of inflammable mineral substances. They are of different degrees of consistency, from a thin fluid to a solid; but the solids are for the most part liquefiable at a moderate heat. Bitumen, as we have already stated under ASPHALTUM, was formerly employed to a considerable extent in the arts of domestic life. The Egyptian, after the lapse of thousands of years, may still be said to preserve his identity in our museums by the agency of this mineral, and when the swathing clothes are unrolled many of the bodies have been found in a high state of perfection. Bitumen is either elastic or compact; the first of these is of various shades of brown. It is found in abundance in the Odin mine near Castleton in Derbyshire, in a secondary limestone.

Compact bitumen is of a brownish black colour; one variety may be impressed by the nail, and is called maltha; another is very brittle, and is in commerce called asphalt. On the banks of the Dead Sea, and in the neighbourhood of the latter body, is found a species of stone called "mussa" by the Arabs, which on attrition exhales an intolerable odour, and burns like bitumen. It is of a jet-black colour, and takes a fine polish. Maundrel saw pieces of it two feet square in the convent of St. John in the Wilderness. The inhabitants of that country employ it in paving mosques, churches, and other places of public resort. The natives of Bethlehem affirm that it is endowed with powerful antiseptic virtues, and bracelets of it are worn by attendants on the sick as an antidote against disease. Bituminous shale, which forms the Brandschiefer of Werner, is of a brownish black colour, and occurs in rocks of the coal formation, where it frequently alternates with and passes into slate-clay, and also into coal. It is also found in the coal districts of our island, and in several parts of the north of Europe. See PITCH, COAL, MINERAL.

BIXINEÆ. The Arnotto family. A natural order of dicotyledonous plants, containing six genera and upwards of twenty species. The order is by some included under the *Flacourtianeæ*. It is nearly allied to the *Cistineæ* and *Homalineæ*.

Its botanical characters are:—Sepals or leaves of the calyx varying from four to seven, with an imbricated æstivation; petals five, sometimes wanting; stamens indefinite, inserted on a disk; anthers two-celled; ovary superior, sessile, one-celled; style single, or in two or four divisions; fruit, a many-seeded, single-celled capsule or berry. The plants included in the order are trees or shrubs, generally smooth and having alternate leaves with pellucid dots. They are chiefly tropical exotics, found in the hotter parts of America and in the Mauritius. They are not remarkable for their beauty, or for the useful purposes to which they are applied.

Their properties will be best shown by the following examples:—The chief genus (whence the order is named) is called *Bixa*, a term derived from the American name of the plants. The red pulp which

Bixa.

covers the seeds of the *Bixa Orellana* yields the substance known by the name of arnotto. It used to be denominated *Terra orellana*, or *orleana*, and is called by the French, *rocou*. The seeds are separated from the pulp by maceration in hot water, and the pulp is then made into balls or cakes, which when dried constitute the arnotto of commerce. Good arnotto is soft to the touch, and dissolves entirely in water. It is slightly purgative and stomachic, and is used in Jamaica and other warm countries as a remedy for dysentery and disorders of the kidneys. Dyers form with it the colour called aurora, and when mixed with lemon juice and a gum it forms a crimson paint with which the Indians adorn their persons. By the Spaniards it is used for the purpose of adding to the colour and flavour of chocolate and soups. In Gloucestershire and other counties it is employed to colour cheese, and in Holland butter is dyed with it. The bark of the tree is made into ropes in the West Indies, and the wood is used for the purpose of procuring fire by friction. The other genera of the order are, *Ludia*, *Lætia*, *Prockia*, *Banara*, and *Azara*. The bark of *Ludia heterophylla* and *sessiliflora* has emetic properties. The azaras are Chilian shrubs, with fragrant flowers not known in the gardens of Europe.

BLACK-BREASTED, or TITHYS REDSTART (*Phœnicura tithys*. *Motacilla erythaca*, Linnæus. *Sylvia tithys*, Temminck.) This is a common bird in Germany, Prussia, and the east of Europe, becoming gradually more and more scarce towards the west, and in Britain has only been discovered very lately. It is about the size and shape of a robin; the whole upper parts to the rump are bluish grey; the base of the bill, region of the eyes, the sides of the neck, throat and breast, black, margined in the winter with greyish edgings, which gradually disappear in the spring; middle of the abdomen greyish white; flanks and sides blackish grey; quills blackish; the secondaries and tertials slightly margined with dull white; rump and tail bright reddish rust colour; the two middle feathers of the latter dark brown. In the female the whole of the body is of a uniform yellowish grey, the quills and secondaries being rather darker; the rump and tail as in the male bird, but not quite so bright.

The male may be described briefly to resemble the common redstart of this country, but is a trifle larger, and is without the distinct bar of white upon the forehead and the reddish brown plumage on the breast, which distinguish that species. It much resembles it also in habit, frequenting the vicinity of old trees and various out-buildings, old park walls, and the ruins of ancient castles, &c., but is considerably less shy in its disposition, and in the countries it inhabits plentifully may often be seen pouring forth its song from the roof of a house or from the garden-wall, occasionally darting off to snap at a passing insect, in the manner of the various species of fly-catchers. Its notes closely resemble those of the common redstart, but its song, though very similar, is more monotonous and tiresome. Its food also is the same, consisting of insects and their larvæ, the former of which are frequently taken on the wing.

All the redstart genus are remarkable for a singular manner of constantly shaking the tail. In the present species the shake is different from that of the common redstart of this country, which latter is a slower motion, gradually dying away in the course of three or four oscillations, each less than the preceding one, and appearing exactly as though the tail were loose, and ready to fall off. In the tithys redstart the oscillations are quicker and of less extent, not gradually dying away, but the last shake being fully equal to the first. These birds never alight on a spray without their tails moving in this singular manner, which gives them a remarkable and very characteristic appearance. The tithys redstart appears to build less in the holes of trees than the common species, but constructs its nest more in the clefts of rocks, in holes of walls, and in other similar situations, and is said to lay five or six eggs, of a spotless bluish white.

BLACKCAP (*Curruca atricapilla*, Brisson). A variety of small black-headed birds are designated in different parts of Britain by the term *Blackcap*. The great titmouse (*Parus fringillago*), the marsh titmouse (*P. palustris*), the black-headed or reed bunting (*Emberiza schœniclus*), the stonechat (*Rubetra rubicola*), and even the black-headed gull, are all frequently called by this name; but the bird which by naturalists is universally recognised as the blackcap is a species of fruit-eating warbler, or fauvette, abundant in most parts of Europe, and which extends its summer migrations even to the inhospitable shores of Lapland. Throughout Britain this is well known as a summer bird of passage, and is also one of the earliest to arrive, a few sometimes appearing in the southern counties about the middle of March, reminding us, by their charming melody from the leafless spray, that winter is on the wane, and summer and sunshine are at hand. It is a handsome species, though plain and unassuming in its garb; being black upon the crown; the back, wings, and tail, greyish olive, with the back of the neck and whole under parts pure ash-colour, paler on the throat, and becoming white upon the belly. The legs and feet are a dusky lead colour. The female is very similar to the male, only that the crown of the head is of a rusty hue; and the young of the year resemble the adult female, the young males, however, being rather smaller and darker coloured than the other sex.

The blackcap is undoubtedly one of the finest of British song birds, and in some counties of England is commonly known by the name of *mock-nightingale*, from the similarity of parts of its song to some of the notes of that celebrated bird. Sitting calmly, embowered in thick foliage, his bosom resting on a bough, he pours forth, without effort, a delightful flow of soft and pleasing melody; then suddenly elevating his voice, and raising the black feathers of his crown, he warbles aloud a cheering, liquid strain, for which, at least in these islands, he certainly stands unrivalled. There are few unacquainted with this note, though the blackcap does not always get the credit of it, some attributing it to the blackbird, and others calling it "the livelier summer strain" of the robin redbreast. It resembles the latter much more nearly than it does the blackbird's song, but may always be at once distinguished by its far more animated and lively tone, being without any admixture of that peculiar plaintiveness which ever characterises the song of the robin. There is something inexpressibly sweet in the common call-note of the blackcap to its mate.

The most favourite haunts of this bird are gardens and orchards, though it is abundantly found wherever trees and bushes grow together, passing most of its time in the former, and usually selecting the latter for nidification. The nest is sometimes placed near the ground, amongst the herbage, or at the bottom of a bush, but more frequently in a forked branch at four or five feet from the ground, and sometimes at the height of nine or ten feet. It is of a neat construction, composed of the dried stems of grass, often put together with a little wool, and sometimes with a little green moss on the outside; the inside is lined with fibrous roots, amongst which is usually placed some horse-hair. The eggs are four or five in number, generally of a pale reddish brown, mottled, or rather stained with a deeper colour, and sometimes sprinkled also with a few ash-coloured spots, chiefly at the larger end; but they are subject to much variation in colour. About a fortnight is required to hatch them, and both male and female perform the office of incubation by turns. The young are, even from the first, brought up chiefly on berries and fruit, whenever such food can be obtained, but, in default of this, are fed upon caterpillars, and various other insects.

The adult blackcaps are strictly fructivorous, preferring fruit of all kinds to any other sort of food whatever, and in confinement will thrive well, and sing, on this alone. Even on their first arrival in the spring they subsist chiefly on various berries, and of six, examined in the beginning of April, one only contained in its stomach the remains of insects, the others having been feeding on the berries of privet and ivy. They may nevertheless, however, be often observed examining the trees and bushes for insect food.

The blackcap is one of the hardiest of our summer visitants. Lewin shot one in Kent in January, but most probably this had passed the summer far to the north. Of three or four dozen British migrating birds that were kept in a room without a fire, two species only, this and the tree pipit (*Anthus arboreus*), survived the winter. There were four or five blackcaps, and of these not one was lost. It is in confinement a remarkably healthy species, and will do well on any sort of food that is usually given to soft-billed birds, but should not be allowed much meat. It rarely, however, becomes very familiar, unless when taken young, but often retains its wild and timid nature for years.

We may mention here a curious habit which, in confinement, is observable in several of the smaller birds, but more particularly in the fruit-eating warblers. They will occasionally be taken with a sudden and remarkable fit of activity, darting backwards and forwards about their cage, now here, now there, faster than the eye can follow, with crest and feathers of the throat erect, and uttering all the time a loud *check*, or *tchut*, which varies a little in the different species. After continuing thus for two or three minutes, they cease almost as suddenly as they began, and hop quietly about as if nothing had happened.

BLACKWELLIA (Commelin). A genus of five species of hot-house evergreen shrubs, belonging to the class and order *Dodecandria Pentagynia* of Linnæus, and to the natural order *Homalineæ*. Generic character: calyx nearly superior, in five reflexed lobes, often bearing glands; corolla, five small petals inserted on the calyx; stamens imposed on the calyx, and dilated at the base, anthers somewhat round, opening at the top; style filiform; seed vessel one-celled, with many seeds. The *B. fagifolia* is said to have fine bunches of "starry white fragrant flowers."

BLACK-WOOD is the *Melhania melanoxylon* of the *Hortus Keweusis*. It is an ornamental hot-house tree, said to be a native of St. Helena.

BLADDER KETMIA is the *Hibiscus trionum* of Linnæus. It is an ornamental annual, and is usually sown in our flower borders; being a native of Italy.

BLADDER-NUT is the *Staphylea pinnata* of Linnæus. Of this family there are three species; one of which is a tree from Jamaica, and two are shrubs, one of which, the *S. pinnata*, is found wild about Pontefract in Yorkshire. These plants belong to the fifth class and third order of the sexual system, and to the natural order *Celastrineæ*. Generic character: calyx, inferior, large, coloured; corolla, five-petalled, drooping; capsule, two or three inflated; seeds, two on each cell. The inflated seed vessel gives the name to the plants.

BLADDER SENNA is the *Colutea arborescens* of Linnæus. There are five species, natives of the south of Europe. Class and order *Diadelphia Decandria*, and natural order *Leguminosæ*. Generic character: calyx, of five teeth; two callosities at the base of the standard, keel obtuse; stigma uncinate; pod with a foot-stalk, inflated, membranaceous. Although this is not the true senna of the shops, the plants are supposed to possess qualities somewhat similar, and may be used either as laxatives or purgatives.

BLÆRIA (Linnæus). A genus of Cape of Good Hope shrubs, containing eleven species, all more or less ornamental. They belong to the class and order *Tetrandria Monogynia*, and natural order *Ericeæ*. Generic character: calyx, four-cleft; corolla, somewhat bell-shaped, and also four-cleft; stamens imposed on the receptacle, in some species protruded; anthers, two-celled, without horns, rarely with; style simple, exserted; stigma obtuse; capsule four-celled, quadrangular, angles bursting. These plants have some resemblance to heaths, and as such deserve admission into every green-house collection.

BLAKEA (Linnæus). A genus of two species of beautiful tropical shrubs, belonging to the class and order *Dodecandria Monogynia*, and to the natural order *Melastomeæ*. Generic character: calyx, membranaceous, six-angled, limb repandous, the base surrounded by an involucrum-like fringe of from four to six leaflets; corolla composed of six petals; stamens seated below the germen, anthers standing in a circle; style simple; stigma peltate; capsule a berry, invested by the calyx, six-celled; seed, angularly oval. The Blakea is one of our finest stove plants, and as it is frequently in flower, is on this account more valuable. One peculiar characteristic of the Blakeas is the regular division of the foot-stalk of the leaves, by which the face or disk is separated into a given number of spaces; hence the specific names *trinervia*, and *quinquenervia*.

BLANDFORDIA (Smith). A family of two species of herbaceous perennials, natives of New Holland. Class and order *Hexandria Monogynia*, natural order, *Hemerocallideæ*. Generic character: periantheum, simple; calyx tubular, opening into five lobes; stamens inserted in the tube; anthers, date-shaped, standing on their base; style, awl-shaped, stigma simple; capsule prism-shaped, three-parted; seeds in two rows attached to the margin of the suture; testa, lax and downy. The Blandfordias are fine showy plants, with umbels of flowers, and well worthy cultivation.

BLAPS (Fabricius). A genus of beetles, belonging to the section *Heteromera* and division *Melastoma* of Latreille, forming the type of the family *Blapsidæ* of Leach. The insects composing this family are of obscure or black colours; they are destitute of wings, and the maxillary palpi are terminated by a large hatchet-shaped joint; the body is oblong or oval. The elytra are generally soldered together, and deflexed at the sides so as to embrace the margins of the abdomen. They frequent dark, close, and damp places, as stables, cellars, wash-houses, &c., where they lay concealed during the day, under stones, in holes, &c. They are furnished with an internal apparatus for secreting a liquid of a brown colour, and of an acrid, irritating, and very disagreeable odour, which is ejected at the sides, and not from the extremity of the terminal segment of the body, to the distance of six or eight inches. The hind legs are only furnished with four tarsal articulations. The species are of a moderate or small size. The insects are nearly related to the Tenebrionidæ and Pimeliidæ both in their structure and habits; from the former they are easily distinguished by their apterous and broader-formed body, and by the conical terminal joint of the palpi, and from the latter by the character of the palpi. Although destitute of wings, nature has not given them by way of compensation, the power of running with that agility which distinguishes those ground beetles (Carabidæ), which are similarly circumstanced. This slowness of motion is, indeed, an attendant peculiarity resulting from the nature of their food, which consists, not of living insects like that of the Carabidæ, but of putrescent animal or vegetable matter.

Here then we have, amongst some of the lowest animals, an example of that adaptation of means to the end, which is more perceptible, simply from the increased facility of observation, amongst the larger animals. Carnivorous animals, or rather, animals of prey—living prey—are necessarily endowed with great celerity of motion, to enable them to obtain their necessary supplies of food, which would otherwise escape pursuit; and we accordingly find the tiger beetles, ground beetles, and others exceedingly active, even where destitute of wings but herbivorous animals, and especially such as feed upon putrescent matter, are almost universally slow in their motions. There are, indeed, exceptions to this rule, especially amongst such animals as are destitute of means of defence, but in the beetles under consideration, we observe security against the attacks of enemies in the hardness of the covering of the body, and in the fœtid odour produced by the emission of the fluid from the extremity of the body.

In Mr. Stephen's Works on British Entomology, this family comprises only the two British genera—*Misolampus* and *Blaps*. This arrangement is formed upon that of Dr. Leach, which was again taken from the first edition of the *Règne Animal;* but in the later editions of that work, the family is considerably extended, and embraces the greater part of Mr. Stephen's second section of the family *Tenebrionidæ.*

According to the last mentioned edition, which is indeed the latest authority upon the subject, the genera are thus arranged :—

1. Elytra more or less acuminate. Tarsi not dilated.

1 (*a*). Mentum small, less simple or spined.

Genera. *Blaps,* oxura, acanthomera, misolampus, gonopus.

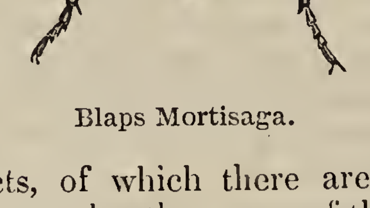
1 (*b*). Mentum very large ; thorax broadest in front, or gradually dilated at the sides.

Genus. Asida.

2. Elytra not acuminate. Tarsi of the fore legs more or less dilated in the males.

Genera. *Pedinus,* opatrinus, dendarus, *Phylan, Heliophilus,* eurynotus, isocerus, blapstinus, and platyscelis.

Of the genera recorded above, those only mentioned in italics are natives of Great Britain, misolampus being of doubtful locality as such. Recurring therefore to the first of these, blaps (Fabricius), which includes by far the largest of the British species, we find it at once distinguished, in addition to the characters given above, by the nearly square thorax, the rather broad elytra, and the great length of the third joint of the antennæ.



Blaps Mortisaga.

These insects, of which there are three British species, are known by the name of the darkling, or church-yard beetles, and it seems not improbable that the latter circumstance has occasioned their appearance to be regarded by the ignorant and superstitious as an evil omen. Linnæus informs us that this is the case in Sweden. By the ancients, these insects appear to have been regarded as a species of blatta ; indeed, Mouffet, who assiduously collected the learning of the ancients respecting insects, gives the blaps mortisaga, and the male and female cockroach, as the three species, of which the genus blatta was composed. Like the latter insects, the blaps was an object of general disgust, on account of its ill scent, yet it was recommended as an infallible nostrum when applied with cedar oil, in incurable ulcers. An Egyptian species is, however, recorded to be in great favour with the Turkish women, who eat it fried in butter, for the purpose of making them fat, and also to be applied as a remedy to alleviate pain in the ear, and to cure the sting of the scorpions. For the former purpose it also appears to have been applied even in England, in the days of Mouffet. It is also recorded by Mr. Baker, the celebrated microscopic observer, respecting the blaps mortisaga, that he kept a specimen alive under a glass upwards of three years without food (Phil. Trans. 1740). The faculty of sustaining a long abstinence from all kinds of food, of which numerous examples might be cited, is regarded by Messrs. Kirby and Spence, as dependant in some degree upon the nature of their food ; vegetable feeders requiring a constant supply, whilst those which are predaceous and exposed to the danger of being long without food, are often endowed with the powers of fasting to a remarkable degree. This argument is not, however, applicable to the case of the darkling beetle, which, indeed, seems to be much more easily accounted for upon the principles which in another part of this celebrated work these authors have mentioned, namely, that if by any circumstance the union of insects is deferred beyond the ordinary period, their lives may be protracted far beyond the usual term, and hence that the great age to which Mr. Baker's blaps attained, was owing to its being a virgin when taken, and subsequently kept from any sexual intercourse. A parallel case is stated by these authors too amongst vegetables, where an annual plant, if kept from seeding, will become biennial, as likewise if they are sown too late in the year to produce seeds. But it is not alone in its powers of abstinence that its tenacity of life was observed, for the same insect had previously revived after being immersed in spirits of wine a whole night*. This circumstance may perhaps enable us in some degree to account for an extraordinary case reported in the Dublin Medical Transactions of 1824—1828, by Dr. Pickells, of Cork, and which, from the number and competency of the observers, there appears not to be the slightest reason to doubt. For several years, a middle-aged female continued to throw up incredible numbers of grubs, chiefly of the blaps mortisaga and maggots of a dipterous insect. "Of the larvæ of the beetle," says Dr. Pickells, quoted in Insect Transformations, "I am sure I considerably underrate when I say, that not less than seven hundred have been thrown up from the stomach at different times since the commencement of my attendance. A great proportion were destroyed by herself to avoid publicity, many too escaped immediately by running into holes in the floor. Upwards of ninety were submitted to Dr. Thomson's examination, nearly all of which, including two of the specimens of the meal worm (tenebrio molitor) I saw myself thrown up at different times." It appears that this female had some time previously, in the performance of a strange superstition, been in the daily habit

* A similar circumstance, which occurred with a lady-bird (coccinella), fortunately for Entomologists, induced Mr. Kirby to turn his attention to insects, and Mr. Curtis has observed the same fact after an immersion of twenty-four hours. It is to be observed, that in both instances the insects possess the power of secreting a very acrid liquid.

of drinking a quantity of water mixed with clay, taken from the graves of two Catholic priests, to purchase eternal immunity from disease and sin; and that upon one occasion she had lain upon her mother's grave during a night, and had been exposed to heavy rain. Now, as we cannot agree with the former of the suggestions of Mouffet, respecting this very insect, "An vero hæc ex putri materia oriatur, vel mutua commistione maris et fœminæ generetur, ignoramus," although the development of intestinal worms has always been one of the strongholds of the sticklers for the doctrine of equivocal generation—we must conclude that the grubs voided by the above-mentioned woman were produced from eggs which it is most probable were introduced into the stomach with the clay water which she drank, and the occasional length of time taken for the hatching of insects' eggs, or the duration of the larva state in beetles for several years, may account for the continued discharge of larvæ. It is also to be observed, that one pupa and one perfect insect alone were voided; and from the figure given of these of the natural size and magnified, the insect does not appear to be the species above named, being much too small and narrow.

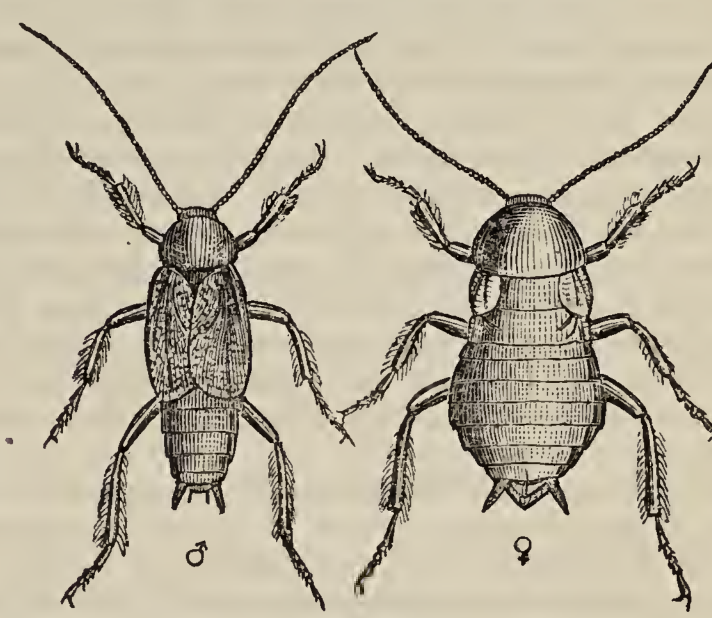
Of the other genera, composing the first section of the family, nothing appears known of their habits. The species of *Asida* frequent sandy districts, whilst *Pedinus* and the genera of the second section are chiefly found upon the sea coast.

BLATTA (Linnæus). The Cock-roach. A genus of orthopterous insects, forming the type of the family *Blattidæ* of Stephens, and belonging to the section *Cursoria* of Latreille. As a group they are distinguished by the tarsi furnished with five joints, the under wings folded longitudinally only, and not transversely as in the earwigs, the head concealed by the anterior margin of the thorax, the body oval or rounded and generally flattened, and the fore legs formed only for running, and not for prehension as in the mantidæ; the elytra are leathery, nervose, and lapping over each other at the inner edge. These characters induced Dr. Leach to raise these insects to the rank of a distinct order named *Dictyoptera*, but the distinguishing features of the group are far too slight to warrant its establishment, and entomologists have therefore not adopted this mode of arrangement. The antennæ are very long and thread-like, consisting of an immense number of minute articulations. The mouth is furnished with a pair of powerful jaws, under jaws, &c., and the palpi are long. The thorax has somewhat the appearance of a shield, the elytra are generally as long as the body, the extremity of the abdomen is furnished with a pair of minute conical articulated appendages. The legs are long and armed with minute spines.

These insects are of moderate size, but some species acquire the length of an inch and a half or two inches. They are nocturnal in their habits, extremely active, and the majority reside in the interior of houses, where they delight to take up their abode in the neighbourhood of fire-places in kitchens, &c., but especially in bake-houses, and other situations where much cooking takes place, where they inhabit the clefts of walls near ovens by day, coming forth by night in myriads, but retreating with the utmost precipitation to their holes immediately that a candle is intruded amongst them. They are extremely voracious, destroying almost all sorts of provisions, but more particularly bread and other vegetable matters. It is very difficult to extirpate these disgusting insects, which, in addition to the destruction which they cause, emit an exceedingly disagreeable odour, which attaches to whatever they have crept over. Perhaps the most advantageous method of destroying them is to use a small wooden box with sloping sides, having a circular aperture at the top with glass edges, out of which it is impossible for them to escape. This should be nightly baited, and the contents thrown the following morning into scalding water. This plan is certainly superior to the employment of red poisoned wafers.

These animals were known to the ancients, who named them *insecta lucifuga*, on account of their shunning the light. The insects which they termed *blattæ* were certainly distinct, although it is not easy to decide as to what they really were.

The species which are truly indigenous in England are of comparatively small size, and are generally found in woods; but the species which frequent our houses, occasionally in such myriads as to cover the floors of the lower apartments in the metropolis at night, are of more southern origin, the ordinary species (*B. Orientalis*) being a native of Asia. It is



Blatta Orientales (Male and Female).

probable that its introduction was owing to the navigation of the Levant, being brought over in ships' cargoes. They generally swarm on board ship; and it is evident that such was also the case in the time of the ancients, from the following passage from Mouffet:—" In Philippo navi quam nobilissimus ille Neptunus (Dracum equitem intelligo) aromatibus onustam vi cepit, ingens blattarum alatarum multitudo inveniebatur." At the present day we have heard that the boys on board old ships have been employed at leisure times in catching and stringing these insects, receiving a trifling reward for every score caught. It is to the same cause that the American cockroach (*B. Americana*), a much larger species than the ordinary one, is gradually acquiring a settlement in London and other ports. But the ravages of these insects in warm climates appear to be far greater than amongst us, from the following account given by Drury of the *B. gigantea*, which he had himself observed:—" The cockroaches are a race of pestiferous beings, equally noisome and mishievous to natives and strangers, but particularly to collectors. These nasty and voracious insects fly out in the evenings and commit monstrous depredations; they plunder and erode all kinds of victuals, dressed and undressed, and damage all sorts of clothing, especially those which are touched with powder, pomatum, and similar substances; every thing made of leather, books, paper, and various other articles, which if they do not destroy, at least they soil, as they frequently deposit a drop of their excrement where they settle, and some way or other, by that means, damage what they cannot devour. They fly into the flame of candles, and sometimes into the dishes, are very fond of ink and oil, into which they are apt to fall and perish. In this case they soon turn most offensively putrid, so that a man might as well sit over the cadaverons body of a large animal as write with the ink in which they have died. They often fly into persons' faces and bosoms, and their legs being armed with sharp spines, the pricking excites a sudden horror not easily described. In old houses they swarm by myriads, making every part filthy beyond description wherever they harbour, which in the day-time is in dark corners, behind all sorts of clothes, in trunks, boxes, and, in short, in every place where they can be concealed. In old timber and deal houses, when the family is retired at night to sleep, this insect, among other disagreeable properties, has the power of making a noise, which very much resembles a pretty smart knocking with the knuckle on the wainscotting. The *B. gigantea* of Linnæus in the West Indies is therefore frequently known by the name of the drummer. Three or four of these noisy creatures will sometimes be impelled to answer one another, and cause such a drumming noise that none but those who are very good sleepers can rest for them. What is most disagreeable, those who have not gauze curtains are sometimes attacked by them in their sleep; the sick and dying have their extremities attacked; and the ends of the toes and fingers of the dead are frequently stripped both of the skin and flesh."—Drury, Illust. Nat. Hist. vol. iii. Preface.

A small species of Blatta, the *B. Lapponica* of Linnæus, is stated by that author to swarm in the huts of the Laplanders, and occasionally to devour, in conjunction with the *Silpha Lapponica*, the whole supply of dried fish in a single day. The species thus named by English entomologists is found in woods, and, from the difference in its habits, it may reasonably be supposed to be a different species.

But the most singular circumstance connected with these insects consists in the manner in which the eggs are deposited. Instead of these being laid singly, as is generally the case amongst insects, nature has given the females a most curious instinct for the preservation of their offspring. In fact, the females deposit a large oblong mass, convex at the sides, and flattened at the edges, which serves as a case for an entire family of young blattæ. This mass, which is of large size, being nearly half the entire size of the

abdomen of the female, is borne about by her for a considerable period. At first it is white, but gradually becomes dark brown. Although composed of a single piece, the edge along one side is slit, the margins of each side of the slit being denticulated and fitting into each other, and being cemented together so strongly that the other portions are even less strong than at the union of the sutures. Nature has however provided the enclosed insects with a key to this prison, enabling them to escape at the fitting period; this consists of a fluid which they emit, and which softens the cement of the denticulated margins, and affording to the young captives the means of escape from a situation in which they had previously attained a sufficiency of strength to enable them to follow their habits. On their quitting the case the cleft shuts again so accurately that it appears as entire as before. On opening this cocoon, as it may be called, it is found to contain about sixteen eggs of an oblong oval form, arranged in a double series, in which the young are brought to a considerable state of maturity. This singular proceeding occupies the female about a week, and suggests several interesting points of inquiry as to the manner in which the eggs are arranged by the female, the nature of the envelope, the cause of its being so long borne about by the parent, &c. It has indeed been said, that so careful is the female of her egg pouch, that she covers it upon quitting it with the materials of the substance upon which she places it, so that neither man nor any prying mouse or other animal can detect it; but it would seem that this assertion has been made by confounding the blattæ with the tineæ, since the former, as we have noticed, simply deposits her case of eggs in some secure situation. The larvæ and pupæ are equally active with the imago, and not less destructive, differing only in their smaller size and in entirely wanting or having but the rudiments of wings and elytra.

There are about a dozen indigenous British species of this genus, all of which are rare; but the number of exotic species is very great, and they are but little known, scarcely any entomologist having paid attention to the group, which notwithstanding contains some very curious forms. Latreille has divided the family into two genera, *Blatta* and *Kakerlac* (the name by which the blattæ are distinguished by the American colonists), giving the *B. orientales* as the type of the latter, which differs from the former in the females being destitute of wings. As, however, the *orientales* is the type of the Linnæan genus blatta, we have distinguished the *B. Lapponica*, and other British species composing the Latreillan genus blatta, under the name of ectobius, and which have tegmina and wings in both sexes. The other genera are *Blaberus*, *Panesthia*, *Pseudernops*, *Corydia*, *Phoraspis*, and *Perisphera*, all recently established by M. Serville in the Annales des Sciences Naturelles, upon various exotic species.

BLEABERRY is the *Vaccinium uliginosum* of Linnæus; a British plant found on wild moorland places. The berries are eatable, but of inferior quality.

BLECHNUM (Linnæus). A genus of exotic ferns, consisting of ten species; divided into two sections, viz. with fronds pinnated, leaves entire; and fronds pinnate, leaves serrulated or denticulated. They require a hot or green-house.

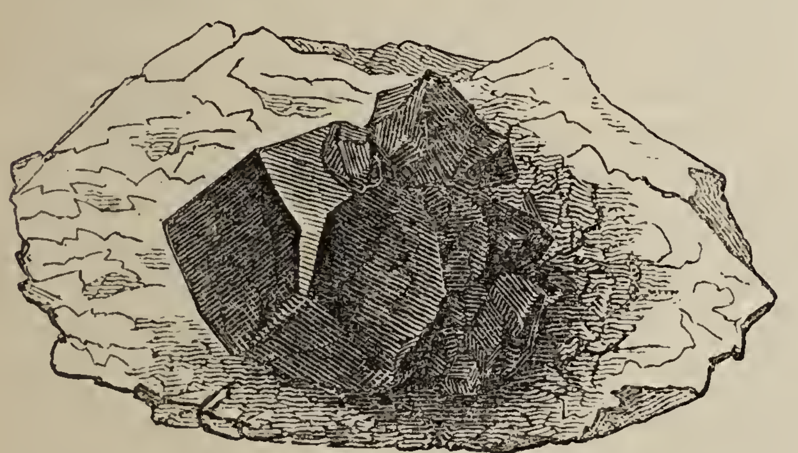
BLECHUM (Jussieu). A family of four species, hot-house perennial herbs, introduced from the West Indies. Class and order *Didynamia Angiosperma*, and natural order *Acanthaceæ*. Generic character: calyx, five-parted, persisting; corolla, funnel-shaped, the limb five-cleft; stamens, two-celled; style filiform, stigma cloven; capsule one-celled, two-valved. The Blechums rank among ornamental plants; but not conspicuously beautiful.

BLENDE. This mineral varies considerably in its external appearance and other general characteristics. The zinc-blende, so well known in our lead mines, is called by Mohs "garnet-blende," merely from its resemblance to that mineral. The yellow zinc-blende occurs along with galena or lead-glance, copper-pyrites, red cobalt, and heavy-spar, in veins that traverse quartz-rock, at Clifton Mine, near Tyndrum in Perthshire; also in Flintshire.

Very beautiful specimens are met with in Bohemia, where it is associated with galena, grey copper, iron-pyrites, brown-spar, and quartz; and sometimes also with native silver, silver-glance, or red silver. It is also found at Scharfenberg in Saxony; Rammelsberg in the Hartz, in veins in transition rocks. The green varieties are found at Gumerud in Norway, associated with galena, and smalt-blue apatite, in transition rocks; and it is accompanied by red manganese, at Nagyag in Transylvania. The foliated brown zinc-blende usually occurs massive and disseminated; also in granular distinct concretions, varying considerably in magnitude. It is found in Scotland; in the lead mines in England; and in various other parts of the world.

Black zinc-blende is principally valued on account of the zinc which it affords. In order to obtain that metal from it, it is first roasted, to drive off the sulphur, and then ground with charcoal, and exposed to heat in a crucible, when the metal is reduced, and sublimes into a lute, so placed as to convey it into water, where it condenses in small drops. By our English miners, blende is named "black jack."

A specimen of blende in the collection of minerals at the British Museum is represented in the accompanying engraving.



The prismatic antimony blende is a rare mineral, and is considered as an ore of silver in the districts where it occurs. For an account of the rhomboidal ruby blende see SILVER.

BLENNY (*Blennius*). A genus of *Acanthopterygeous*, or spinous-finned fishes, belonging to Cuvier's family of *Gobioidæ*, or the gudgeons. The genus has received the name blenny from the mucous matter with which the skins are covered; βλεννα being the Greek for mucus.

All the species, which are rather numerous, have a very easily distinguishing character in the ventral fins, which are placed before the pectorals, and have only two rays in each. Their bodies are long and compressed. They have, strictly speaking, only one dorsal fin, but that is sometimes divided into two lobes, which to partial observation gives it the appearance of two distinct and separate fins. The rays of the dorsal are all entire, or without articulation, but they are soft and flexible. The stomach is small, and the intestine short and without any cæca. They are also destitute of an air bladder. Many of them are viviparous, or bring forth their young alive. They are found in small shoals, among rocks or near the shores; and they are very lively fishes, leaping, swimming, and sometimes getting out of the water, where they have the power of living longer than many fishes, probably on account of the mucous secretion with which they are covered. They are in general small fishes, and of little or no use to man in an economical point of view.

Lacepede includes twenty-three species in the genus, which he divides into four sections or subgenera, according to the characters of the head and the dorsal fin. The first of these have two lobes in the dorsal, and filamentous appendages to the head; the second have only one lobe and the filaments; the third have two lobes in the dorsal, but no appendages to the head; and the fourth have one lobe, and no appendages. It does not, however, appear that any particular difference of habit can be indicated by these characters, as we are in a great measure ignorant of the uses of the filaments attached to the heads of fishes, and also to the difference of action arising from the dorsal fin being single in double. Cuvier takes a different method, including about eight or nine species as true blennies, and ranging the others into different genera according to their characters.

The true blennies have the teeth long, closely set, forming only one row in each jaw, and terminated in front, in some of the species, by a recurved tooth longer than the rest. They have the head obtuse, the muzzle short, and the line of the forehead nearly vertical. Their intestinal canal is short and wide. The greater number have a fleshy or cartilaginous appendage over each eye, which is divided into different branches; and some of them have a similar one on each temple. The following are some of the species.

Blennius ocellaris (the eye-spot blenny, or "butterfly fish"). This is a small species, seldom exceeding four inches in length. It is brown with a greenish tinge, and spotted. The dorsal fin is formed into two lobes, the first the highest, and the first spine of it the largest. It is upon this fin that the spot from which it gets its name is situated. The centre of the spot is a circular line of black with a purplish tinge, surrounded by a circle of white, and then outside with another of the same colour as the central disc. The eyes are elevated nearly to the same height as the line at the top of the head; the irides of them have a silvery lustre; and the appendages over them are fringed on their posterior margins.

This is rather a rare species in the British seas; and when it is met with it appears to be brought by the current from the warm shores of Europe, as it has been met with only or chiefly on the south coast of England, and the shores of the Irish Channel. It is, however, much more abundant in the Mediterranean. It is always found near the shores, or otherwise in shallow water among stones and marine plants; and it sometimes, in that sea, attains the length of six or seven inches; but its flesh is tasteless, and it is not sought after by the fishermen. The surface of its body abounds in the viscid or mucous matter from which the genus is named.

Blennius tentacularis. This species is rather longer than the former. The head is compressed and blunt, the eyes stand higher than the line of the crown;

and they have the irides reddish orange. There are four filaments over the eyes, forming a double crest fringed on both sides. The dorsal fin has only one lobe, and the first ray is short. The jaws are of equal length, and each furnished with an even row of teeth. There is a very characteristic spot, of a black colour, extending across the fourth and fifth rays of the dorsal fin. This species is found both in the Mediterranean and the Atlantic; but it is very rare as a British fish, and found only on the southern shores.

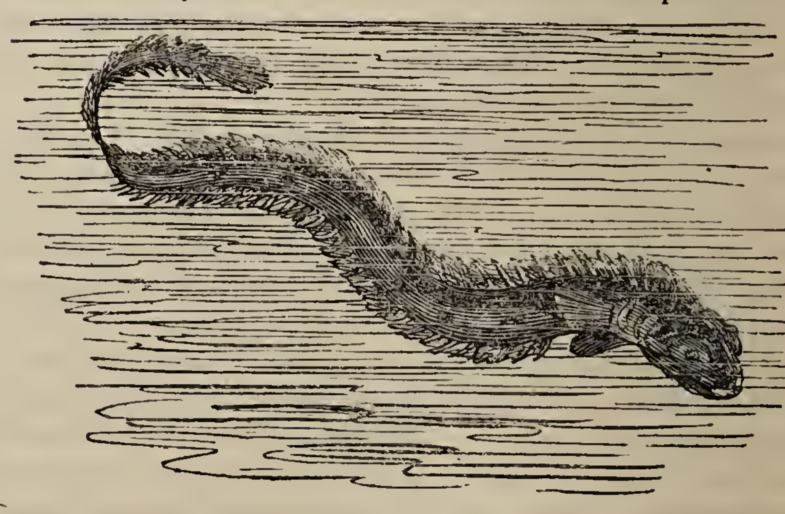
Blennius gattorugine. This species has only two filaments over the eyes, and one lobe in the dorsal fin. The body is reddish, the fins marked by oblique bands of brown; the eyes elevated above the line of the crown, and with orange irides. This species is also very rare as a British fish, and found only on the south and south-west coasts. It reaches to about seven inches in length.

Blennius palmicornis, has the appendage over the eye divided into smaller filaments for the greater part of its length, and only one dorsal fin. The head is small, the eyes projecting, with the irides reddish, and near the crown of the head. The jaws, of equal length, covered with an even row of teeth each. This species also inhabits the Mediterranean and the Atlantic. Its flesh is said to be better than that of most of the genus; but it has been occasionally confounded with the species immediately preceding.

The remaining species of the genus have not the produced filaments over the eyes so prominent as those which have been enumerated; but they have a sort of membranous enlargement on the crown; and it is somewhat curious that this appendage to the heads of these fishes, enlarges and puts on a bloom of colour in the pairing season, in the same manner as those on the heads of various species of birds. There is a farther analogy, though it is but faintly shadowed out by the observations which have yet been made; for "the laws of the fishes," are an obscure, though far from an uninteresting part of natural history. The birds which have this seasonal bloom in the fleshy appendages of the head, and not merely in the brighter tints of nuptial feathers, are generally, though not all, polygamous; and *there is some reason to believe* that the viviparous, or rather that the ovoviparous blennius, in which this seasonal enlargement and bloom of the crest are most conspicuous, are also polygamous. On the other hand, birds which bloom only in the feathers, and fishes which bloom in the fins, or the spots on the skin, as is the case with most of the spawning fishes, are chiefly monogamous. Thus there seems to be in two classes of vertebrated animals, which are very unlike each other in their forms, their haunts, and their habits, some similarity in the part of the body, on which the external sign of the most important of their physiological actions makes its appearance. But the subject has been so little studied in the case of fishes, that inferences from it are by no means safe.

Blennius galerita (crested or helmeted blenny). This species has only one lobe in the dorsal fin; it is spotted and rayed with blue, and has a black eye-shaped spot behind the eye. The appendage from which it gets the appellation of crested, is an elevated duplicature of the skin which crosses the top of the head, and to which it can communicate some motion. It is found in the Atlantic and Mediterranean, and is supposed to be rather more dispersed northward than some of the others. It is about seven inches in length, and a very active little fish, frequenting the rocks and shores, but very difficult to be caught with the hand, in consequence of the slipperiness of its body from the mucous secretion. The ground colour on the upper part is usually brown, and that on the under part bright green and black; but the colours are understood to vary in different individuals, and in the same at different ages and different seasons. It is not improbable that these differences have caused it to be multiplied into several species; and the same has probably been the case with some of the others. This one is very tenacious of life after it is out of the water, which is accounted for by the smallness of the gill openings, and the mucous covering of the skin. We have elsewhere had occasion to remark (in the article Anabas) that as long as the gills of a fish can be kept so moist that all their filaments are covered with a coating of water, the fish will, unless for the drying of the surface of its body, live and breathe out of the water. This is a proof of what was said in the article Air, about the impossibility of fishes decomposing water so as to obtain the oxygen out of *its composition.* They merely breathe the air which is contained in the water in a state of mechanical mixture; and thus if there is a complete coating of water through which the air must come to the breathing apparatus, it matters less whether that coating be the fiftieth part of an inch or fifty feet, so that it is entire over the whole apparatus, and no air can reach that but through the aqueous coating. Those surface fishes which pant and die almost the instant that they are exposed to the air, always have the gill openings large and free, and of course the air speedily so dries the gills that they are unfit for performing their function. We shall notice only one other species.

Blennius pholis (common blenny, viviparous blenny, or viviparous gunnell of some authors). This species has no appendages to the head, and the crest is little elevated, though it is subject to the seasonal bloom of colour already alluded to. This species has the gape wide; the upper jaw advanced a little in front of the under one. The teeth pointed, strong, and closely set. The opening of the nostrils is in a sort of tube; the facial line very vertical; the eyes large and prominent; and the irides of a reddish colour. The cavity of the belly is very short. The dorsal fin has only one lobe; but there is a depression in



Blenny.

the middle. The general colour is olive brown marbled with paler spots and black, some of which are very minute; the under part is yellowish. It attains the length of twelve or fifteen inches.

This species is common upon most parts of the

British shores; and is known by various local names, such as the "guffer," the "eel-trout," and the "green bone," the last from the circumstance of the back bone becoming green when the fish is boiled. It is also called the "stone perch," though it has none of the characters of the perch family.

During great part of the year it lurks under stones in the shallows, and especially near the estuaries of rivers; and it is supposed sometimes not to retire with the tide, but to conceal itself under stones till the water return. When thus in the shallows, it is very frequently seen, and not very difficult to approach; but if caught, it glides through the fingers with more facility than even the eel, and it is on this account that it is called the eel-trout. In summer, about the time when the wild cruciferæ come into bloom in the corn-fields, it takes to the water and becomes a swimmer; but remains in the bays and estuaries as a surface swimmer. It is there readily caught with a baited hook, so much so that it is often an annoyance to those who fish on the grounds which it frequents in the hope of meeting with something better; as it takes the bait so much more readily than those, that it spoils the sport of the summer fisher in those safe and quiet places. When caught it is of little or no use, as its flesh is meagre and tasteless. It is ovoviviparous; and the fact of its being so has been long known.

The blennies appear a very useless genus; but they are curious in their forms, and they hold a particular place among the finny tribes. They are, strictly speaking, shore fishes: yet from the fact of some of them appearing only occasionally upon our shores, it is probable that they are, at some seasons much more discursive than is generally supposed, for at the places where the stragglers are found, there are more in the same settled habitations among the sea weed and stones, as they resort to where they are known to be resident.

Of the nearly allied species, many of which have been described as blennies, though they differ from them in their leading characters, some more, some less, there are some which are found in the British seas, and others only in the southern parts of the world. Of these some grow to the length of two or three feet; but even these are of little value in an economical point of view. See Myxodes, Salarias, Clinos, Cirrhibarbus, Murœnoides, Ophistognathus, and Zoarcis for the particulars.

BLEPHARIS. A genus of spinous-finned fishes, belonging to the mackerel tribe, and to the family or sub-division of that tribe, to which Cuvier has given the name of *Vomer*. The whole of the spinous-finned fishes are very difficult of arrangement, as the form and position of the fins, the usual grounds of arrangement in fishes, cannot be so readily applied to them as to the soft-finned ones. The mackerel family are all surface-fishes, rapid swimmers, voracious feeders, altogether very active in their motions, their flesh in general wholesome and agreeable to the taste, but in some of the species rather dry. See Scomberoidæ.

Linnæus and Bloch included the whole of the division *Vomer* in the genus *Zeus* (the dory), but Cuvier has separated it, and formed the very various fishes of which it is composed, into six sub-genera, of which *Blepharis* is one. The bodies of all these fishes are remarkably compressed; so much so, that though, when seen from above or below, they do not appear thicker in proportion to the length, than fishes of more ordinary form, they appear very deep when viewed on the side.

It is worthy of notice that while many of the fishes which remain near the bottom in the shallows or on the banks, have the body so much depressed or flattened, that they get the common name of flat fish; many of those which inhabit near the surface have the enlargement in depth, and the compression laterally. The flat ground fishes are all soft-finned, and have the fins often margining nearly the whole body, and the skin and fins containing a great quantity of gelatine; but they are, in general, not much produced, and no portions of them project far beyond the rest. In these flat fishes, though the body is depressed as regards the position in which it is usually carried, it is really compressed; and the lines on which the fins appear, are not the lateral lines of the fish, but the dorsal and ventral lines, in the same manner as those to which the fins of fishes which are not flat, and all the laterally compressed ones, such as the genus under consideration, are attached.

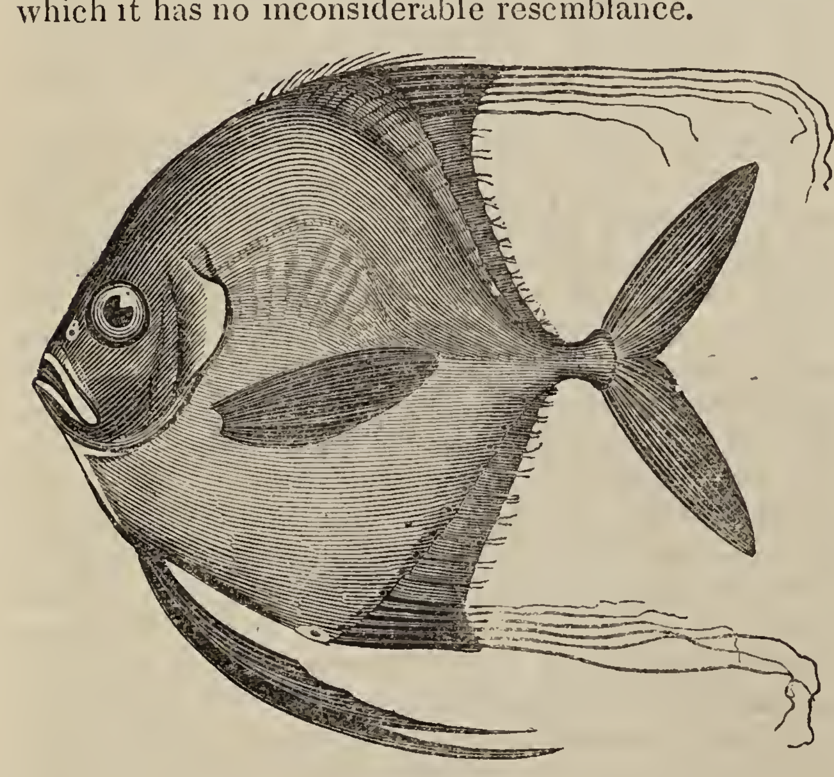
Thus, the flat fish and the compressed fish are both flattened in the same way with reference to the posterior portion of the spine and the way in which the muscles act in giving motion to the body,—only the flat fish carries itself with the greater portion of the body borne with the side under, while the compressed fish has the belly in that direction. A twist of the head brings the eyes to one side of the body, and gives an oblique position to the mouth, so that, in looking to a sole, a flounder, or a turbot, a line passing through the eyes will be seen to be parallel to the mesial plane of the body, or the plane passing through the ridge of the back and the centre of the belly, and not at right angles to that bone, as in other fishes, and indeed almost every other animal.

This is not the proper place for inquiry into the purpose which this very peculiar form of the body answers in the economy of these animals (see Flat-Fishes); but still there is so much both of resemblance and of contrast between those fishes which have the body compressed, and swim with it on the flat, and those which swim with it on the edge, that much information respecting their habits might be drawn from it. Indeed, there is reason to suppose that, if this were properly studied, it might explain the different uses of the several kinds of fins and of scales to fishes in the operation of swimming.

Both descriptions of animals, though they belong to very different parts of the system, according to the characters upon which it is at present founded, have yet some very striking coincidences. Both are smooth fishes, either with no perceptible scales, or with the scales so very small that they are of comparatively little use in swimming; in both, the flesh is wholesome and agreeable; and both, from the smallness of the scales, have to depend wholly on the fins and the flexures of the body as the means of progressive motion. But the fins of the flat fishes are small and soft, and the chief action of the body is in the vertical direction, or that which acts more powerfully in ascent and descent than in progressive motion. The fins of the compressed fishes which swim with the body on edge, are, on the other hand, produced, and have strong spinous rays, while most of the division *vomer*, and the genus *blepharis* in an especial manner, have filaments attached to some of the fins. Farther, the flat fishes have the colour and texture which answer to those of the back in ordinary fishes, extending over one side of the body, from the dorsal line to the vertical, and the colour and texture which answer to those of the belly extending over the other side, without any very strongly-marked lateral line at the turn of the muscular plates in either. Although these two surfaces are in reality, and with reference to the spine and the muscles, the two lateral sides of the fish, yet in their covering they have thus the appearance of being, all along, the one the back and the other the belly. In the compressed ones which swim on the edge, as blepharis does, the colours of the upper and under parts, the back and belly, answer to those of ordinary fishes. The lateral line is, in many species, distinct, and in some it has a remarkable curvature upward, at the place where the cavity of the fish is situated. It should seem, therefore, that the coverings of the upper and under sides of fishes have reference to the position in which they are carried, and not to the parts of the fish upon which they are placed; while the way in which the largest diameter of the section is placed has reference to the place which the fish holds in the water, and the style of swimming.

The compressed fishes which swim on edge, all inhabit near the surface, and they are rapid swimmers, and rather discursive in their motions; whereas those which swim on the flat of the body keep nearer the bottom, swim slowly, and do not range far. The fish which swims on edge, has the tail much more effectively formed as a swimming organ, and the fins much more firm as well as much more produced. The filaments which are attached to the fins also appear to be of use in steadying the fish, and preventing it from swinging or turning on the flat as it swims, which it would have a tendency to do, if it had not these appendages to steady it.

There is but one species of *blepharis* (the name of which by the way is the Greek for filaments, *ciliæ*, the hairs of the eyelids). It is found in the tropical seas only, and principally, we believe, in the neighbourhood of the West Indian Islands, in some of which it is called "the shoe maker," or the "cobler-fish," in allusion probably to the thread-like appendages to the fins. It is the *Zeus ciliaris* of Bloch, but it has probably been confounded with some oriental species to which it has no inconsiderable resemblance.



Blepharis.

The external characters, as may be seen from the figure, are: the body much compressed and elevated; the profile in nearly the ordinary position, the muzzle not so protractile as in the dorey, the ventral fins very large, the anal and second dorsal with very long filaments, and the spines of the first dorsal short. The large ventral fins no doubt co-operate with the filaments of the anal and the dorsal in enabling them to preserve the position of their short and thin bodies. They, and indeed the whole of the division to which they belong, are very curious fishes.

BLESSED THISTLE is the *Centaurea benedicta* of Linnæus. An ornamental annual, indigenous to Spain, and belonging to the natural order *Compositæ.*

BLETHISA (Bonelli). A genus of coleopterous insects belonging to the section *Pentamera Adephaga*, family *Carabidæ*, and sub-family *Elaphridæ*, and nearly allied on the one hand to *Elaphrus*, from which the species are distinguished by the somewhat square thorax, and by the elytra being deeply excavated, and on the other hand to the *Pelophila* of Dejean (of which genus an individual has occurred in Ireland), from which it is separated by its slightly dilated anterior tarsi in the males. The species of this genus are few in number, Dejean only recording three, all of which are natives of the North of Europe: one only has, however, occurred in England, the *Carabus multipunctatus* of Linnæus, and which is found in damp situations running upon the mud of ponds. It is a handsome species, about half an inch long, of a fine brassy colour, with a brighter margin, and the elytra have four rows of deep impressions.

BLETIA (Ruiz and Pavon). A family of herbaceous, tuberous rooted perennials, natives of China, West Indies, &c. Class and order *Gynandria Monandria*, and natural order *Orchideæ*. Generic character: sepals of calyx, spreading, nearly equal; labellum open, cupped, or a little tubular, clasping the base of the column, or spurred, apex dilated, somewhat lobed and undulating; column cylindrical, curved and channeled before, apex obtuse, anthers terminal, covered with a lid. There are nine species of Bletia, all handsome, some of them splendid. The *B. Tankervilliæ* was the *Limodorum Tankervilliæ* of the *Hortus Kewensis*, and has had various other names by different botanists; it is certainly one of the finest of the Orchideæ.

BLIGHIA (Hortus Kewensis). A single African tree, named in honour of Captain Bligh, who first carried the bread-fruit to the West Indies. Class and order *Octandria Monogynia*, and in the natural order *Sapindaceæ*. Generic character: calyx five-parted; petals furnished with vaulted scales at the base; disk fleshy, crenated, bearing the stamens; filaments thickest in the middle; anthers twinned, two-celled; style scarcely any, stigma simple; fruit fleshy, six-lobed, three-celled, three-valved, one seed in each cell. This is called the Akee tree in the West Indies; the arillus of the fruit being richly palatable.

BLIGHT. A term of very common occurrence, implying the sudden appearance of great numbers of minute grubs, especially upon fruit trees in the spring, attributed by persons who have not investigated the nature of insects, and their various transformations, to the operations of particular winds; thus, of an easterly wind, we often hear it said that it is a blight, or that there is blight in the air. In like manner, the plant-lice upon rose trees and other plants, are termed blight. Now, if it be granted that the wind has any thing at all to do with the matter, one of three things must occur: either the blight must be spontaneously generated by the action of certain currents of air, or the eggs from which the various blights or grubs are produced must be floating about in the air, or, lastly, the prevalence of certain winds must have an influence in giving birth to animals enclosed in eggs deposited by parent insects upon the spot upon which the blight is seen. As the first of these propositions depends entirely upon the doctrine of equivocal generation, a doctrine which is exploded by every naturalist (except such as endeavour to supply from their own prejudiced imaginations those points in the economy of nature which the minuteness of the objects or the difficulty of their investigation have rendered it next to impossible to prove by actual examination), we shall enter into no attempts to refute it, merely observing that in every instance amongst insects where an attentive observation has been made upon the nature of their production, it has been found that the birth of every individual has been the result of the impregnation of the female and the subsequent development of eggs, which are either hatched after deposition, or within the body of the parent. The second proposition, however, that the eggs are carried about in the air, merits more particular observation, as it depends upon a theory adopted by many distinguished writers. Thus, Dr. Good observes, " That the atmosphere is freighted with myriads of insect eggs that elude our senses, and that such eggs, when they meet with a proper bed, are hatched into a perfect form, is clear to any one who has attended to the rapid and wonderful effects of what in common language is called a blight upon plantations and gardens," —and in like manner the eloquent Chalmers, discoursing upon the boundlessness of the creation, observes, " About the time of the invention of the telescope another instrument was formed, which laid open a scene no less wonderful, and rewarded the inquisitive spirit of man. This was the microscope. The one led me to see a system in every star, the other leads me to see a world in every atom; the one taught me that this mighty globe, with the whole burden of its people and its countries, is but a grain of sand on the high field of immensity, the other teaches me that every grain of sand may harbour within it the tribes and the families of a busy population. The one told me of the insignificance of the world I tread upon, the other redeems it from all its insignificance, for it tells me that in the leaves of every forest, and in the flowers of every garden, and in the waters of every rivulet, there are worlds teeming with life, and numberless as are the glories of the firmament. The one has suggested to me that beyond and above all that is visible to man, there may be fields of creation which sweep immensity along and carry the impress of the Almighty's hand to the remotest scenes of the universe, the other suggests to me that within and beneath all that minuteness which the aided eye of man has been able to explore, there may be a region of invisibles, and that could we draw aside the mysterious curtain which shrouds it from our senses, we might see a theatre of as many wonders as astronomy has unfolded—a universe within the compass of a point so small, as to elude all the powers of the microscope, but where the wonder-working God finds room for the exercise of all his attributes, where he can raise another mechanism of worlds, and fill and animate them all with the evidence of his glory." This is a beautiful view of the subject, and far be it from us to lessen its effects, by limiting any of those fine ideas to which it will naturally give rise. Still we are compelled, to a certain extent, to narrow its acceptation. That the microscope discovers an infinity of animalcules, far too small for our unaided sight, is not to be doubted; and that numberless others, which the microscope cannot reach, exist, is perhaps equally certain; but it is in *fluid* matters that the most minute of these creatures are found. If they floated in the air, or if they pervaded all substances, it cannot be doubted that the field of a high-powered microscope would necessarily discover some of the larger of them wafted about within its focus, when " nothing but emptiness" was placed within its power. But this is not the case; an observer may watch all day, and he will not see any aerial monster, invisible to human unassisted sight, pass across his field of view; but let him place the smallest drop of fluid in the focus of his microscope, and it will be found to swarm with life, so as fully to warrant all the eloquence which Dr. Chalmers has used upon the subject. In this point of view, therefore, the question assumes a high degree of importance, as connected with a circumstance which has been repeatedly noticed in various works relative to that dreadful scourge which unfortunately appears to have taken up its abode with us—we allude to the cholera morbus. By some writers this pestilence has been considered as attributable to swarms of insects. Thus it is recorded, as a curious fact, that its arrival at Moscow was preceded by a cloud of little green flies, which darkened the air, and covered persons from head to foot when they entered the streets, which flies, by some medical men (see Neale on Animate Contagion), have been thought to have a considerable influence in propagating the disease. On the other hand, it was stated in the public journals, that in some places flies had entirely disappeared on the breaking out of this plague; and yet, within a very few weeks, it has been mentioned in the American papers, that the flies which, at the period of the former breaking out of the disease, had disappeared, were now swarming. Now, all these seem to have been circumstances of not very extraordinary occurrence, which have, nevertheless, been seized upon by persons whose attention has been more especially directed to the phenomena of natural objects for the purpose of discovering the nature of the disease in question. Thus the flight of myriads of green flies was evidently a swarm of aphides, similar instances of which, unattended by the disease in question, or any other malady, are recorded in works upon Entomology. That such view of the subject is not far from correct, may be presumed from the fact, that the appearance of the disease has not, except in the few recorded cases, been attended by those flights of insects; whereas, had they been the real causes of the cholera, they would necessarily have been noticed wherever this dreadful malady had shown itself. Other medical men, however, entertained an opinion, which seems to be perfectly analogous to the supposed cause of blight. Thus Dr. Hahnemann considered that the disease was caused by insects, but which are invisible to the naked eye, and which adhere to the skin, hair, and clothes—a perfect *blight*, in fact, according to the most approved acceptation of the word. Let us, however, look a little further into the nature of the blight of our fruit-trees, and we shall perhaps be enabled, by analogy at least, to demonstrate, that the fearful disease in question does not originate in the manner above noticed.

Now, if we carefully feed the blight of an apple-tree, for instance, under a glass, we shall find that it ultimately becomes a small moth, which moth, after and even without impregnation, if it be a female, deposits eggs of a sensible size, not fertile, of course, in the latter case. Setting aside, therefore, other considerations, it cannot be doubted, that if these eggs were carried about by the winds, they would be evidently visible; but no such thing occurs; all that is perceived is "an easterly wind, attended by a blue mist," or "a peculiar haze or mist, loaded," as it is asserted, "with poisonous miasm." And the same may be said of the eggs of other species of blight, that is, of insect blight, even of the aphides. They are all sufficiently large to be visible by the microscope, if they were wafted about in the air, and yet none are to be perceived. Moreover, it is to be observed, that in the case of the blight of our fruit-trees, it is perfectly well ascertained, that the eggs from which the grubs are produced in the spring are deposited in the preceding autumn; whence it would follow, that if they were merely dropt into the air, they would necessarily be floating until the following spring, during six months wintry weather—a rather improbable thing, we should suppose, regard being also had to the great specific gravity of eggs of insects.

But this hypothesis, in several other points of view, seems equally irreconcileable with nature. If the eggs from which blight is supposed to be produced were really floating in the air, it would necessarily follow that immense numbers of such eggs must perish, such only surviving as happened to be wafted to those particular parts of a tree to which it is to be observed that the blight attaches itself; this will invariably be found to be the tender young shoots and buds. But this supposition is so perfectly at variance with that beautiful regulation in nature by which nothing is made in vain, that it will only be necessary, for its more satisfactory refutation, to notice the great anxiety and care which parent insects invariably manifest in depositing their eggs, even where they are compelled, for the fulfilment of this object, to visit an element totally different from that in which they are accustomed to pass their perfect state; a single example of which may be noticed in the dragon-fly (*libellula*), the females of which may constantly be observed standing upon the edge of a pond, &c., thrusting their long abdomen a considerable depth into the water, in order to place their eggs in security, in such situations where the young, when hatched, will find a due supply of food.

But it may be urged, that although placed in such particular spots by the parent insect, the eggs producing blight are liable, during the six months which are passed in this state, to be carried off by the violence of the winds and weather. If this, however, were the case, all the anxiety of the parent fly would be in vain. Nature has consequently provided against this, by endowing the parent fly with the instinct to cover the eggs with various kinds of envelopes, either with webs spun by themselves, or with materials derived from their own bodies, as in the case of various moths, &c., or from adjacent substances. Most commonly, however, the female leaves her cluster of eggs without any other covering than the varnish with which they are besmeared in their passage from the oviduct, by means of which they are not only firmly gummed to the substance upon which they are placed, but are also defended from the cold and winds of winter, so as to allow the young grubs to burst forth into life and activity in the following spring, carrying destruction in their path.

Thus have we, as we trust satisfactorily, shown that the eggs from which the various kinds of blight are produced, do not float at random in the wind, and that there is not, as it is said, "a blight in the air." We have now, therefore, to consider the prevalence which certain winds appear to have in giving birth to grubs enclosed in eggs deposited by the parent insects upon the spots in which the blight is observed, and here the common observation of mankind, although employed upon effects instead of causes, must be allowed to have some weight. It is not perhaps to be doubted, that the action of certain winds, depending upon variations in temperature, and other metereological changes, which may be even entirely unappreciable by our most minute observations, has the power of bringing forth what is termed blight, the instantaneous appearance of which in vast numbers, at the same time, and the consequent ravages which they occasion being noticed by the commonest observer of nature; hence it is that the sudden appearance of these destructive myriads is at once attributed to the wind, to which, in fact, it is partially attributable, but which, amongst the ignorant, at once obtains the credit of generating and depositing the blight. It has been generally considered by naturalists, that the eggs deposited in the preceding autumn, having been laid at the same time, and exposed to similar atmospheric changes, are necessarily hatched at the same time in the spring, when, in fact, intelligence is obtained by the enclosed grubs, from the peculiar state of the air, that the fitting time for bursting forth from the egg is arrived. This opinion, which, in fact, is by far the nearest to truth of all which have been hitherto given, does not, however, account for the great size which the supposed newly-hatched blight are observed to have attained. The subject, however, has recently been submitted to a minute series of observations by Mr. Lewis, whose researches will be found detailed in the first number of the Transactions of the Entomological Society.

We have said, that swarms of plant-lice upon rose-trees, and other shrubs, are often considered as blight, and intimately connected with them, as well as the preceding subject, is what is termed honey-dew, respecting which Dr. Good observes—"I have seen, as probably many who read this work have also, a hop ground completely overrun and desolated by the aphis humuli, or hop green louse, within twelve hours after a honey-dew (which is a peculiar haze or mist, loaded with poisonous miasm) has slowly crept through the plantation, and stimulated the leaves of the hop to a morbid secretion of a saccharine and viscid juice, which, whilst it destroys the young shoots by exhaustion, renders them a favourite resort for this insect, and a cherishing nidus for myriads of little dots that are its eggs." Now, the opinion which we have already given as to the action of peculiar winds upon the blight-eggs will enable us satisfactorily to explain the sudden appearance of the aphis humuli within so short a time after the appearance of this "peculiar haze," without referring it to the circumstance of the eggs of these insects being carried about by such wind. Indeed, it seems evident that Dr. Good considered that the action of the "peculiar haze" was directed only to stimulating the leaves of the hop to a morbid secretion, which it is not to be conceived would have the effect of producing of itself a swarm of aphides. We will not, in this place, enter into the inquiry, whether the wind in question might not have a twofold influence both upon the insects' eggs and the leaves of the plant, nor will we stop to decide whether the saccharine and viscid juice be a morbid secretion of the leaves, or merely the excrementitious matter of the aphides, the eggs of which had been alone influenced by the action of the wind, and hatched, our object in this article being chiefly directed to an explanation of the sudden appearance of insects, termed blight, and which we trust that we have succeeded in giving, by stripping the subject of the marvellous, and tracing its causes to the well-known rules of insect life. We will only, in conclusion, remark, with reference to the latter part of our observations, that so completely are the aphides dependent upon atmospheric peculiarities, that in the present remarkable season, although these insects swarmed to so great an extent in the spring months, as entirely to stop the growth of the roses, yet, throughout the summer, and up to the present time (September), we have not been able to meet with specimens sufficient to prosecute experiments upon their habits and economy.

BLISTER-FLY. See Cantharis.

BLITE. An English weed, the *Amarantus blitum* of Linnæus. A small inconspicuous plant, usually found growing on dunghills.

BLOOD, *in physiology*, the vital fluid of animals, or that by which they, in all their varieties, are distinguished from the other kingdom of organised beings, the vegetable tribes. It is written that "the blood is the life," and though this must be regarded as a figurative expression, as must also those other cases in which "blood" is used as the designation for different tribes or families of man, or for different races of other animals, yet there is no animal life without blood; the nature and action of this fluid are intimately connected with the development of life, and also of the living organisation and the quantity of living action; so that the blood is more typical of life and living action than any other part of the animal.

It may be considered as the primary or rudimental matter, out of which all the other parts of an animal are formed at the first, and the grand means by which they are kept in repair; and as we have no other abstract notion of life, taken in so wide a sense as to include all living creatures, but motion, or to speak more correctly self-motion, so we find that the energy of life is always in proportion to the degree of motion in the blood. The act of turning into blood is, thus, the specific act of animalisation, the ultimate part of the process of assimilating; and in the formed animal, after it begins to subsist upon food of whatever kind, there is no changing of any sort of aliment into any one structure or part of the animal, without first turning that substance into blood. Nor does it appear that there is in the mature animal, whatever may be its age, any means by which the food, even if it is the blood of another animal, can be converted into blood of the feeder, without a direct mixture with the blood as already formed. Some account of the progress and changes of the food, from its first entering the alimentary canal to the final discharge of the chyle into the vein by the thoracic duct, will be found in the article Assimilation. But, as there stated, the prepared food carried to the vein by this duct, is not only not blood, but unfit for mingling with that blood which goes directly to the nourishment and support of the animal frame, till it has been first sent to the lungs and undergone the action of the air in respiration there; and, though so far as we know, the experiment has not been made, it is highly probable that if the contents of the thoracic duct were mixed directly with the blood in the systematic arteries, or that which goes directly to the different parts of the animal, it would contaminate that fluid, or become a poison.

In all cases in which animal poisons animal, the blood is the part more immediately affected by the virus. The direct poisons which are secreted by healthy animals are deadly only to the blood, taken into it by direct injection or by absorption—which probably takes place to some extent throughout the whole venous system. There are some animals, and animal substances which, taken into the stomach act as poisons; but those which do so when killed in a healthy state, and not subjected to corruption afterwards, are comparatively few; and the appearances which the body presents when so poisoned, very much resemble those which are consequent upon death from animal virus, whether the venom of animals naturally poisonous, or the morbid matter of disease or putrescence. It is the blood which is tainted, and the primary appearances are spots and discolorations on the surface of the body, which if the morbid matter is not too powerful in its operation, and the body is capable of re-acting, often proceed to suppuration, in a manner similar to those diseases which are understood to arise from inoculation.

Poisons from mineral substances, and also some of those from vegetable ones, give rise to similar appearances; but these are, in most cases, if not invariably, secondary, and induced by a disease in the blood, consequent upon the specific action of the mineral or the vegetable poison. The specific action of the mineral poison is, as we might naturally expect, analogous to the ordinary action of mineral upon mineral, that is, it is chemical, it corrodes, or decomposes; and up to a certain point, the action of even the most deadly mineral poison may be not only harmless, but positively salutary. Arsenic itself is, in skilful hands, a very valuable medicine; and so are iodine and prussic acid, though these last are to be regarded as vegetable substances rather than minerals.

The specific action of vegetable poisons, considered strictly as such, is on the sensibility of the animal, or as it is usually expressed, on "the nervous system;" though as the vegetable is not so much removed from the mineral as the animal is, many vegetable poisons have also a corrosive or, as it may be termed, a mineral or chemical action. These poisons, like the mineral ones, are harmless or medicinal, up to a certain point; and those deadly effects may, in most cases, if not in all, be said to be secondary. But, as they are still organic substances, or the products of organisation, they approximate more nearly to direct poisons acting upon the vital fluid than the mineral ones, though their chemical effects are, for the same reason, not so violent. Hence the common notion that active or drastic vegetable medicines are safer than mineral ones of the same power, is both a prejudice and an error; and one which, in the hands of ignorant and impudent empirics (and they cannot be the one without being the other,) is productive of incalculable mischief to the credulous.

Animal virus is, on the other hand, never medicinal; and no active animal substance can be employed in the cure of disease, even in the smallest doses. Animal substances are however much more easily assimilated than vegetable ones; and therefore they can be advantageously employed in regimen, and also mechanically in blunting the acridity of other substances. But wherever an animal substance acts upon the body in any more vigorous manner than that of relieving some of the working structures, or of shielding them from the action of some other deleterious substance, it always acts as a systematic poison. Farther, where any part of the body is destroyed by the action of a distinct animal virus, whether that virus is one of inoculation, or of a disease originating in the system, the part so destroyed is never reproduced; and even a wound which heals by inflammation and granulation, and not by the first intention, always leaves a scar. The case of some putrid diseases attacking the animal system only once, and being mitigated by inoculation, or prevented by inoculation with the virus of another disease, as in the prevention of human *variola* by *vaccination*, whilst the body, in other cases, remains as subject to a second attack of the disease as it was to the first one, is an anomaly which we are not very able to explain, and which belongs to the medical rather than the physiological consideration of the animal economy. But the effects of those diseases of inoculation, whether with virus obtained from the same or a different species of animal, have the same effects, where they destroy ever so small a portion by suppuration. The scar which they leave is never like the scar of a common wound, or that produced by the application of nitrate of silver or any other caustic. Even in the case of vaccination, which may be considered as the most simple of the whole, if the scar which is left be smooth, like that from a common wound or other topical injury by which the system is not affected, the certain conclusion is that the operation has failed, and must be repeated; and the honeycombed appearance of the scar, as if part of the substance were eaten away, is the best, and, after the inflammation is gone, almost the only certain evidence which we have of the success of the operation.

To those who are not much in the habit of reflecting upon such subjects, it may seem that these observations, or the points to which they are directed, have little to do with the popular history of animated nature. But so far is this from being the case, that it is for want of attention to those general means of distinguishing the several kingdoms of nature from each other, and of knowing and describing each by something more profound and permanent than mere external appearances, that people in general take much less interest in the study of nature, and derive much less pleasure, and even profit, from it, than it is calculated to afford; and also, that those who, with but little of the general principles of philosophy, and consequently small capacity for comprehending the action of general principles, drudge at the details of some one department, till they become technical adepts therein, and obtain such renown as this minor species of learning is calculated to win, sometimes jumble together the primary distinctions of kingdom from kingdom, vitiate the whole subject to the ignorant, and make themselves most lamentably ridiculous in the eyes of the few who are better informed.

The action of mineral upon mineral, vegetable upon vegetable, and animal upon animal, may in so far help us to the knowledge of each in itself; but we can see the limits of each, and understand their operations fully, only by attending to their action upon each other. Now, if the preceding sentences of this article have been read with even a moderate degree of attention, it will be seen that, when we take the action of each of the three upon the animal system, in those cases in which that system itself is most exclusively passive, it follows that, on this account, the nature of the one which is active can be best ascertained. But, the only cases in which the animal structure is passive to the action of minerals and vegetables, are those in which these act as poisons, and a very little reflection will show that such must be the fact. A mineral acts only as matter—a vegetable only as organised or growing matter, which, when it ceases to add to its volume in some way or other, ceases to perform the functions of an organised body—but in the animal there is a distinct power, apart from growth or addition of substance, which, among its other functions, renovates or replaces the old matter, which has become unfit for its economy, by new matter obtained through assimilation; and while the animal continues capable of effecting this renewal it lives, even though the body should be gradually diminishing in volume, as is the case in the decrepitude of man, and of some other animals, when allowed to perish by natural decay. There is nothing similar to this in the other kingdoms of nature. When a mineral diminishes in size, it is by decomposition, or by a closer union of the parts; and though there are apparent decreases in the volumes of vegetables, these take place only when the proper vegetable action ceases. When the heart, or oldest part of an aged tree, decays, the portions which remain alive make their seasonal additions of wood in the same manner, although not always to the same extent, as if the whole tree were in action. So also, when the bleak winds appear to "eat the grass off the fields," it is no more than a temporary fainting of the plant, so to speak, which, if carried beyond a certain limit, would destroy its action altogether.

Thus, if we would characterise and distinguish the three kingdoms of nature by their actions, which are, for many reasons, the best means for such a purpose, we must say that the vegetable is more active than the mineral, and the animal more active than the vegetable; and therefore, when the action between one of one kingdom and one of another is neutral, that of the more active must so far predominate over that of the less, as to give its own character both to the mode of action and to the result. The victory, so to speak, is so decidedly on the part of the more energetic of the two, that it may be said, and in common language it is said, to *use* the other.

We have seen that a mineral acts upon the animal body as if that also were a mineral; and though we have but little knowledge of the mode in which vegetables act upon each other, yet they exert an action upon the animal system so different from that of poisonous minerals and animal virus of whatever kind, that it may be considered peculiar and characteristic. Even in the case of those "tree-nettles," and other stinging plants, the action of which upon one part of the body is followed by a rash or a swelling of other parts, or even of the whole, the effect appears to be secondary, more confined to the surface, and less affecting the general system than the animal poisons. A numbing or suspension of the sensal energy, rather than a corruption of the system through the medium of the blood, appears to be the effect even of these. When, however, one animal acts upon another, not by specific organs, which have a mechanical effect, but physiologically, it acts on the blood.

As life is known to us only as motion, so the blood of an animal is the indication of life only in so far as it moves or circulates. This motion is faster in some animals and slower in others; there are some in which it is hardly perceptible, and there are others in which (as in the case of hybernation, and the more temporary one of fainting) it appears to be merely suspended. But when these suspensions take place, whether for a longer or a shorter period, all the other functions of the animals are suspended also. The first sign of life in the hybernating or the fainting animal is a renewal of the circulation.

Thus we are warranted in concluding, that the circulation of the blood is the original and characteristic function of animal life. Nor are we left to inference on this point, though inference here comes as near to demonstration as it possibly can come. It is true that, in the perfectly developed animal, all the functions, and all the systems by means of which those functions are performed, are so intimately connected, form so much parts of one whole, which can exist only as a whole, that if any one of them is deranged, it deranges all the others. But, when we examine the animal in its rudimental state, and trace its progress towards maturity, we find that the system of the blood is in all cases the first which is developed. When we say " in all cases, " we of course mean all those which observation can reach, for there are some which we have no means of observing, and others which, from the colour of the blood, we are unable satisfactorily to observe. In the case of all animals which have red blood, blood and blood-vessels are the first indications of rudimental life. This is very apparent in the eggs of birds; and, though there observations are not so easily made, the same is the case in the eggs of fishes. When the rudiment of the chicken is first discoverable, it is as a heart and blood-vessels; and, as was long ago observed by Haller, these can be distinctly seen before there is a single vestige either of brain or of lungs. This first rudimental stage may be considered as the very lowest state of animal life, the simplest one of organisation in the chicken; and as there are different degrees of perfection, or, to speak more accurately, of organic development in animals, according to the different parts which they are to act in nature's economy, it is not only perfectly consistent, but even in strict accordance with what we observe of that economy, that there are animals which never get beyond this first rudimental stage of organisation. But we can trace nothing of the kind in vegetables, whether in their rudimental stages, or when they are most fully developed. Therefore we have the character of the animal, as such, stamped at the first development of the germ, and in the simplest of the kingdom: or rather, that character is of itself the development—the animal as distinct in kind from every other production of nature. Therefore, we must discard all the attempts which have been made to confound the physiology of plants with that of animals, and all the conclusions which have been verbally drawn from those attempts, as equally repugnant to rational theory and practical observation, and wholly unworthy of any one having the slightest pretensions to philosophy.

We are in the habit of saying that certain systems or structures of animals, or that certain animals altogether, are organised upon particular parts, as that vertebrated animals are organised upon the spinal column, that other races are organised upon the alimentary canal, and that others again are articulated upon the crust or the integument. In as far as the action of the animals is concerned, these references of particular organisations and marks of organisation to certain structures, as organs or bases, are no doubt true; but it is to be understood that the primary and grand organisation of every animal is upon the system of the blood, as that in all the species is the universal elementary matter out of which every animal structure and animal whatever is formed. We know not how far absorption at the surface may, in some cases, assist internal assimilation, or even upon emergency render it unnecessary, just as we do not know how far the application of air to the surface of the blood vessels may assist the lungs or gills, or even act as a substitute for them in respiration; but we cannot imagine a case in which the body of an animal can either grow or be nourished without a circulation of the blood. We have reason to believe, too, that, in all cases, the circulation of the blood, without which there can be no action of animal life, is carried on by muscular exertion, over which what is called the will of the animal has no controul;—and, by the way, this furnishes an unanswerable argument against the existence of *will* as usually defined by writers on physiology, whether animal or mental. Those actions of the animal frame which are supposed to result from the exercise of this imaginary power of will, are all immediately muscular, or ultimately resolvable into muscular action of some kind or other; for even the most doting believer in this self-contradictory notion never went so far as to alledge that he could " will a thought;" and yet as all human action is the result of thought, even in those cases which are called " thoughtless," there is no need for inventing an original power, which demonstratively has no concern with the origin of the business, to bring up that portion of the rear which must follow the unwilled part. As well might he who has the fountain say that he wills the stream, or he who has the tree claim the power of willing the apples. The cause of the outward act, whether in man or in any other animal, is the inward impulse; and though we may not be in every or in any case able to trace it to its primary origin, no finite being can create the impulse any more than it can create itself. As the animal impulse must be supposed to be always stimulated by something material—something which has an entity or separate existence, and not by a relation which is cognisable by mind only, we may naturally suppose that it begins with the development of the vital system, in the first pulse of the rudimental heart; but that there is not any external knowledge of it till sensation, either general or located to a particular organ for a particular use, connects it with the external world.

In this, as well as in every other point of view, a knowledge of the blood and vital system of animals, as their grand characteristic, becomes of the highest importance, not only to the proper understanding of all the other parts of the animal economy, but in itself as one of the most interesting subjects in nature, and one in which the Divine wisdom and power are more strikingly displayed than in any other part of the material creation. We can in part understand the mechanical structures of animals, and in part imitate them; but when we come to consider the blood, we may well be lost in wonder. We find it primarily, and as we may say, in vessels that do not belong to the new animal, when that animal is in that twilight dawn of its being, the mysterious darkness of which no light of human philosophy can dispel or even penetrate.

This blood is constant to the grand division, the class, the group, and all the minor subdivisions of animals down to the species and the variety; but in no one animal, excepting those which are propagated by what may perhaps be considered as mechanical divisions of the bodies of existing ones, can the blood of one generation be considered as a portion of that of the preceding one. In all other cases there is a line of separation, a mysterious boundary, wholly beyond the reach of human ken, which makes the young, whether viviparous, oviparous, or of that mixed mode of production which partakes of the characters of both, a distinct and separate animal: *of* the parent certainly, but not *a part* of the parent. The blood is new blood; and because the mystery of the transformation will not unveil itself to the most searching eye of philosophy, every new animal which is brought forth, be the mode, as far as observable, what it may, is as much a miracle to human understanding as the production of an animal where parent there is none. The thousandth, the millionth, the *n*th generation (that of which no arithmetic can express the number) thus carries the mind as necessarily and immediately to the Creator as the consideration of the primal parent which His creative fiat spake into being. We cannot in this or in any other case follow the chain of natural causes till we come to the primary link—the part, so to speak, at which the springs of life are touched by the immediate finger of God; but if we follow the contemplation in the true spirit of rational and at the same time devout philosophy (and here these are not two), we feel something more than mortal beam upon the mind. But it is a glory too radiant for material eyes, and will not remain till we question it; yet it leaves a hope which takes the grief out of all the vicissitudes of our mortal life, and destroys all apprehension of its close.

This is the grand climax of the study of the blood, and indeed of the whole active principles of the animated tribes; but the steps to it are also pleasant as well as profitable, and they are both open and inviting to our inquiry. We shall, therefore, offer a few more detached remarks on the nature, or rather the functions, of the vital fluid; and as these are most striking in the warm-blooded animals, we shall refer chiefly to them. It is necessary here, however, to make a very short explanation, as well to prevent the uninformed reader from being misled, as to keep our meaning from being perverted by the captious. When we apply the term "vital fluid" to the blood, we do not mean to assert that the blood is the seat of life, or that, considered as blood and apart from the organisation of the animal to which it belongs, and from the living action of that organisation, it is possessed of life of any kind, or in any degree. The blood has no sensibility under any circumstances, and no life or capacity of acting wholesomely upon the system, unless when it is in healthy circulation in its own vessels. And when there is what is popularly called a diseased state of the blood, it is not to be understood that it is in itself vitiated, even when it is mingled with the venom of a reptile, or with any other animal poison, whether imparted to the system or produced in it. It is not the blood itself which is poisoned in these cases, it is the blood which poisons the other parts of the system, by becoming unfit for acting in concert with them, or, as we say, stimulating them in the way which is necessary to the healthful action of the whole body in all its systems. If these systems preserve their functions, the blood may partially die (so to express it) within the system, without the smallest injury to the action, or the smallest danger to any part of the system. In the case of partial bruises which are, according to the common saying, "black and blue," there is always a quantity of blood coagulated, which in time may be extracted as a dark powder or a sort of cake, under which a healthy skin has formed. Something similar takes place in those discolorations or patches of the skin, which are vulgarly known by the name of "dead men's pinches," and which, though they are unseemly while they last, are really the results of healthy action in the system, sufficient to throw offensive matter to the surface. The same sort of process often takes place in wounds, which are healed over without being cleared of extravasated blood. The writer of this article had a personal instance of this in a pretty deep incised wound in a fleshy part of the body, which healed over, not exactly by the first intention, but in a short time, and with no great pain. For several years there was an occasional itching, with sometimes slight pain, under the scar; and about eight or nine years after the healing, the scar became black like a bruise; and after an intolerable itching, the integuments gave way, and a pellet of coagulated blood was discharged, after which there was no more itching or pain in the seat of the scar. Cases of this kind often occur in different parts of the body, without any wound or other external injury. They are not unfrequently formed in cases of aneurism, sometimes in those of varix; and they occur not only in the common fleshy parts, but in the heart and even in the brain. When they occur in these inner parts, which are considered as more eminently vital, ignorance sometimes transforms them into worms of strange colour and nature, and sets them down as the causes of disease and even of death, though they are perfectly harmless, and have no tendency to extend to the other parts of the system that death which they themselves have undergone.

These facts, and many more of a similar nature, could be adduced, to show, that when we call the blood the vital fluid, no distinct or specific vitality, at all analogous to that of animals in which organisation is much developed, and sensation or action of any kind vigorous, can be imputed to it. This might be inferred also from what has been said of the blood being the beginning or rudimental part of life, and a system of blood-vessels of some sort or other always being present in the lowest state of animal development, whether in the fœtal state of the animal or in the mature state of the less developed ones. All that empirics say about diseases of the blood, as such, and nostrums for their removal, must therefore be regarded as falling within the category of nonsense, which on the subject of health and disease is an exceedingly ample one. Still the blood may take up, either by inoculation, by absorption, or by the common process of assimilation or chylefaction, substances which render its action, upon the containing vessels and the system generally, pernicious instead of wholesome; and in very many instances in which curative preparations are exhibited, they are understood to act upon the system through the medium of the blood, which is sometimes reached by the process of chylefaction, sometimes by that of absorption, and sometimes again by tension or by relaxation of the vessels, according to circumstances. These views of the subject and means of acting upon the system belong to medicine rather than to natural history, though some knowledge of them is necessary for the prevention of mistakes and errors in that science.

Nature and Action of the Blood. In briefly glancing at this part of the subject, it is not necessary to enter into any investigation of the chemical nature and composition of the blood, because the action of that fluid upon the animal system is not chemical, that is, it does not obey the same laws which are obeyed in the chemical action of dead matter. Indeed, the whole action of the animal system is in opposition to these laws. The energy of life, though undefinable in any other way than by its phenomena, is more mighty than these laws, and holds them suspended as long as the organisation of the individual is capable of obeying the living impulse. When disease invades and deranges the system, the natural or chemical powers or properties of the component substances of the organisation begin to operate, and the disease takes more or less of a putrid type, so much so that, in certain states of disease, it appears that the matter given out by the affected body, even when in the form of insensible perspiration, and not discernible by any test, is capable of communicating the disease to healthy bodies in that mysterious way which we call infection. But it is not till the whole body has ceased to live, and a time, longer or shorter according to circumstances, has passed over it (always shorter the more the disease has of a putrid type, and the more energetic the action of nature around), that it yields wholly to the laws of inorganic chemistry—of that chemistry in which alone we can make experiments, and in so far explain principles by means of these experiments.

From these considerations, it is evident that, if we attempt to apply our common chemistry to investigate the composition of the blood, and thence venture to give explanations of any of the functions of life, we are in error; because we are attempting to explain the actions of the living body by means of agencies, the suspension of which is involved in the very notion and definition of life, and which cannot, by possibility, be exerted upon any part of the body till life itself is extinct.

It is necessary for us to be constantly upon our guard lest we should confound dead and living action, because there is, not in the ignorant only, but in the scientific, and indeed in them more than in the ignorant, a constant tendency to this confusion. This arises from the succession of fashions in philosophy, which follow the same law as fashions in common matters, but are far more inveterate, and we may add, far more mischievous, because they affect the whole character of society, intellectual and moral, while the others, if they do this at all, do it only at second hand. When the principles of mechanical philosophy were in their prime, and, as it were, held the whole field of science, it was the fashion to attempt the explanation of everything upon mechanical principles, and not only the action of the living body, in all those functions which are necessary for the preservation of the individual, but sensation and perception, and even thought, were attempted to be explained on the same laws which determine the motion of the planets in their orbits, or the tidal motions of the ocean waters. When chemical science, (the principles of which being of a more complicated and less obvious nature, necessarily came after those of mechanical philosophy,) had made such advances as to take the lead and become the fashion, the whole action of the living body was considered as chemical, and explainable by the laws of chemical attractions and repulsions, with their attendant compositions and decompositions. This was not, in an intellectual point of view, carried so far as the other; for no one ever gravely supposed that sensation, far less thought, was a result of chemical action, or ventured to recommend alembics and crucibles with sand-baths and fires, as appropriate substitutes for the old and vulgar process of thinking. They did not even attempt, by chemical means, to give sight to the eye or hearing to the ear, as had been partially done by the application of mechanical instruments, but in so far as what may be called the proper functions of the body, those which develope its organisation and preserve it in a living and healthy state were concerned, chemistry was the rule of action, and when the body became diseased, chemistry was the grand means of cure. It is true, that a mixer of medicines had been called a "chemist" before this time; but a chemist, in the general sense of the trm, means one who is possessed of, or who deals in secrets; and in the composition of medicines there are some real secrets, and many more which belong to that class which are most safely kept—those in which there is nothing that can be revealed. In addition to these two general modes of endeavouring to explain the functions of the living body by means of principles, the resistance of which forms the best definition of life, there were always minor modes of a transcendental nature (or which could not be reduced to any principles) breaking in still farther to confuse a subject which is certain at all times to claim much attention, but which has at no time been explained, or even clearly defined.

Life, that which puts into action all the organs and structures of the animal body, is so interesting in wild nature, and so useful in domestication, is the portion of creation which all are most desirous of understanding; and, whatever may have been the case with any other subject, there is no human being, learned or unlearned, that has not thought and speculated about this one.

> "Who, to dumb forgetfulness a prey,
> This pleasing anxious being e'er resigned!"

is true, not only when we consign to the earth the mortal remains of those who have been dear to us, but of our own living bodies, and of those of all the creatures which live around us. Hence, be it as crabbed or as absurd as it may, a book upon the functions of life, and more especially one upon the functions of human life, is sure to find readers, upon the same principle that he who pretends loudly enough to cure human disease is sure to find encouragement, be his knowledge ever so limited, and his nostrums ever so baneful. This universal craving might be, and no doubt was intended to be, one of the great inlets of knowledge; but unfortunately it is just as greedy of error; and hence, as is the case with all those which, under proper regulation, are capable of effecting much good, it is made the means of much evil.

Nor is it easy to say whether the pretender, who seeks merely that living which he is incapable of obtaining by honest industry, or the man of science, who seeks for fame in an honourable way, has done the most mischief here. The latter of the two is deeply learned in the laws of matter, and, like a pedant who darkens language, naturally obscure enough, by his constant efforts to show his learning, or a man who has become so much inured to the technicalities of his craft, that he speaks in an unknown tongue to all who are unacquainted with the minutiæ of that craft—he will be constantly introducing his mechanical philosophy and his chemistry, whether they are consistent with the subject or not.

Chemistry, in that form which admits of experiment, and can be reduced to a system in the schools, cannot in any way help to explain one single function of a living animal. Even in the formation of carbonic acid in breathing, the result is a chemical result certainly, at all events, it is a result which could be obtained by means of a common chemical experiment,—in other words, a product similar to that which results from the process of breathing could be obtained by other means; but the process is not the same, and we dare not call that chemical; it is similar with all the operations which are carried on in the living body; in as far as matter is put in motion they are mechanical, and in as far as they tend to decompose any substance they are chemical; but the energy by which these are accomplished is neither the one nor the other—it is physiological, belongs to the living state only, and when that state is at an end, it exists no more, and leaves not upon matter any trace of its existence.

In what may be called corporeal physiology, to distinguish it from the more subtle subject of the physiology of thought, the consideration of the blood is by far the most important one; and therefore, if we are not strictly physiological in it, if we call in the assistance of chemistry, or of any thing foreign to the nature of living action, we lay an unstable foundation, and the whole structure of our future knowledge becomes of small value. In the following remarks on the nature of the blood, we shall therefore consider the physiological phenomena as the foundation and principle of the whole, though we may have occasion to advert to some of the chemical ingredients of the blood in illustration, but only as proofs that there is an action, not as explanations of either the cause or the manner of that action.

Blood, when immediately taken from the vessels of a living animal of any of the more completely developed vertebrated classes, appears a homogeneous fluid, of somewhat viscid consistency, rather heavier than water, of a red colour, and of the temperature of the body from which it is taken, in man this being about 98° of the common thermometer. This, while it retains its primary heat, may be considered as living blood, or the nearest approach which direct observation can make to it in the vessels of the animal; but whether it is exactly the same, we have no means of ascertaining; for blood is a fluid so susceptible to action, and capable of being acted upon (or acting) in so many ways, that we can have no positive knowledge of the effect which the contact of the atmosphere, however momentary, or the mere taking of it out of the circulation, nay, the mere momentary stoppage of that circulation, may have upon it.

This consideration tends very much to paralyse, at the outset, all our inferences from what we can discover of the blood when out of the system, of the functions which it performs, and the manner in which it performs them, when in the system.

After blood has been for some time out of the vessels, it separates into two parts, the one a yellowish fluid, called serum, and the other an accumulation of red particles, called crassamentum, or clot, which floats in the serum, and may be divided by a knife, which the serum cannot be. The experiments on the subject have not been made with sufficient precision, or in sufficient number; but it would seem that this coagulation of the blood, or separation of the serum from the clot, takes place soonest in the blood of those animals which are the most perfectly developed in their organisation, and which have the circulation most rapid; but this is still too vague for allowing any conclusion to be safely founded upon it.

If, during the time that it is coagulating, the blood be gently agitated or stirred, the clot acquires a fibrous consistency, which, when closely examined, has the appearance of a kind of net-work, or of short feathery fibres, which take hold of each other in all directions. If, instead of being gently stirred, the blood is violently, or even briskly agitated, the clot does not separate either in a uniform mass, as when left still, or in a fibrous tissue, as when stirred or agitated gently.

It is obviously not the presence of atmospheric air which produces this change in the consistency, and apparently in the composition of blood, for, as has been said, blood coagulates in the interior of the body, sometimes extravasated, and sometimes in its own vessels; and it would seem that, in those cases, it is the clot of the blood which remains, the serous part being taken up by the absorbents. Hence it is probable that, in all cases in which inflammation, suppuration, or gangrene follow upon the extravasation of blood in the system, one of the causes, at least, is the incapacity of the absorbents to take up the serum, for in those portions which are found harmlessly bedded in the substance of the body, it is the clot only which is left.

If the fibrous clot which is obtained by gentle agitation of the blood be repeatedly washed in water, the colouring matter is entirely removed, and the fibres, or *fibrin*, as the substance is called, become nearly colourless, and is tough and elastic. Fibrin, in the same state of adhesion and elasticity, cannot be obtained either from blood which is left at rest, or from that which is subjected to violent agitation; but what correspondence there is between the degree of agitation necessary to prevent the separation of the fibrin, and the rate of healthy circulation in the animal from which the blood is taken, has not been ascertained by experience, though it is unquestionably a point of very great importance, and the one, the solution of which is most likely to throw light (if any inquiry can throw light) upon the manner in which the repairs of the different animal structures, or even their formations at first, are elaborated from the blood.

We have it established by direct observation, that, where blood is allowed to remain still, or where the agitation or stirring of it is below a certain point, the clot separates in a viscid and jelly-like mass, but without any appearance of organic structure. We have also, by rational inference from what takes place in the living body, where the serum of extravasated or otherwise stagnant blood is, and also where it is not, taken up by absorption. Farther, as the blood when in the vessels has no sensation, is not organised, and therefore though the means of life, and the element out of which all the organs of living structure are made and repaired, we cannot conclude, at least we have no just ground for concluding, that the blood, when in the vessels, is very different from what it is when immediately drawn from them; but that, if it could be kept from atmospheric contact, the same temperature as it had in the healthy body preserved, and the same rate of motion kept up as it has in the circulation—then the blood would, for a time at least, be capable of the same action which it has in the vessels. Hence, we may conclude, in so far as any conclusion can be drawn from evidence which consists in great part of probabilities only, that there may be a state of the circulation so lagging, that the non-fibrous clot will have a tendency to form, and may actually form in the vessels; and as we may presume that any state of the system which induces this lagging circulation, must be accompanied by such diminished action of the other parts, as that the absorption shall not take place, this would bring the whole system to that state in which we have said that inflammation, suppuration, and ultimately gangrene, take place topically, and dissolution would be the inevitable consequence.

This is probably the final stage in very many fatal diseases; and it appears to attend the whole course of those which are technically called low and putrid, or those in which the pulse is below the healthy quantity, in velocity, in volume, or in both. We have some corroboration of this, in so far as the dead subject can be admitted in corroboration of what is supposed to take place in the living, in the fact that the flesh of animals, even when killed in the healthy state, becomes much sooner putrid if the blood remains in it; and that the flesh of animals labouring under putrid disease, even though killed before that disease becomes mortal, or even altogether suspends any of their common actions is unwholesome, and has more or less the effect of a poison on those who eat it. This is farther corroborated by the fact that the diseases which are superinduced by tainted meat are always of the low or putrid type.

The common saying that "extremes meet" is in so far verified in this matter; for many maladies which begin with an excessive action of the system wear it out, and assume a low and putrid character before dissolution. And where there is still some strength of effort in the system, we find that nature turns that effort into an attempt to make the morbidity topical—to throw it upon some one part, and thus relieve the general system till it can rally and maintain the life; and though these efforts fail, of course, in all cases which end fatally, perhaps there is no case in which they are not to some extent made, unless it be in those where the whole system is so equally and gradually worn that it yields to the very first derangement, and the fortunate subject drops off, as the matured leaf falls in autumn, without a groan and without a pain.

In this we can trace one of the deviations in the current of the blood in the living body from that wholesome state in which the vital fluid is always ready for the furnishing of *fibrin*, which we may, perhaps, without much impropriety consider as the first or elementary product of complete assimilation, —the first stage of organisation, or the general material of which all the varied structures in the body of an animal are formed, and by the constant application of which, according to the degree of waste that takes place, they are kept in repair.

But we have also seen, that where the recent blood is agitated beyond a certain degree, it is also rendered incapable of forming fibrin, and retains its fluidity without any tendency in the two parts to separate. And, as this is the more readily effected by artificial means the more recent that the blood is, we may naturally suppose that a circulation may take place in the living body so rapid as to produce the same effect. That the indication of this must be an increase of pulsation, which is the only means we have of judging of an increased circulation, is perfectly evident. This is produced by violent action of whatever kind, whether it arise from external or internal causes; and though the blood, when circulating with this unnatural rapidity is not primarily so prone to putrefaction as it is in the opposite state, yet it is just as incapable of supplying the requisite nourishment to the several parts. At the same time, the more rapid circulation, which must be attended with increased action of the whole body, tends to fatigue and wear out the labouring vessels, deprived as they are of their proper support and nourishment by this violent action. It is from this that we see how, if some part of the system does not give way, and produce either dissolution or cure, according as the part which yields is vital or not vital (in the ordinary sense of these words,) the over action of the system, or what is technically called a disease of inflammatory type, should in the end degenerate into the low or putrid one. But there is always an effort of the system to save itself, in this case as well as in the other; only, as the diseased action is the reverse, we may expect that the symptoms of the effort will be different. Such is the case: the violent action of the system, the increased pulse and augmented heat have a tendency to produce topical inflammation and suppuration, and if this action takes place in time, and not in a vital part, it removes the systematic disease, and what remains may be treated nearly in the same manner as if it were a topical injury arising from an external cause. It is easy however to see that it must be treated with far greater caution. In the case of such a result from external injury, the system, by the very fact of being able to keep the injury on the confines, shows its soundness and power of resistance; whereas, though the system is able to throw a general malady to a topical situation, there is always a degree of exhaustion of the system produced by the effort, which makes any topical application which has a tendency to drive back the malady upon the system, peculiarly dangerous. We have instances of this in the "driving in," as it is called, of a rash, in the checking of perspiration, and in an almost endless variety of cases. If a topical disease is original or primary, we may attack it in its locality; but if it is symptomatic or secondary, we must take care lest we deprive nature of her own means of cure.

Some of the remarks which are contained in those latter paragraphs may appear to have a medical more than a physiological air; but the subject is of such a nature that we cannot understand even the elementary action of the blood, without reference to the same subject in different states of the circulation; and if one of those be the healthy state, the other must of necessity be a diseased one. We have it indicated in the fact that the recent blood will not *fibrise* (to coin a word for the sake of brevity,) if it is either too little or too much agitated; thus we obtain a sort of foundation, though not a very perfect one, for our physiological consideration of the blood.

Between these two limits, both equally fatal, and varying in the case of almost every species of animal, there is an average ratio of circulation which may be considered as the circulation of health, and which varies as much in the different races as those limits between which it may be said to be the middle point. The circulation in the race is always the more rapid, the more active and the more continuous in action, and also the more completely the organisation is developed; and in the individual it rises with increased action, whether external or internal, and sinks with repose. It is more rapid in the young and growing state than when the mature stature is attained; and those animals which are subject to short fits of very violent action, with long pauses between, have corresponding differences in the action of the system of the blood.

Birds, as having to perform the most violent action of any of the vertebrated animals, have the most rapid circulation; and among them the vegetable feeders, which have most labour both in the finding of their food, and in the assimilation of it, have the most rapid circulation and the highest temperature. The mammalia follow next in order, and after them the reptiles, and lastly the fishes. That such is the general or average distribution is true; but there are so many anomalies in all the classes, arising from the adaptations of different animals of the same class to different latitudes and different situations, that no theory which descends to more minuteness than that of a general connexion between a rapid action of the system of the blood, and a corresponding activity in the general habits of the animal, can be implicitly depended upon.

Something similar as to the correspondence between rapidity of circulation and energy of action, may be traced among the invertebrated animals. Of these, the winged ones have the warmest temperature, and thence, from the general analogy, we may premise that they have the most rapid circulation; and in all cases the supply of food required is in proportion to the circulation. Not indeed as regards the quantity taken at one time; for many of the species which feed most voraciously when they do feed, are capable of bearing the longest periods of abstinence. The blood of the invertebrated animals is, in most cases, bluish or whitish, and but rarely red; but in what respects it differs physiologically from the blood of vertebrated animals, we have no satisfactory means of ascertaining; and, as we have already said, chemical analysis can be supposed to throw little or no light upon the action of this fluid.

Many conjectures have been made, and many theories proposed and overturned, with regard to the specific action of the blood; but the subject still remains, and will probably for ever remain, involved in great obscurity. There are some circumstances which give at least a semblance of probability to Hunter's hypothesis of "the life of the blood," that is a vital action *in* or *of* the fluid itself, without a pre-existent cause, dependent upon or residing in any organisation. This may be inferred from the facts already mentioned, that the first rudimental appearance of the germ consists of blood and blood vessels. But this is not enough for the establishment of the hypothesis. The blood cannot exist or act to any useful purpose without the containing vessels; and therefore, though the muscular structure of the heart (for the heart in all animals, of whatever class or kind, is muscular) may not be formed *before* the blood which it contains and propels, yet we cannot suppose it to be formed *after*. Besides, though these may be the first rudiments of organic structure in the young animals, they are not the original germ, nor can their action be regarded as the first action of the germ. The germs of some animals can retain their vitality for very long, and even indefinite periods of time, and some of them admit of being boiled or frozen, or both; and still, under favourable circumstances, they awaken into life. Towards the awakening in these cases too, no further interference of an animal is required, so that in some of its forms, animal life can lie dormant, in a very low state of organisation, (if indeed we can with any propriety call eggs organised bodies,) a state in which there is nothing developed which we can call either blood or a blood vessel. When the egg, which is the usual form of those permanent germs, is placed under favourable circumstances, the life in it begins to act; therefore we might as well predicate life of the heat and humidity, or whatever other circumstances it may be which stimulate the germ and produce the development, as of the blood vessels and blood which are the results of a previous action. This action is no doubt very simple and rudimental. But still, however simple and rudimental it may be, we know that it must take place; because we have the visible results of it in the vessels and the blood, and though these are the results, and not the action or its cause, still all the evidence which we can have of any action or any cause of action, however powerful we may imagine it to be, is precisely of the same description. We know, and we can by possibility know nothing but results; and yet we are so constituted that we can no more suppose any result to take place without a cause adequate to its accomplishment, then we can believe any one object to be at one and the same time in two different places, or to be itself and, at the same time another.

Hence it is impossible for us to believe that the primary and rudimental life of any animal as a germ can be seated in that blood which does not begin to exist till after the action of the germ and in consequence of it; and therefore the blood cannot be the depositary of the original life; and if we suppose that it subsequently becomes endowed with a sort of organic vitality, we are not entitled to consider the blood as exclusively or pre-eminently endowed with a vitality which obviously belongs to the whole animal as an organic structure.

If the expression can be allowed, the apparent vitality of the blood appears to be the result of muscular energy, for when the heart is no longer able to propel the blood, that fluid stagnates, and ceases to perform its function, and life is at an end. Thus as, on the one hand, what we term the life or living action of the blood, takes place only consequent to a previous action, so the cessation of life in the blood appears to be preceded by a cessation of life in that organisation, by which the blood is circulated over the system.

There are some rather curious analogies which would lead us to suppose that there is some very extensive connexion, or at all events resemblance, between the fibrin of the blood, and the muscles, and also between the serum of the blood and the membranous tissues of the body. In many animals the muscles approach to the colour of blood, and they are the only parts of the animal which do so. Little useful inference can indeed be drawn from this, because the muscles of many of the red-blooded animals are white, or nearly so; and all muscles may be made white by repeated washing, while the fibrin of which chiefly they are composed continues unchanged. The same has been remarked of the crassamentum of blood; and when the two have been thus freed from colouring matter, they appear as if portions of the same substance.

There are also some curious coincidences between the coagulation of the crassamentum of the blood, and the contraction of the muscles. They are both operations which we do not understand; and though we call the one an attraction which those particles of the blood which are fit for forming fibrin have for each other, and not for the particles of the serum, or for the coats of the vessel in which the blood is contained, and the other irritability, or any thing else, or though we call each a different kind of attraction, or both the same kind, only modified by the different textures of the substances in which they act, we make no progress whatever toward the understanding of them. We have more words certainly; and those words may, as words often do in other cases, satisfy the ignorant, and lead them to conclude that we have more knowledge than they, but they would not make us one jot the wiser.

But though this very peculiar and incomprehensible action takes place in different substances apparently, and also in different states of those substances,—as contraction in the living muscle, and coagulation in the blood after it is removed from the body, or when it has become stagnant,—yet it is possible that they are one and the same action, differently modified. That unnaturally violent contraction of the muscles to which the name of cramp is given, bears nearly the same relation to the healthy action of the muscle, that coagulation bears to the healthy state of the blood. It appears, from the phenomena which occur in recent blood, and from its consistency when it is taken from the vessel of the living body, that there is no fibrin ready formed in it, into any thing that we can call an organic structure even of the most rudimental kind. There is only, so to speak, a capacity in the particles to form this substance, under circumstances which are favourable to it. If the fluid passes quietly into a state of repose, there is coagulation, but not the formation of fibrin, nor can any future operation turn the jelly-like substance thus formed (which however is not jelly,) into fibrous matter. So also if it is violently agitated, the tendency to form fibrin is destroyed, and no subsequent treatment can then favour the spontaneous coagulation. It is said, that if the agitation is violent enough, the uncoagulable result acquires generally a considerable degree of that milky odour (but not the colour of course) which the serum of blood gives out when heated. It is also said to have some resemblance to the catameniary fluid, which, though of the colour of the vital fluid, is understood to be really a secretion of the mammæ, incoagulable, and not forming fibrin by any treatment. It is to be regretted that the experiments of the late Dr. John Smith, of Edinburgh, upon the nature of this secretion, should have been lost to the world by his premature death; for it is a subject which, worked out with due care, and without hypothesis, is calculated to throw light upon some of the most curious points in physiology, more especially the unknown bourne which separates, and at the same time connects, the blood of every two consecutive generations. This is a subject, however, upon which, for obvious reasons, we cannot enter in a popular work.

In like manner as that portion of the blood which is predisposed to the formation of fibrin passes into coagulum, when the blood as it comes from the living vessel is allowed to rest, so the muscle, when it passes from the living to the dead state, under ordinary circumstances, passes into a state of rigidity; or all the muscles pass equally into a state of contraction, from which they do not again relax till their substance begins to yield to the ordinary action of decomposition. Here also there is a resemblance between the coagulable portion of the blood, in so far as we can suppose a resemblance to be traceable between a fluid apparently homogeneous, and a soft solid made up of fibrous fasciculi.

One of the most remarkable evidences of this similarity in the blood and the muscle, is to be found in the similar effects of certain violent kinds of action upon both. Almost all those actions differ in the agents by which they are produced, and indeed in most of the circumstances, but they agree in preventing the coagulation of the blood and the stiffening of the muscles, and they also all, in so far as we can understand the rationale of their action, agree in bearing some resemblance to that rapid or violent agitation of the blood which destroys its tendency to coagulate when out of the body. It is rather remarkable, and should show us that, in our physiological investigations, we ought not to lay too much stress upon mechanical or chemical appearances or effects, that some of those actions are merely momentary, and some of more prolonged duration, some of them act by direct mechanical agency, some have nothing of common mechanics in them, some are produced by vegetable agents, and some by animal ones, and some have their proximate, if not their primary causes in the body itself.

Gun-shot wounds may be mentioned as one instance, and the more speedily that death ensues after the receiving of the wound, the state of the body is the more completely relaxed. The wind of a cannon shot when it causes death, which it sometimes does when it passes very near, has almost the same effect in relaxing the body as a gun-shot wound; and instant death from a blow on the stomach, or from a concussion or other injury to the brain has still the same effect. These last two instances are against the hypothesis that either the blood or the muscles can be the peculiar seat of life; for the injury done to the source of chylefaction or to that of the nervous energy produces the same effect on the blood and the muscles, as other injuries which are understood to go more directly to those parts of the body. Perhaps the most complete prostration of the body, in which the muscles remain quite soft and the blood liquid, is that produced by electric matter when its violence is sufficient to produce death, whether it come in the form of lightning or of any other; but if there is no topical violence produced by this agent, the case is not quite so hopeless as in some of the others which occur less instantaneously; as the copious affusion of cold water, if applied instantly, sometimes makes the body re-act. Excessive exertion in man and other animals, and excessive mental excitement in man have the same results; and some of the more deadly poisons both animal and vegetable have still the same. The bodies of animals perishing by any of these, or any other means which prevents the stiffening of the muscles after death, become much sooner putrid than those which stiffen; and as the vessels lose their contractile power at the same time that the tone of the blood is broken down, the flesh of the animals, if it is to be used as food, cannot be so completely cleared of blood. It is on this account, as well as on that of the tendency to putrefaction, that the flesh of overdriven cattle is so very unwholesome.

The coincidence of so many causes operating upon so many different parts of the body, and in so varied ways, and yet all producing effects so simultaneous and so similar, in destroying the power of coagulation or of the formation of fibrin in the blood, and of contractility in the muscles, show beyond all doubt that there is a similarity, if not an absolute sameness, in those two parts of the animal system. The co-existence, or co-production, of contained blood and containing muscular vessels, in the very first stage of organisation in the young animal, is a farther confirmation of this; and when, as in this case, we find the physiological proof nearly complete, we may safely call in that of the chemical composition in which the fibrin of blood and muscular fibre completely agree.

The very same evidence, however, prevents us from concluding that the blood or the muscular fibre, or the union of the two is the immediate seat of life. Indeed, it leaves the question of life and its locality exactly where they were found—that is, as matters beyond the range of philosophical inquiry, and therefore without the pale of useful and legitimate speculation. A blow upon the stomach sufficient to cause death, or a concussion of the brain producing the same result, has more effect upon this peculiar quality, both of the blood and the muscle, which may be considered as their specific modification of life, than if the blood were wholly spilt upon the ground, and the muscles hacked by innumerable wounds. Indeed the wounding of the muscles tends to increase the contractile power of those which remain, and no wound of a muscle is, in the first instance, mortal, though it may become so by ulceration and gangrene, the putrid matter of which is taken into the system by absorption. Those who are killed by sword wounds die with the body in a state of great excitement; and the probability is that they feel much more pain than those who perish by gun-shot. The crimping of fish, by cutting the flakes of the muscles before life is extinct, and then applying a stimulant to the wounds, though withal a most barbarous operation, if people are to be supposed to feel for that on which they feed, shows that the contractility of the muscles even of a fish, in which what is called (not very intelligibly) *muscular irritation*, is understood to be much less sensible than in the warm blooded animals, is not very greatly destroyed even by a number of deeply incised wounds.

In the case of the blood again, the removal of a portion of that may be considered the severest mechanical injury which it can receive; and this instead of having any tendency to destroy either its supposed vitality, or its capacity of healthful action, is very often a means of restoring the blood to a healthy state in those cases where it may be said to be diseased, and of recovering the whole body in the case of many casualties and not a few diseases. In many cases where by stunning, contusion, or many other means, the action of life is suspended, that action can generally be restored if blood can be made to flow from an opened vein; and if the vital heat is not gone through length of time, or there has been something more than a mere mechanical injury without mortal wound, the impossibility of obtaining blood from a vein, is one of the most hopeless symptoms.

Though there is not much meaning in great part of which is said and written on the subject of diseased states of the blood, there are some diseases of which the character is indicated by the appearance which the coagulum of the blood assumes, when it is allowed to settle. One of those in which the blood has a very dark appearance, and comes from the veins as if it had already undergone a sort of imperfect or spurious coagulation in the system, and which is the result of an imperfect or diminished circulation bordering upon the putrid type, can be better explained in the article CIRCULATION, as in that article we propose to explain the action of respiration on the blood, as well as the mere motion of the blood in the vessels. But there is another case, that in which the coagulum exhibits what is technically called "the buffy coat," from its resemblance to buff leather. This is characteristic of inflammatory disease, in which the circulation is greatly increased both in rapidity and violence, and attended with much heat, showing that the system labours, or that there is much resistance to the increased motion of the fluid. This increased resistance does not take place so much in the larger vessels, as in the capillaries, by which the minute extremities of the arteries and veins are united to each other, and through which the circulating blood must pass. It falls not within the scope of natural history to examine the causes by which this resistance is produced; it may arise from stimulus of the propelling organs, or from a decayed state of the capillaries themselves, brought on by interrupted perspiration, and by many other causes. The buffy coat consists of matter analogous to pus, which is brought from the capillaries by the veins, and if continued to a certain extent it would change the character of the disease by the gradual accumulation of a poison in the system. The taking up of foreign matter by the veins, is not however the sole cause, or even always a cause of the appearance of this buffy coat. There may be a decomposition of the blood in this inflammatory state, by means of which the colouring matter (the red globules) which is rather an adjunct to the fibrin than a constituent part of it, falls to the bottom, and leaves the fibrin itself upon the surface; but in those cases there is very generally an admixture of matter resembling pus, and not unfrequently such matter predominates. The carrying of this matter, or of blood which in any way exhibits the buffy coat, to the lungs, on the walls of the cells of which the capillary ramifications of the vessels are peculiarly fine, is always attended with an aggravation of the disease, and if the lungs are weak, there is some danger of the disease being thrown upon them.

Many experiments have, since the improvement of pneumatic chemistry, been made with a view of ascertaining the action of different gases on the blood, but the performance of such experiments is rather a nice operation, and when they are performed, they are of no great value, because, in the living subject, gases do not come into contact with the naked blood. The place where any gas comes most nearly into contact with the blood of animals is in the breathing apparatus, whether lungs or gills, and the explanation of the action there is one part of what we propose to reserve till the article Circulation. We may, however, in the meantime, mention generally, that oxygen appears to retard the process of coagulation, but that it is accelerated by carbonic acid, and by all the gases generally which are unfit for the purpose of respiration; that the application of oxygen tends to heighten the scarlet colour of the blood, but that those gases which accelerate the process of coagulation tend to make the colour darker and blacker. The effect of oxygen may be seen in any case where blood is allowed to coagulate exposed to the atmosphere, for in such cases the upper, or exposed surface, is of a very intense and beautiful red, while that which is below, and with which the air does not come in contact, is of a more dingy hue. Whether, in this case, the oxygen of the air produces the same effect upon the blood as it does when applied through the coats of the pulmonary vessels in the process of respiration—that is, whether it attracts carbon from the blood, and forms carbonic acid with that carbon, is not exactly known, but there is a specific difference between the action of oxygen upon blood when out of the vessels and when in them. In both cases the colour of the blood is changed to a finer red by the action of the oxygen; but while that gas retards coagulation in blood exposed to the free air, it appears to accelerate the same operation in the vessels; for arterial blood coagulates sooner and more readily than the darker blood of the veins, although, when a coagulum once forms in the darker-coloured venous blood, it is of much firmer consistence.

Why the case should be different with blood exposed to the free air has not been very satisfactorily explained, but one can very readily see the advantage of the effect produced by oxygen upon the blood within the vessels. The more readily that the blood coagulates when taken out of the system, the more easily must it come to that state in which it forms into fibrin in the system; and the less completely that it passes into a solid coagulum, the greater may we suppose to be its susceptibility to vital action; for coagulation is the state of final and irreclaimable inertia in the blood, except in those cases of violent action in which the crassamentum is broken down, and the power either of forming fibrin or of coagulating prevented.

The red particles of the blood which, along with fibrin, or matter disposed to form fibrin, make up the whole volume of the crassamentum, or clot, have, as is the case with all natural substances, the use of which is not very well known, given rise to much speculation. According to what may be considered the most accurate measurement of these particles, they do not exceed the two-hundredth part of an inch in diameter, and therefore they fall under the denomination of objects wholly microscopic, the descriptions of which are always to be received with caution, as the refraction, and other colouring tendencies of the instrument, are apt to change both the apparent size and the apparent colour of that which is seen through it. There have been many differences of opinion about the size, the form, and the use of these particles, but none of them are very satisfactory, and they are too minute for enabling us to hope for any thing very conclusive. They are said to differ in magnitude and also in form, not only in different animals, but in the same animal during different stages of its development.

Though the use of these red particles in the animal economy is not known, and though no satisfactory inference can be drawn from the examination of bodies in themselves so minute, unconnected with the system and with each other, any farther than that they float in the blood, intimately and equally distributed through its mass in ordinary and healthy states, attaching themselves in the fibrin when it forms either into clot or into a fibrous consistency, and tending to precipitate in those inflammatory states of the blood in which it shows the buffy coat when drawn from a vein; yet they must answer some very important purpose connected with life and living action in those animals which have their organisation much developed. Little knowledge can be hoped to be obtained from an examination of their forms, or of their chemical composition as matter; for the investigation of living action, and the means by which that action is performed, is an investigation of connections, not of single parts—of relations, not of forms; and when they are in such a state as that we can obtain any, even the slightest knowledge of their chemical properties, they are out of their connection; the relation between life and them is at an end; they can be examined as dead matter only; and all the conclusions at which we are capable of arriving, relate only to the part which they are capable of performing in the economy of dead matter.

It has been said that these minute particles, or globules (for even their figure is not fully ascertained), consist of an external coat or tunic, a contained fluid, and a central nucleus. If such be the case (for even this is obscure), there is in them some resemblance in arrangement of parts to that which occurs in an egg; and as probably the majority of the eggs of animals are stimulated into action by external causes, we might perhaps conclude that those red particles of the blood form the portion of it which is most sensible to such causes, and which, easily excited in itself, extends excitement to the rest of the system. But the analogy, even if it were good for any thing, fails, because these particles are certainly not germs of any kind, and out of the system they resign themselves to that chemical decomposition to which all organic matter is subject when the life which it once exercised is at an end.

It were very desirable to know something about those red particles, because they are common to the blood of all vertebrated animals; because, as the blood is most abundant in the most perfectly developed races, they must be most numerous in them; because they contain an ingredient which does not appear to be formed in any other part of the system, at least in such abundance; and because they have a tendency to separate from the blood (at least partially) in cases of inflammatory disease; and above all, because it is in them chiefly that the effects of air in the grand operation of breathing are chiefly visible. These considerations bring us apparently so near to something like use in the globules, that one feels strongly tempted to leap the boundary, and declare and speculate about real use; but alas! there is "a gulf fixed," and that gulf is fathomless.

Even in the humble matter of a chemical analysis, these globules set our most careful operations at defiance. We can never be sure that we have separated them entirely from the other parts of the blood, and in those cases wherein this appears to have been most closely approximated, the greater part of the products obtained from their decomposition were found to be the same as those in the rest of the blood—only, about an eightieth part of their volume resisted the fire, and of that more than the half, and about one hundred and fiftieth part of the active mass, consisted of oxide of iron. When merely acted upon by saline mixtures, but not decomposed, these particles show much sensibility to chemical action. Some substances make them contract, some expand them, some brighten their colour, and some render them darker; but in every case these are the ultimate results, and we are unable to draw from them any other conclusion than that these bodies are very sensible to chemical action; but what are their relative degrees of sensibility when in the living circulation, and when out of it, we have no means of ascertaining.

It is usually understood, that too free a use of common culinary salt darkens not only the colour of the blood, but the complexion generally. Salt provisions have a tendency to produce scurvy, in which the blood is dark; and a darkening effect, with a tendency to the irritation of the smaller vessels, is produced by too free a use of stimulating liquors. But, any conclusion which we might fancy ourselves able to draw from these cases is met by others of a quite opposite kind, or at least, apparently arising from opposite causes. Exposure to cold, or any thing which gives great rigidity to the small vessels near the surface, produces an effect analogous to that of stimulating liquors; and too meagre food brings on scurvy as well as salt provisions. Besides, as we never can obtain any other than a systematic result when we make experiments on the living body, we are not able clearly to decide which is the part first and chiefly affected.

The most important part of the inquiry is certainly that which relates to the change of the blood in respiration, and the consequent differences between venous and arterial blood; and it is in the red particles that this change, or the difference which this change produces, is most apparent. Whence the excess of carbon with which the blood becomes loaded in its return from the systematic circulation, and which imparts to it its dark colour, comes, we are unable to ascertain. It may come in part from those portions of the body which the blood reaches, it may come from the substances which are taken up by the absorbents, or it may come from the alimentary chyle. It is indeed not improbable that it comes from all three; for the blood in the vein has assumed the dark colour at an early stage of its return; and the matters which the thoracic duct empties into the subclavian, whether products of digestion or of absorption, are not fit for the circulation until they have undergone the operation of the air in the breathing apparatus.

It is doubtful whether the red globules of the blood owe the whole of their colour to the presence of the iron; but the iron does at all events accompany the colouring matter rather than the other parts. It is in such quantity that there are computed to be about two ounces in the blood of an ordinary man in a healthy state. There is also a trace of iron, although a fainter trace, in red muscle; and the redder the muscle, the trace of iron is the more apparent. It does not appear to exist, at least in such quantity as to be detectible by any of the common chemical means, in those parts of the body which are not reddish, or in those animals which have not red blood; but these facts are not conclusive evidences against its existing there in a very minute quantity.

The red particles of the blood and the muscles are the parts of the animal most easily excited; and we have already seen that the crassamentum, or cruor, of the blood, including both the part which can be converted into fibrin and the red particles which accompany that in the blood, and the fibrin which is developed in the muscles and appears to derive its colour from that of the blood, are excited in the same way by very different causes. From these coincidences, it is very difficult to refrain from speculating about the rationale of muscular action. We do not mean as to whether it is mechanical or chemical; because, although as being displayed in and by matter which still retains its properties as matter, though subdued or suspended while that matter forms part of the living animal, it must be both mechanical and chemical in its relations, yet in itself and primary it is neither; it is physiological not physical—using the first of these terms as descriptive of the phenomena of organisation, and the second as descriptive of the phenomena of matter when not organised.

Still, this, which we may properly regard as the primary action of animals, that to which all their other actions are owing, and in the suspension of which all these are suspended, must be regarded as material—that is as a result of matter and not of mind. Mind has no mechanical action. Knowledge is its province, but it cannot of itself stir one atom of matter a single hairbreadth. Hence in man the organisation and the life of the animal are as necessary and perfect for mechanical purposes as the thought is for mental ones; and thus far man is as subject to death and material dissolution as any other creature, and in all the states and functions of his material frame he follows the same law as the rest. It were in vain, therefore, to seek for an explanation of animal action as a result of any thing like mind; because mind could not accomplish it without having the properties of matter, that is, without being matter. When, therefore, we speak of "animal spirits" as being the cause of activity, we only encumber ourselves with additional words without any additional meaning; and in the individual case, the words should be reversed, and that which we call animal spirits should be called a "spirited animal," the word spirit in that case having reference to the energy or manner of the action, not to its cause.

But if this primary action of the animal be, as it unquestionably is, a phenomenon or property of matter only, with what other portion of the material creation shall we connect it, or where else shall we find its counterpart? Where too shall we look for its origin? for unless we go back to the moment of creation, we must have a natural cause for every natural effect—a natural antecedent for every natural consequent; otherwise, we stand in need of creation and miracle every day; by which means the original creation becomes no creation at all; and if so, then there can be no miracle, and no daily creation; and the whole becomes an absurdity. Such is the conclusion to which all the sceptical doctrines lead, if we carry them but a single step beyond the doubting point—that point at which the mind loses the way and will not seek direction in that quarter where alone it is to be found. Yet it is not accurately called the doubting point, it is really the point of too easy belief—that at which our vanity turns away from the truth, and gives full and doting credence to the absurdity.

This animal action, which we find most remarkably displayed in the blood and the muscle, is then a phenomenon of matter, and of matter only; and as such every case of it must have an antecedent or a cause, not merely a cause to put it in motion at the time or for the instant, but a cause to which its capacity or faculty of being put in motion must be owing. Is it of the parent, descending from generation to generation? It is not. The parent does not in any instance communicate motion or action of any kind to the offspring. Even in the case of uterine production, in which, from position and some other circumstances, might be led to believe that there is the closest connexion, there is no transmission of animal action from the mother to the young. There is a partition, and there are two distinct lives. All the organisation on the one side, whether for that particular state, or for more permanence, is of and from the life of the parent; and all on the other side is of and from the life of the offspring. There is no community of circulation, no community of muscular action, no community of nervous affection, and no community in any one particular that can be named. Either may be indisposed while the other is in health, and either may die the other remaining alive. The young may be cast off as an untimely thing, or it may turn to corruption *in situ*, and yet the parent may escape. And if no casualty happens, it separates in the fulness of time; and unless in those membranes which were its own, that is, the products of its own organisation, there is no wound nor laceration. The parting is one of health, and the final step of a healing process, just as the seed falls off when it is fully ripe, or the leaf when the seasonal action of the tree is at an end; or more appropriately, the egg of the oviparous animal, which is actually dissolved from all connexion with the parent, and elaborating its own structure, by a curious preliminary action of life, before it comes to be deposited in the external nest.

Thus, even in this the most wonderful portion of nature, or of science of any kind, in which the mind can be occupied, we seek in vain for the origin of the living action—that which is in the blood and the muscle, and which the stroke of the lightning, and the other causes to which allusion has been made, can destroy in an instant. In the succession of races, we find that there is a continuation of matter, but no continuation of that motion which we consider, and rightly consider, as the indication of life. That may be, and is, within certain limits, similar in the species through all its generations; but in every individual it is new, the life of that individual and of none else. And here we can see clearly that it is mortal life, that as it begins with the individual, so with the individual it ends. Not one tittle of the experience of the material parent descends to the material offspring, but as life begins *ab origine* in the individual, so does all the experience of life. Not so with mind: there the memorial remains, and in the simple fact that we of the present generation may be wise in the wisdom of generations gone by, we have a proof and at the same time an illustrative example of the immortality of mind, and of its entire difference from matter.

Where, then, is that action of life in the animal which belongs to it as matter, and begins and perishes with the individual? Is it of the organisation? No; for it is by this very action that the organisation is evolved. Is it true that we cannot pronounce that there is life till we can see its effects; and as the first action of life in many animals is the evolution of its own structure, we cannot pronounce that there is life till some rudimental part of that organisation is formed; we cannot, for instance, say that the egg is not addled, and as such only a portion of matter fit for going to the store-house of nature's materials, till we see the primary action in it—the presence of the rudimental heart and the rudimental blood, the former a muscular structure, and the latter capable of elaborating that peculiar kind of muscular substance. These are the first evidences which we can obtain; but they are not the beginning; they are the results,—and results of self-action in the egg, though that action requires certain external stimuli—certain other actions of matter before it begins.

Thus the action precedes the organised substance; and therefore the action must be analogous to something which is not cognisable by the ordinary tests of matter. And when we look around, we find that this is not the only case in which results are brought about by means which cannot be brought to our ordinary tests of matter. The action of heat is all-powerful, so much so, that no strength of matter can withstand it; and yet it counts as nothing by the balance, and measures not a hair-breadth by the line. Light is in the same predicament; and when a certain intensity is arrived at, light and heat are inseparable. Electricity, by mechanical friction, or by chemical decomposition, and magnetism, apparently dependent upon the relative positions of one substance with another, are also, at certain degrees of intensity, inseparable from heat and light. There is, therefore, an obvious connexion between all these phenomena, or all these actions—for we cannot consider them as matter or substance under any modification—as no intensity of any or all of them can be made to amount to a material quantity. We see their effects only in some kinds or combinations of matter; and in different kinds or combinations, or in the same under different states; but they differ in their apparent intensities. Our natural perceptions are limited to that which it is necessary for us to know; and as we extend the bounds of our knowledge, the means of extending that knowledge further and making it more minute, extend along with them. The same science which sought to explore the heavens, found out the telescope, and the desire of being better acquainted with the minute, led to the construction of the microscope; therefore we need not despair in any matter which lies within the scope of the material creation. Those energies, which we have hitherto been able to observe in particular substances, and under particular circumstances only, may be afterwards found to influence all substances under all circumstances; and, among others, the living body in all its states. They, including animal life in the number, are probably all modifications of one energy; but we must not pursue the subject further. See LIFE.

BLOOD FLOWER. The *Hæmanthus coccineus* of Linnæus. A splendid family of bulbous plants, natives of Africa. They belong to *Hexandria Monogynia* of the sexual system, and to the order *Amaryllideæ* of Jussieu. Generic character: spatha consists of from four to six valves, containing many flowers, and persisting; corolla tubular below, limb six-parted, regular, erect; stamens springing from the tube of the corolla, protruding; filaments awl-shaped, anthers incumbent; style simple; berry three-celled, seeds trigonal. Like all the lily tribe this genus is most showy; and if a single flower enriches our assemblages of plants, how much more magnificent must acres of them appear in their native place! Amid the burning sands of Sierra Leone they appear in all their glory; the desert is cheered by the brilliant patches of the blood-flower, seen profusely scattered around; and though in the dry season the vitality of almost all herbaceous vegetation suffers, yet that of the *Hæmanthus* is safe,—secure in its investment of thick abbreviated leaves, which guard the living principle.

BLOODWORT is the *Sanguinaria Canadensis* of Linnæus. This plant is also called *Pucoon.*

BLOW-FLY (*Musca* [*Sarcophaga*] *carnaria*, Linnæus). A species of dipterous insect, belonging to the family *Muscidæ*, exceedingly troublesome in summer, in consequence of its incessant endeavours to deposit its offspring upon our animal food. It is of a black colour, with four longitudinal grey lines on the thorax; the abdomen is chequered with black and grey, and the legs are black. It is as large as, but more slender than the bluebottle-fly. These insects are of great service in the economy of nature, their province being the consumption of dead and decaying animal matter; and in order that the most effectual measures may be taken for the performance of this duty, nature has endowed them with the singular power of hatching their young in their own bodies, so that no time is lost by the insects remaining in the egg-state when deposited upon the decaying carcase. These insects have consequently been termed viviparous; but Messrs. Kirby and Spence object to this term, since none of these embryos are nourished, as in the true viviparous animals, within a uterus, by means of a placenta, but receive their development within true eggs, which are hatched in the body of the mother. This is confirmed by the observations of Degrer, who discovered eggs in the body of this fly. The numberless minute larvæ contained in the abdomen of the blow-fly are arranged in a remarkable manner; being of an oblong form, they are placed in an upright situation, side by side, against each other, and are coiled up in such position, somewhat resembling a roll of riband, which, when unfolded, was discovered by Reaumur to be nearly two inches and a half long, although the body of the parent is scarcely one-tenth of that size. Each of these larvæ has a distinct envelope, of the finest membrane, which, however, is not entirely divided from that of those adjoining to it, but appears to be one tube, which becomes extremely slender between each individual, so as, when drawn out, to look like a chain. In another species of *musca*, which Reaumur observed to be similarly ovo-viviparous, the young larvæ were found to be heaped together without any other order than that of being longitudinally laid side by side.

But it is not alone in the production of living offspring that these insects are so admirably fitted for the performance of the functions assigned to them. It was asserted by Linnæus, that three flesh flies would consume a dead horse as quickly as a lion. This, however, must be understood as having reference to the offspring of such three flies; and as a proof of such assertion, it has been ascertained, that a single female of the *Musca carnaria* will give birth to 20,000 young, which must, of course, be gradually developed, as they will necessarily occupy several days in being deposited by the parent. Each of these grubs, in twenty-four hours, will, in consequence of its intense voracity, have increased in weight not less than two hundred times, and in five days they acquire their full size. It requires about the same period to undergo the pupa state, so that, in a fortnight's time, there are descendants of the first brood in existence. When ready to appear in the perfect state, and to quit the shell-like cocoon in which they have passed the pupa state, the enclosed flies bursting forth at one of the extremities of their case. This is effected by the dilatation of the leather-like front of the head, which is alternately pushed forward and withdrawn, and by the swelling out of the cheeks; by this means a small circular cap, which appears in this group of insects to be especially employed for this purpose, is detached, producing an aperture sufficiently large for the escape of the fly, which at this time exhibits as it were only the rudiments of wings, these organs being twisted up in several crumple-like folds, but which, in the space of a very few minutes, are gradually stretched out, when the fly appears in its perfect form, and is ready to assume all the energies of its species.

BLUE-BIRD, or BLUE-ROBIN (*Sialia*, Swainson). An American genus of small dentirostral birds, allied to the robins and chats of the old continent, but sufficiently distinct from these to form a separate and natural division. The form is rather similar to that of a robin, but somewhat more slender; the bill is of a stouter make, the wings are longer, and more fitted for protracted flight, and the tarsi are considerably shorter; the whole form, indeed, indicating more arboreal habits than those of their nearest analogues in the old world, and it does not appear, from the minute descriptions of various observers, that they find their food so much on the ground; although, like the robin of this country, they are sure to be seen hopping fearlessly about wherever ground has been turned up. Three species only are known at present, and these are showy birds, remarkable for the rich sky or ultramarine blue of the uppe parts, and which forms the predominant tint of their plumage. Their bills and feet are always black.

These birds belong to a highly natural and tolerably well defined group or division of the *Sylviadæ*, or warbler family, and which various writers have designated by the term *Saxicolinæ*, from the wheat-ear genus, *Saxicola*, considered the standard of the division. It contains also the robin, chat, fantail, and redstart genera, with several other forms from different parts of the globe, amongst which may be reckoned an interesting genus in New Holland (*Petroica*), performing in that country the office of the redstarts and robins of Europe and Asia, the chats of Africa, and the blue-robins of North America.

All these various birds have a considerable resemblance in their appearance, in their actions, and general character. Their forms are thick and short, and most of the species stand high upon the legs, and are well adapted either for perching, or for light and agile movements on the ground; which latter are mostly performed by hopping, though a few of the species (as the chats of this country) can also creep rapidly forward with alternate steps: yet this is not their usual manner of progress, and is only resorted to when they are frightened, or when a cloud passes over the sun, as they run to a place of shelter, with their under parts almost touching the ground: a single genus, however, the fantails (see *blue-breast*), use only the walking, or rather running mode of progression. The plumage of these birds is generally very dense and thick, with two or more colours, seldom brilliant, but often rich and sometimes boldly contrasted; and many of the species have terminal winter edgings to their feathers, which gradually disappear in spring: the nestling, or first plumage, is invariably more or less mottled, or spotted with a lighter colour on the upper parts, and slightly edged with black on the under; a circumstance peculiar among the sylviadæ to this division, and reminding us of the flycatchers and thrushes, to each of which families certain of the species present various approximations, both in structure and habits. The tail is usually capable of much motion, but chiefly of being flirted up and down, is never long, and in many of the species (as the wheatears, chats, and blue-breast) is rather short, but in these is very capable of expansion. Their flights are usually confined to short distances (though many species migrate), and their manner of flying is somewhat peculiar, as they commonly drop from their perch to within a few inches of the ground, proceed close to the surface, and then mount often for several feet to alight; settling generally on the topmost twig of a tree or bush, or on the very summit of a hillock, or building, whence, possessing great power of vision, they can espy a beetle or other insect crawling among the grass at a very considerable distance, as Wilson (the American ornithologist) observes of the blue-robins, the subject of the present article. All the species have this habit of usually perching on the very highest point of an object, and many of the more typical chiefly inhabit open downs and commons, and even mountainous districts, where, perched on a slight eminence, their vision can command a considerable extent of surface. They are mostly very solitary birds, or seen only in pairs, the majority of them never associating in flocks, though the abundance of certain species in particular situations would lead to the supposition that they were social; the American blue-robins, indeed, appear to form the only exception, and these certainly migrate in society; but many sorts of birds collect in flocks to perform their seasonal migrations, the habits of which (as those of the blue-robins) are solitary at other times; but the European robin, chats, and redstarts, even cross the ocean in solitude, as the writer of this article has remarked in every instance which has come to his knowledge of these birds alighting on the rigging of ships . indeed, so little are they inclined to be social, that if two robins happen to alight on the same vessel, hostilities between them are always soon commenced, one usually takes possession of the bows, and the other of the stern, and they fight on the least invasion of each other's territory. The common redstart is equally pugnacious; and a flock of either of these birds would be as much a phenomenon as one of mountain eagles.

The food of the *Saxicolinæ* consists of earthworms, and various insects, which are chiefly sought for on the ground; and, like the nightingales (to which some of them are nearly allied), they appear most fond of the larvæ of beetles, in search of which the redstarts often enter the hollows of decayed trees, and examine the rotten wood; these latter, also, together with the blue-breast, and the Australian *Petroicæ*, capture insects on the wing like the flycatchers, and may often be seen hovering around a bunch of leaves, examining them for caterpillars and spiders. Others, as the robins, chats, and especially the American blue-robins, feed occasionally on various small fruits and berries, which are swallowed whole. They have all the power of hovering in the air, and many of them often sing while on the wing, the wheatears whilst hovering, and the redstarts as they fly from tree to tree. Even their very notes are, to a certain extent, extremely similar; and their songs are always uttered in short detached staves, like those of the thrushes, and never (as in the skylark, or the blackcap, and various other warblers) in a continuous unbroken strain. Their nests (which are of loose construction, though containing much material) are never situate on a forked branch, nor fixed among the twigs of a bush, but rest always on a solid and substantial basis, either (according to the genus) in the hole of a tree, the nook of a rock or building, or on the ground, under cover of a stone or clod of earth, or of thick herbage. The eggs vary from four to seven, and, in every known instance except the robin, are of a uniform blue or bluish white, and mostly spotless.

Upon the whole, this is a very natural and tolerably well marked group, although, as in every other numerous division, it is difficult to draw a single general character to which some few of the species do not offer an exception. It is a group, however, very easily recognised by all who pay attention to birds. The chief distinctive characters of the blue-robins have already been mentioned; they are formed more for flight, and for perching, than for seeking their food upon the ground; and their bills are of a stouter and stronger make than those of most of the other birds of this division. Accordingly, we find, in Wilson's admirable account of the common species of the United States,

SIALIA WILSONII (*Sylvia sialis*, Latham). He states, that "their principal food are insects, particularly *large beetles*, and others of the coleopterous kinds that lurk among old, dead, and decaying trees. Spiders are also a favourite repast with them. In the fall, they occasionally regale themselves on the berries of the sour gum; and, as winter approaches, on those of the red cedar, and on the fruit of a rough hairy vine that runs up and cleaves fast to the trunks of trees. Ripe persimmon is another of their favourite dishes, and many other fruits and seeds." This species is six inches and three-quarters in length, with the wings remarkably full and broad; the whole upper parts are of a rich sky-blue, with purple reflections; the bill and legs black; inside of the mouth, and soles of the feet, yellow; the shafts of all the wing and tail-feathers are black; throat, neck, breast, and sides, reddish chestnut; wings, dusky black at the tip; belly and vent, white. The female is easily distinguishable by the duller cast of the back, the plumage of which is skirted with light brown, and by the red on the breast being much fainter, and not descending nearly so low as in the male; the young are brownish on the upper parts, and not very much mottled. A curious fact has been noticed by the honourable and Rev. W. Herbert, of the plumage of this species; we believe, in individuals kept by him in confinement, in this country, he says "the American blue-bird produces brown feathers in its summer moult, which are very suddenly turned to blue." It is most probable that this change also takes place in a state of nature, though the fact has not hitherto been noticed by those who have described the bird.

This species is found over the whole United States; as also in the Bahama islands, where many of them winter; and in Mexico, Brazil, and Guiana; though probably another and closely allied species, the *S. Mexicana*, has often been confounded with it in these latter countries.

The third species, *Sialia arctica*, inhabits the far countries, and was discovered by the naturalists who accompanied the last overland expedition. This also is a beautiful bird; the upper parts are rich ultramarine blue, and the under parts greenish blue, inclining on the abdomen to greyish; the vent-feathers, and under tail-coverts, white. The bill is narrower at the base, but larger and more strongly formed than that of *S. Wilsonii*, which species the bird much resembles in size and general appearance.

In describing the common species of the United States (*S. Wilsonii*), Wilson eloquently observes, that "the pleasing manners and sociable disposition of this little bird, entitle him to particular notice. As one of the first messengers of spring, bringing the charming tidings to our very doors, he bears his own recommendation always along with him, and meets with a hearty welcome from every body.

"Though generally accounted a bird of passage, yet, so early as in the middle of February, if the weather be open, he usually makes his appearance about his old haunts, the barn, orchard, and fence posts. Storms and deep snows sometimes succeeding, he disappears for a time; but about the middle of March is again seen, accompanied by his mate, visiting the box in the garden, or the hole in the old apple tree, the cradle of some generations of his ancestors. 'When he first begins his amours,' says a curious and correct observer*, 'it is pleasing to behold his courtship, his solicitude to please and to secure the favour of his beloved female. He uses the tenderest expressions, sits close by her, caresses and sings to her his most endearing warblings. When seated together, if he espies an insect delicious to her taste, he takes it up, flies with it to her, spreads his wing over her, and puts it in her mouth.' If a rival makes his appearance,—for they are ardent in their loves,—he quits her in a moment, attacks and pursues the intruder as he shifts from place to place, in tones that bespeak the jealousy of his affection, conducts him with many reproofs beyond the extremities of his territory, and returns to warble out his transports of triumph beside his beloved mate. The preliminaries being thus settled, and the spot fixed on, they begin to clear out the old nest, and the rubbish of the former year, and to prepare for the reception of their future offspring. Soon after this, another sociable little pilgrim, the house wren, *Troglodytes Œdon*, also arrives from the south, and finding such a snug berth preoccupied, shows his spite by watching a convenient opportunity, and, in the absence of the owner, popping in and pulling out sticks; but takes special care to make off as fast as possible.

"The female lays five, and sometimes six eggs, of a pale blue colour, and raises two, and sometimes three broods in a season; the male taking the youngest under his particular care while the female is again sitting * * * *. Their spring and summer song is a soft, agreeable, and oft-repeated warble, uttered with open quivering wings, and is extremely pleasing. In his motions and general character, he has a great resemblance to the robin-redbreast of Britain; and, had he the brown olive of that bird, instead of his own blue, could scarcely be distinguished from him. Like him, he is known to almost every child; and shows as much confidence in man by associating with him in summer, as the other by his familiarity in winter. He is also of a mild and peaceful disposition, seldom fighting or quarrelling with other birds. His society is courted by the inhabitants of the country, and few farmers neglect to provide for him, in some suitable situation, a snug little summer-house, ready fitted and rent free. For this he more than sufficiently repays them by the cheerfulness of his song, and the multitude of injurious insects which he daily destroys. Towards fall, that is, in the month of October, his song changes to a single plaintive note, as he passes over the yellow many coloured woods; and its melancholy air recalls to our minds the approaching decay of the face of nature. Even after the trees are stripped of their leaves, he still lingers over his native fields, as if loth to leave them. About the middle of November, few or none of them are seen; but, with every return of mild and open weather, we hear his plaintive note amidst the fields, or in the air, seeming to deplore the devastation of winter. Indeed, he appears scarcely ever totally to forsake us, but to follow fair weather through all its journeyings till the return of spring.

* * * "The blue-bird, in summer and fall, is fond of frequenting open pasture fields; and there perching on the stalks of the great mullein, to look out for passing insects. A whole family of them are often seen thus situated, as if receiving lessons of dexterity from their more expert parents, who can espy a beetle crawling among the grass at a considerable distance; and, after feeding on it, instantly resume their former position."

We see, in this last passage (as Sir W. Jardine observes, in his note to Wilson), the exact habits of the European chats portrayed. "They invariably select the summit of some elevation, a hillock, a stone, bush, or some of the taller wild plants, and if occasionally on a tree, the topmost branch is always preferred; there they perch, uttering their monotonous call, which increases in anxiety and frequency as we approach the nest, or the young before they are able to fly; or they alight at intervals, run" (or rather hop about like a robin) "for some distance, and again remount to a fresh station. When not annoyed, they retain the same elevated situations, looking out for food, taking the insects seldom on the wing, but generally by a sudden spring, or by leaping down, and returning immediately with the prey in their bill, where it is retained for a few minutes, while they repeat their uniform note. The young, as soon as

* Mr. W. Bartram, the venerable friend of Wilson.

they are able to fly, have the same manners with their parents, and at the season when these are first on the wing, some extensive commons have appeared almost entirely in motion with our common species*."

Speaking of the migration of the blue-birds, Wilson observes, that "nothing is more common in Pennsylvania than to see large flocks of these birds, in spring and fall, passing at considerable heights in the air; from the south in the former, and from the north in the latter season. I have seen, in the month of October, about an hour after sunrise, ten or fifteen of them descend from a great height, and settle on the top of a tall detached tree, appearing from their silence and sedateness, to be strangers, and fatigued. After a pause of a few minutes, they began to dress and arrange their plumage, and continued so employed for ten or fifteen minutes more; then, on a few warning notes being given, perhaps by the leader of the party, the whole remounted to a vast height, steering in a direct line for the south-west. In passing along the chain of the Bahamas towards the West Indies, no great difficulty can occur, from the frequency of these islands; nor even to the Bermudas, which are said to be six hundred miles from the nearest continent. This may seem an extraordinary flight for so small a bird; but it is, nevertheless, a fact that it is performed. If we suppose the blue-bird in this case to fly only at the rate of a mile per minute, which is less than I have actually ascertained him to do over land, ten or eleven hours would be sufficient to accomplish the journey; besides the chances he would have of resting by the way, from the number of vessels that generally navigate those seas. In like manner, two days at most, allowing for numerous stages for rest, would conduct him from the remotest regions of Mexico to any part of the United States." Many blue-robins, however, it would appear, never leave the United States' territory, a few solitary individuals being seen there even in the depths of winter, especially about the cedar trees, whence they issue and approach the cultivated grounds at every interval of fine weather.

The blue-robins are interesting birds, not only from their pleasing familiarity, but from their general distribution and number of the individuals in North America, where they are the only *Saxicolinæ*, and where they consequently appear to occupy the station, and to perform the office, which in other parts of the world, are filled by a considerable number of birds, of various species, and even genera. They are birds which follow cultivation, and have doubtless greatly increased in numbers since the country was reclaimed by Europeans, and will still continue to increase, as the forests are cut down, and their sites become adapted to their habits.

BLUE-BOTTLE, or FLESH-FLY. The *Musca vomitoria*, Linnæus, and several other allied species of dipterous insects, are ordinarily known under this name. They are amongst the largest species of the genus found in this country, and generally of a blue colour, whence their name; some species, however, with similar habits, are green, as the *Musca Cæsar*. In their habits, however, they very nearly resemble the blow-fly, but with this principal difference, namely, that they are deposited in the form of eggs by the parent flies. But here, again, we find nature equally rich in resources, since the eggs, instead of lying for days or weeks in an unhatched state, as is generally the case with insect eggs, are hatched in the course of a couple of hours. The insatiable voracity of the grubs hatched from these eggs is not less than that of the blow-fly. Of this Messrs. Kirby and Spence have given a remarkable instance, in which these flies attacked the living body of a poor man who incautiously laid himself down in a field, having been taken rather unwell, the flies being, in the first instance, attracted by pieces of meat which he had begged and placed between his shirt and his skin; and to such a degree did the grubs swarm upon his body, eating into it in all directions, that he only survived the operation of cleansing his body from them for a few hours. A recent writer has attempted to call in question the unerring instinct of insects in the deposition of their eggs upon those substances most congenial for the food of the young when hatched, and has instanced, in support of his attempts, the case of the common blow-fly, *Musca vomitoria* (or rather *M. carnaria*), which sometimes lays its eggs in the fœtid funguses (*phalli, agarici*, &c.), "apparently under the notion that these are genuine carrion."—Insect Transformations, p. 76. We apprehend, however, that the only notion entertained by the insect is, that the substance upon which the eggs are deposited will serve for food for its young, which it does most effectually. Thus this mistaken "notion" tells against the writer's argument. We have seen the carrion plants, *Hoya carnosa*, swarming with grubs, which there obtain an abundant supply of food, as figured by Rosel (*Muscidum et Culicum*, plate 9, 10.) From the experiments of Spallanzani, it appears that these grubs are able to withstand a heat of 88° Fahrenheit, but that they perished when it was raised to 108°. These experiments were conducted with so much care, that we cannot hesitate in considering Dr. Good's statement, that eggs of the blow-fly deposited upon meat, and broiled with it upon a gridiron in a heat far beyond 212°, instead of being destroyed, are thereby quickened into their larvæ state. The appearance of maggots on broiled meat, as judiciously observed in the work above referred to, p. 119, from which the inference is apparently made, seems rather to indicate that eggs, or more probably ovo-viviparous larvæ, had been deposited there, not before, but after the broiling.

BLUE BREAST; SWEDISH, or BLUE BREASTED FANTAIL. (*Pandicilla Suecica; Motacilla Suecica* of Linnæus.) A small European bird, which lately has been added to the list of stragglers to the British islands, a specimen having been killed in an undoubted wild state, upon a common, near Newcastle upon Tyne. In size and form it much resembles the different redstarts (*Phœnicura*, Swammerdam), but differs from them in several minor particulars, and especially in its mode of progression, which is always ambulatory, or by alternate steps, and never by successive hops, as in those birds. The crown of the head and rest of the upper parts are brown, the latter tinged with greyish, and paler on the margins of the scapulars and wing-coverts; feathers at the base of the bill, and streak over the eye, yellowish white. The chin, throat, and upper part of the breast, rich azure, with a silky white spot in the centre; the blue bordered beneath with a narrow gorget of black, which is succeeded by another of reddish brown. Under parts dirty white, inclining to

* Note to Jardine's Edition of Wilson. Vol. i. p. 60, 61.

grey. The two middle tail-feathers brown, the remainder having their basal half of a bright ferruginous, or brownish orange colour. In the female the upper parts are paler, the chin pale azure blue, mixed with black, streak on each side of the neck, and upper part of the breast, black, intermixed with azure blue, and surrounding a large spot of white. The young are in their first plumage mottled.

This is a handsome and rather interesting bird, somewhat intermediate in character between the redstart, and the pipit and wagtail group; and also having some affinity for the fan-tail flycatchers of America (genus *Setophaga*, Swammerdam), from which it chiefly differs in the make of the bill.

It is a restless, active species, but its habits are very retired and shy; and as it runs upon the ground, or along the branch of a tree, it very frequently spreads its tail open wide, a habit in accordance with the transatlantic birds above-mentioned, the more characteristic species of which (as the *S. ruticilla*), have the tail exactly similar in form and colour. Like those birds, also, and the redstarts of the old continent, the blue-breast often captures insects on the wing, darting after them like the various species of flycatcher.

It is a migratory bird, chiefly inhabiting in summer the more northern countries of Europe, being rare in Germany, France, and Holland. Its haunts are in the forests, where, like the redstarts, it is said to build in the holes of decayed trees and to lay five or six eggs of a pea-green colour. Its notes are, we believe, very simple; and we are unaware of its possessing any proper song. Its food consists of insects and their larvæ, and earth-worms; and in confinement it soon becomes familiar, and is tolerably hardy, much more so than the different *Phœnicuræ*. With these last birds it has been very generally classed, but as we are sure such an arrangement would never be followed by those who have ever seen it alive, we have thought it best to make it here constitute a separate division; considering that, in the feathered creation especially, the associating in the same minimum group species which are not very closely similar, tends, in some measure to retard, rather than to advance, the progress of the science, the habits and manners of little known species being commonly and very naturally inferred, from a knowledge of those of the other species with which they have been grouped: nor is this remark altogether confined to such as are little known; the peculiarities of the bearded reed-bird (*Calamophilus biarmicus*) have been overlooked by most writers who have described it; and this merely, perhaps, because having been placed by Linnæus and most subsequent writers in the genus *Parus*, it has been commonly taken for granted that its general characters were similar to those of the other tits; and the same applies also to the bottletit, or long-tailed titmouse (see BOTTLETIT), a species very common in the British islands. So long, therefore, as the Swedish fan-tail continues classed in *Phœnicura*, its general characters will be presumed to be similar to those of the other redstarts, which latter, if kept only within due restrictions, form an extremely natural and well marked division. On this account, we have affixed the generic name *Pandicilla* to this species, a term expressive of its almost constant habit of horizontally spreading open the tail.

The fan-tail, or blue-breast, as we have already remarked, becomes soon confiding and familiar in captivity; and after moulting in the cage, the blue colour on the breast is always much duller than in the wild birds. These feathers are in winter fringed with whitish tips, which gradually wear off in the spring. In this country, it can only be considered as a very rare straggler, the above-mentioned being the only recorded instance of its occurrence; yet it is not improbable that some may be often compelled by adverse winds to take shelter on the British shores, when attempting to cross from the southernmost point of Norway: the disappearance of birds of passage in the autumn being, in many species, extremely gradual, and often continuing for a number of successive weeks.

BLUE-CAP, BLUE TITMOUSE, or TOMTIT (*Parus cœruleus*). This common little bird would be greatly admired for its beauty, were it only a little less abundant, its plumage when clean being a most delicate admixture of soft and pleasing colours. The forehead, a large triangular patch on each side of the neck, and a line over the eye, which is continued round the back of the head, white. A line of blackish blue commences on each side of the base of the bill, passes through the eyes immediately under the white band, and also meets behind, then descending and forming a broad band, surrounds the triangular patch of white, meets in front, and is continued up to the chin; imparting a sort of harnessed appearance to the bird. Under this, on the lower part of the back of the neck, is another broad spot of white. Crown of the head, wings, and tail, pale blue; the scapulars and greater wing-coverts tipped with white, the latter forming a white band across the wing. The back of a light greyish green, and the whole under parts sulphur yellow, with an ill defined blackish line along the middle of the belly, legs and toes bluish grey. The female differs only in being rather less bright in colour, and in the young the crown of the head is blackish brown.

In this titmouse the bill is shorter and thicker than in the more characteristic species of *Parus*, and the bird consequently exhibits some slight modification of habit. It is very rarely seen to hammer seeds in the manner of the others, nor does it often hold its food with both feet like the rest, but most commonly with one foot. In confinement, the others will entirely subsist on hempseed, which they hold firm between both feet, whilst they pierce a small hole in the husk with repeated knocks of the bill, through which they extract the kernel; but we have never observed the blue tit to hammer seeds in this manner, and though fond of hempseed, it will not, at least in confinement, ever touch it unless it finds some already cracked. The minutest characteristics are, in natural history, often quite worthy of attention, as they sometimes throw considerable light on the habits of an animal.

As restricted to the different species which nidificate in holes, the genus *Parus* forms an extremely natural and well marked division, the more characteristic species of which exhibit a marked resemblance to the jays (genus *Garrulus*) in very many particulars. Their general form and structure, and the loose, pretty texture of their plumage (the webs of the feathers being discomposed), their soft and subdued colours, their omnivorous appetites and hardy constitution, together with their general manners, their harsh chattering notes of alarm, the remarkable degree of cunning and sagacity which they evince, and their habit of constantly placing the foot upon their food whilst picking it to pieces, and of concealing for a future occasion what they cannot eat, all strongly remind us of the jays and magpies, and together confer a peculiar interest on this diminutive but pleasing group. The present species, perhaps, feeds less on oleaginous seeds than some of the others, but it may nevertheless be well termed omnivorous; it subsists in the spring and summer chiefly on insect food, to obtain which, in winter, it often pulls off the buds of trees, whence it has generally by horticulturists been considered an enemy; but we think inconsiderately, for, as is well observed by an eminent naturalist, Mr. Selby, "the trifling injury sometimes committed by the abrasion of a few blossom-buds, is more than compensated by the destruction of innumerable larvæ, and eggs of the insect tribe, which are usually deposited in or about those essential parts of fructification; and which, if allowed to proceed through the necessary changes, would effectually check all hope of produce." Moreover, we are inclined very much to question whether they ever do attack any buds but those on which they perceive the traces of an insect; for we have frequently observed them, when searching for their food upon the fruit trees, to pass by in succession many whole spurs full of blossom-buds, and then to attack eagerly a particular one, on which they no doubt perceive evident indications of the destroyer lurking within.

The blue titmouse feeds also on various kinds of fruit; and at the approach of winter will eat many farinaceous seeds, and even swallow corn whole; being particularly fond of oats, the husks of which it will sometimes hold fast between both feet in the usual manner of the genus, whilst it picks out the grain. It becomes very bold as the season advances, and frequents out-houses, and dust bins, and butchers' shambles, carrying off pieces of suet, picking bones, and eating all manner of garbage, and still searching every chink and cranny for the grubs of insects. It is a constant attendant wherever horse-flesh is kept for the hounds; and sometimes even evinces a sanguinary propensity, by attacking other small birds, when it finds them incapable of resistance, and after having killed them by repeated blows on the skull, devouring their flesh. We have noticed this likewise in other species of *Parus*, but nevertheless consider it to be of very rare occurrence, not one individual in fifty, perhaps, ever displaying any hostile feeling towards other birds.

The nest is generally situate in the holes of trees, or old walls, the former of which it often enlarges, and sometimes almost wholly excavates for itself, if the wood is soft and decayed. It is composed of various mosses, and lined with feathers and hair; and the eggs, six or eight in number, are white, speckled with rust-colour at the larger end. The female is not easily driven from her nest, but if an attempt be made to seize her, bites with severity, at the same time ruffling her feathers, hissing and making the spitting noise of an irritated kitten.

The notes of this species are few and little varied, consisting chiefly of a weak chirp, and a louder harsh chatter, its cry of alarm; in the spring it also utters a soft ringing note, which may be considered its song, and which is certainly not unmusical. It is a bird of very active and lively habits, for ever examining the trees and bushes for insects, and in its search for them constantly assuming the most grotesque and often beautiful attitudes. And it is remarkable for being always about the first among small birds to spy out an enemy, a weasel or an owl, the latter of which it most perseveringly and unremittingly persecutes whenever it ventures forth into daylight.

BOA. A genus of aphidian reptiles which have no poison fangs, or other venomous apparatus, but which are nevertheless very powerful as crushing serpents, as they can very rapidly, and by what seems a sort of absolutely frensied motion, it is so rapid, twist themselves round the bodies of tolerably large animals, and crush them to death. As is the case with all serpents, they have no means of masticating or dividing their prey in any way, and as a compensation, their gape is remarkably wide, and their throat and gullet capable of much dilatation.

The presence or absence of the moveable poison fangs, which are not fixed in the maxillary bones, is not in itself a sufficient criterion of a serpent being poisonous or not poisonous; for there are some which have the fixed teeth perforated with tubes, and are capable of inflicting venomed wounds by means of these. See OPHIDIA. Some of those which have been included in the genus *boa* have this latter kind of poisoning structure; but these are very properly separated from the true boas, which kill their prey by muscular strength only; and after this separation has been made, the genus still contains a number of species.

These formidable reptiles are found only in the warmer parts of the world, generally in those where vegetation is rich, and many of them near the waters rather than in the dry and open places. The Malay peninsula, on the continent of Asia, the Oriental Isles, and Brazil and Guiana in tropical America, are the parts of the world where they are most abundant. It thus seems as though the utmost energy of those powers which produce natural action were required for the development of these animals; and there are few that suffer a greater falling off of their activity when they are brought into cold latitudes. Those which have been brought to Europe as curiosities (for it can be only as curiosities that they are brought, as they are useful to man no where, neither are they in any degree ornamental), have continued to show their periodical voracity while on board ship in the very warm seas; but after they come into the cold latitudes they have to be kept warm by artificial means, otherwise they show hardly any signs of life. Those which have been brought to England and kept alive have, besides their forms, shown hardly any thing else than how tenacious of life these reptiles of the warm climates are, and how long they can live without food where there is not sufficient heat to call their system into activity.

Nothing shows more convincingly the dependence of the different parts of the system of nature upon each other, than those large and formidable reptiles of the warm climates. Though they can wriggle along with considerable rapidity for short distances on land, though most of them can swim, and though they can make very violent momentary efforts in the capture of their prey, yet they are incapable of much change of place by locomotion; and it appears to cost them no small effort before they can be roused even to that activity which is necessary for taking their food. Thus they must remain in their localities and abide what comes; and their powers of endurance are well suited to this state of life. When they are not excited, there appears to be little waste in their system; and their power of swallowing is so great that one full meal serves for weeks; and, for a considerable time after it is taken, the whole energy of the animal appears to be so completely absorbed by the work of digestion, and its powers both of attention and of motion so completely deadened, that it makes no attempt at resistance or even at escape. When hungry or otherwise excited, these animals are very formidable, and their motions are so quick, and their strength in crushing is so great, that it is very hazardous to approach them; but when they have taken a full meal, a naked savage may with impunity go in upon the most powerful of them, and fell it by blows on the head with a club; and so completely are its faculties engrossed by the inward labour of digestion, that instead of making efforts to escape from the blows, it hardly writhes under them, but dies with the same comparative quiet as it is then bearing.

There is some confusion between this and some of the nearly allied genera, as there is about most of the serpents, and indeed of the whole class of reptiles generally speaking, so that the character and conduct of one have sometimes been ascribed to another. There is a proneness to exaggerate every thing about reptiles, and there is a popular aversion, which those who have the best opportunities of examining them have not always the power of overcoming. Besides, their habits are obscure and retiring; and in order to be observed, they must be searched out with more diligence than most animals. The places which they frequent are also not the most inviting, or even the most safe; they are the tangled brakes and margins of marshes in very hot climates, which are unhealthy, and though the reptile of which the observer is in search may not be venomous itself, there is no knowing where venomous ones may be lurking; and as these are usually smaller and more easily put in motion than the larger ones which are not venomous, it requires no small nerve as well as caution to thread the serpents' preserve with the requisite degree of attention. Hence, there are probably more undescribed or inaccurately named and described specimens of reptiles in the collections and museums, than there are of all the other vertebrated animals taken together.

The form and number of the scales, especially those on the under side of the body and tail, have been, in the true serpents, among the chief means of generic distinction. These scales are their proper organs of locomotion, and the only external organs, excepting such as appear on the head or are attached to the extremity of the tail. The external means of distinguishing one serpent from another, when they are in their proper haunts in free nature, are therefore not only much more limited than in the case of animals which have feet or wings, or even fins. They are also obscure, because the parts are small and inconspicuous, and if the number or the form of the scales are the only distinguishing characters, then the species or even the genus of a serpent cannot be ascertained, unless it is killed or captured.

This uncertainty is the cause of another: for, as we cannot understand the character of the one which gets away, we are not sure whether those foundations of character which we adopt are constant or not. We know that, in some of the species, the number of cartilaginous pieces which form the rattle at the extremity of the tail, increases with the age of the animal, and also that some of them are apt to be broken off by accident; and it may be possible that the number and also the form of the scales on others change with age. Colour too is, though necessarily relied on in cases where the means of distinction are so few, not worthy of implicit confidence, especially when we come to the nicer distinction of individuals which have a very strong general resemblance to each other. These difficulties, and taking them altogether they are of a kind not easy to be removed, are but too good an apology for the mist of obscurity which hangs over this department of natural history, and renders it so dark that he who writes on it with the greatest apparent confidence is generally the least worthy of credit.

Taking the distinctive character from the scales on the under part of the belly and tail, the tribe or family of *boa* comprehends all those serpents which have these scales entire, or of one plate extending from side to side without any joint upon the mesial line, and which at the same time have neither a rattle nor a spinous prolongation at the end of the tail. It is by this series of single scales that the family *boa* is distinguished from *coluber*, in which there are two rows of scales along the same part; but there have been specimens observed with some of the scales on the under part double, while the majority were single. It should seem that the larger crushing serpents of the south-east of Asia belong to the coluber family, and to the genus or sub-genus python (see Coluber), while the larger species of true boa are found only in the tropical parts of America; and they seem to be found nearer the water, and generally to inhabit more humid places than the pythons of the East.

The boas have a spinous hook at each side of the vent, the body compressed, and the tail prehensile, or capable of holding on by a tree or a branch, while the rest of the body coils round the captured animal, and sometimes draws it toward the tree, where it is crushed to death. The scales upon the upper part of the body and hinder part of the head are small. The structure of the head and jaws varies considerably, and gives rise to some subdivisions of the genus.

Some of the species attain a very large size, measuring thirty or forty feet in length; and when they are of that size they can master deer and even buffaloes. Their mode of killing is always by crushing in the coils or folds of their bodies, if the prey is so large as to require that operation; and they lick or smear it all over with their glutinous saliva, before they begin to swallow it. When the prey is of smaller size, they seize it at once in the vast opening of their mouths.

No one who sees these animals only in a state of inaction, and with the mouth shut, and the neck of of the usual dimensions which it has in that state, would readily form an idea of the vast extent of their gape and the wideness of their gullet; but the one and the other will so open as to take in an animal of much greater diameter than the serpent itself. All the true serpents have the under jaw articulated in a peculiar manner, which will be explained in the article Ophidia; but we may mention here that the lower jaw is not articulated upon the bones of the cranium, but upon two additional bones; and that these again are not articulated upon the bones of the cranium, but attached by muscles and ligaments, which admit of considerable extension. A portion of the anterior part of each jaw is also formed of ligaments or tendinous matter, which is flexible and capable of being stretched.

This mouth, therefore, not only differs from but is in a great measure the very reverse of those mouths with which we are familiar in ordinary animals. In these the power of the mouth is in shutting the jaws against each other; and whether the teeth be fitted for tearing, for cutting, for grinding, or for simple prehension (as they are in most fishes), the efficiency of the animal, and the danger, if it is a powerful and rapacious one, are in the bite. The snakes, or harmless serpents, which have in the form of their skeletons some rudimental resemblance to the saurian reptiles, have the mouth, though rather loose in its articulation, constructed in a manner similar to the rest of the vertebrated animals; and, therefore, its most powerful action is in the bite, though that bite is, from the looseness of the articulation, very feeble, which is the reason that the animals are so very harmless.

Of the true serpents, those which have poison fangs, have not in general the gape so capable of extension as the boas and others which are without poison apparatus; but even in these it is dilatable to a degree quite unknown among any other animals, and quite sufficient to rank them in the same suborder with the crushing serpents.

In these, the jaws have their greatest action in opening. The sides of the gape, as they appear when the mouth is closed, are not only brought into one plane, but the junction of both jaw-bones in front and that of the lower ones, or rather of the intermediate bones, with the cranium behind, are greatly extended; so that the entire circumference to which the mouth opens as a swallowing organ is much greater than the measure round both jaws to the extremity of the gape when shut. A fox trap, or a purse which opens by a circular strap, the two sides or valves of which fold completely back from each other till they are in the same plane, will afford an approximate notion of this formidable gape. But it is only an approximation, for the stretching of the ligaments which connect the different bones can, upon occasion, double the opening made by the bones themselves. Bringing the gape to this state is a work of some time with the animal, and it seems to excite the muscular part of the body at the same time; for the moment that the mouth is opened to the requisite extent, the snake darts on its prey. The teeth in both jaws, though not biting teeth, or capable of inflicting any deadly or even serious wound, are recurved, so that they assist powerfully in the act of swallowing whatever the great gape can admit. Figures and even stuffed specimens of these snakes are sometimes represented as biting at the throats of those animals round which their folds are coiled; but this would be a very unnecessary operation to them, as it could in no way facilitate their purpose, which is to swallow the animal entire. If the animal is large, the crush of the folds is sufficient to kill it; and if it is small, even that is not necessary, as it is taken into the mouth at once—a gulf from which there is no return.

The smearing with the slimy saliva tends to make the prey slide more easily into the gullet, which dilates to receive it to the same extent as the opening of the mouth. The form of the teeth and the peculiar junction of the jaw bones, in consequence of which they can act either all at the same time or by turns, urges the prey inward, something in the same manner as the awn or beard of a barley-corn moves up a man's sleeve when he moves his arm, or as hairs work into a compact mass in the operation of making a hat, or any other process of felting.

It does not appear that any of these serpents break, or have the power of breaking the skull of their prey; because a case of bone of the form of a skull is very difficult to break by compression all round it. The gape is therefore adapted to admit the head of the animal, and then the rest follows as a matter of course.

The quality of the slimy matter with which the prey is covered has not been examined; but it is not improbable that it has a solvent as well as a smoothing power, and assists in digestion as well as in deglutition. At all events the work of decomposition in the prey soon begins; and as there can be little except solvent action exerted upon it, that action must be very powerful, and it constantly goes on along the whole canal from the mouth till the prey is completely reduced to matter fit for the nourishment of the reptile.

When we consider this wonderful mode of feeding, we need hardly wonder at the stupor which ensues; for, what with the dilatation of the mouth and gullet, what with the action of the jaws and teeth in "working in" the prey, to say nothing of the vast muscular effort requisite in crushing to death an animal, round which the serpent's coils appear not much thicker than those of a cable round a mast, the feeding of one of these crushing serpents is among the most laborious operations which we know of, or can imagine, in the whole range of animated nature. And though there certainly is nothing pleasing in the study of these singular creatures, they form one of the most remarkable, and far from one of the least instructive studies that we meet with in the whole compass of natural history.

We have entered so much into the general structure and action of these reptiles, that we shall be enabled to dispose of the different species very briefly. Cuvier makes five divisions of them, besides the allied subgenera, which have more resemblance to the boas than to any other genus of serpents.

The first are those which have the head, to the point of the muzzle, covered with small scales, the same as those on the body; and the scaly or horny plates on the jaws are not grooved or dimpled. To this division belongs *Boa Constrictor*, the "roebuck serpent," one of the largest and most formidable of the genus. It is easily known by the markings along the back, which are very distinct. These consist of a regular succession of spots, the whole length of the mesial line, alternately black, and in the form of irregular hexagons, and ovals of a yellow colour, and broken by notches at the sides. The annexed figure will give a general idea of this powerful reptile.

It has sometimes been supposed that the boa constrictor exists in the old continent, in the hottest parts of Asia and Africa, and there only; but, as has been mentioned, the probability is that the large serpents found in those places are colubers, and that the true boa constrictor, answering to the generic description, is found only in the richer parts of tropical America.

A second section of the genus have scaly plates behind the eyes, as well as on the sides of the jaws and front of the muzzle, by which they are easily distinguished from the former section, though, like that, they have no dimples or furrows on the jaws. They are also readily distinguished by the markings on the upper part, which consist of a double row of round black spots down the sides of the mesial line, with eye-shaped spots on the flanks. The general colour is brown. The species which forms this section is *Boa scytali* of Linnæus, and *Boa aquatria* of Prince Maximilian. It is much more aquatic than the former; and while that watches for its prey in the thick and tangled parts of the woods, this waits more frequently in the waters, and seizes and swallows the animals which resort there to drink.

Boa Constrictor.

A third section have scaly plates on the muzzle, and those on the sides of the jaws furrowed or dimpled. The species which forms this section is the speckled boa (*Boa cenchris*, Linnæus); its ground colour is yellow, marked along the back with a succession of brown rings, and with variously formed and coloured spots along the flanks.

These three species or sections form the true or characteristic boas. They all attain nearly the same size, and do not differ much in their habits. They all frequent places which are humid, although some inhabit further into the marsh, or are more frequently found in the water than others. They are often found with the prehensile tail curled round a tree by the side of a pool or stream, waiting for their victims, and at other times they are stretched along the water, in which state they bear some resemblance to floating sticks. They are not however, very often seen, because the places to which they resort are very unwholesome, and not very tempting in other respects.

The time of their greatest activity is said to be during the subsiding of the floods after the rains, a season at which the places which are left bare are peculiarly pestilent; but the different species of living creatures to which these places are native, whether animal or vegetable, are then in a state of energy and activity, unknown in more open and healthy places. Indeed it is the very rankness of these places which makes them so rich,—their pestilent qualities, which enable them in the course of a few months, or even weeks, to send forth a vegetation and produce an assemblage of living creatures which would be the work of years for the more sober (but to man more healthy) powers of life in temperate climates.

As the hot season advances, the action of the sun begins to destroy what it was so powerful in producing while the ground was humid. This of course takes place first at the higher level of the inundation, where also the productiveness of the former part of the season commenced; and it gradually creeps onward, as the water dries up and the vegetation withers, toward the channel of the river whose overflow produced the inundation, from which this excess of living action arose. These, in many places the productive surfaces, at least in so far as seasonal plants and seasonal animals are concerned, is reduced to a mere line, and the food of these large serpents becomes scarce, and not easy to be had. But they are tempered to all the changes of climate of which they are so exclusively and peculiarly native; and the excess of heat and drought begins to have an effect upon them not altogether dissimilar to that which they experience when they are carried into colder climates.

It appears to be a general law of nature, and it is one the knowledge of which is of much practical utility, that if any animal can bear with difficulty a change from its natural degree of heat in the one direction, it can bear it just as ill in the other. The power of endurance appears to extend from what may be called the mean natural temperature, about equally toward cold and toward heat. We find that those animals which hybernate during the cold months in high latitudes are most oppressed by heat when the weather is very hot. We have examples of this in the case of moderately low average temperature, in bears, marmots, and bats, which though they become languid or wholly dormant during the rigour of the winter, feel very uncomfortable in the heat of the day during summer; so much so, that they generally keep in concealment then, and come abroad only when the sun is low, or in the twilight. We have an instance of it in a case of much lower average temperature in the common frog. That animal cannot bear a degree of heat equal to the average temperature of health in the human body; and yet it passes into a state of inactivity as soon as the cold of winter begins to set in. In the boas, and it is the same with many other creatures which inhabit similar places, we have instances of constitutions tempered to the very hottest climates only, but which are incapable of bearing the greatest heat even there. Indeed incapacity of enduring the direct heat of the sun when it beats in the intensity of its fervour upon the dry and parched surface, appears to be one of the reasons which confines these creatures to the thickets, the marshes, the banks of the rivers, and, when the sun is hot, and the marsh nearly dry, to the water itself. Nor if we examine all nature shall we find any instance in which the ranges upward and downward are not in proportion to each other. That they shall show the same range according to the scale of the common thermometer,—as for instance that an animal which is in its most natural activity at 60°, and becomes still at 32°, shall become as dull at 90°, is another matter, and one which we cannot expect. The degrees of the thermometer are merely equal expansions of the mercury, or spirit of wine, or other thermometric substance; and we know nothing of the relative powers of heat by which these are effected, only we trace the most apposite analogies in favour of the hypothesis that the force of heat requisite for producing equal expansions not only varies with every degree in the same substance, but that in no two different substances does it vary according to the same law.

Thus, even the boa, all-formidable as it is, dwelling in places where miasmata is foul, and life brought into danger from the tainted air, even if there were danger of no other kind, has got a lesson to teach those who will take the trouble of studying it, and that lesson is of more extensive and more useful application than many which are obtained from more inviting creatures in more healthy localities. Following out our observation a little, we find that this law of the range of temperature which an animal can bear, being equal from the mean toward greater cold and toward greater heat, is not a barren or an isolated law, but one which is intimately connected with the physiological character of the animal, and varies with other variations, not in the larger divisions only, but in different individuals of the same species, even in those of the human race. The range of endurance of temperature appears to be always in proportion to the energy, or perhaps we may say the development, of life, the rapidity of the circulation and respiration, and the readiness of the animal for whatever action best suits its organisation ; and we know that the capacity for constant action in the animal, and the necessity of frequent supplies of food, are also in proportion to these. Animals which have this general activity of system do not become heavy after their meals, and however the cold pinches, though they sometimes shiver, they do not become dormant. They are thus the busy creatures. In this their general habit they make the nearest approximation to man's power of enduring all climates ; they are consequently the best fitted, in their physical constitution, for domestic purposes, and their dispositions are in accordance ; they are the most docile, the most obedient, and the most gentle in their manners. The ruminantia among mammalia, and the gallinidæ and pigeons among the birds, are familiar instances.

Thus, when we come to compare the animals, race by race, with each other, we find the adaptation to savage and civilised countries as perfect as that to different climates and different kinds of surface. The nature of the savage animal is fitted only to the savage land ; and when man takes possession, cultivates, and then alters the physical condition, the savage creature, which would be inconvenient to man, were it to remain in his neighbourhood, finds in this physical change, to which its stubborn nature cannot accommodate itself, that the country which man has thus changed by his culture is no longer its country, and it fades away, and gradually disappears, leaving only its bones in the soil, to testify what the country once was, and to what it may again return, if man shall slacken the hand of his cultivation. There have been some very striking instances of this return of savage animals to places from which they had been expelled by cultivation in the modern history of India. After those intestine wars which had left so many parts of that land of powerful natural action without inhabitants, the jungle overran the fields, and hid every vestige both of culture and of human habitation ; and along with the jungle, the larger species of the cat tribe, the tyrants of the sultry wilds, multiplied in vast numbers, and absolutely appeared to increase faster than one would have, from the previous state of the country, supposed to be their proper rate of increase. Even the lion, whose presence at all in that part of the world, at least for some centuries, had become a question, was found in no inconsiderable number:—so energetic and so active in concert are the powers of wild nature.

But that portion which is more peculiarly valuable to man in a state of civilisation follows the law of civilisation, and increases with its increase. This is apparent not only in the animals, but in the plants upon which those animals feed ; and thus, when we take our survey upon the broad and unfettered principle, we not only see that all the parts of nature act in harmony with each other, but that the whole act so much in concert with man, and so strengthen his hand and encourage his heart in that course of improvement which is most favourable both to his physical comfort and his mental and moral development, that it is impossible to avoid seeing that "Herein is the finger of God : that here is wisdom of plan and perfection of execution above all human skill and power—above all human admiration." Such are the wonderful displays of the wisdom and goodness of the Almighty Creator, which result from the proper contemplation of his works, be the place, the season, or the subject, what they may ; and it is these which render the proper study of natural history so delightfully instructive, and make the abuse of it, by trifling and narrow views, the most pernicious and reprehensible of all idle dissipations. But, to return to the great serpents by the margins of the waters in tropical America.

We have said, that as the intensity of the dry heat increases, these animals become languid, and before its close one may pass through the places of their usual resort without the alarm-note of a single hiss grating on the ear The brick-tinted earth, the withered leaf, the dry reed, ready to take fire spontaneously, if the wind should rustle it before the rain shall have drenched, are all silent in the stilly air and under the burning agency of the sun ; and to a casual observer, who sees the country only in this extreme of one of its seasons, it appears as if Desolation had set his seal there, never to be broken.

But the Genius of the Andes looks down in pity from his throne of eternal snows, amid roaring volcanoes and rending earthquakes, upon those plains all hastening to destruction, The air on the surface of the ground is wonderfully transparent ; objects which were not visible begin to come out, and sounds are heard of which the ear could take no note only a day bygone. The small quantity of water which played between the earth and the nether air seems to have floated upward, as if the earth were about to be deprived of even that unsatisfying draught, and the wail of the exhausted cascade comes shrilly and feebly through the forest, as if it were the prelude of its soon being silent for ever. There is a white cloud upon the distant hill, and the upper air is gummy ; it looks as if all humidity were in motion upwards, escaping to another region—it may be to another planet. As the sun declines, the white cloud blackens, and the last rays of the sun stream in like molten gold. But, unusual in such a climate at such a season, not a drop of dew is formed, and thus the fear is in part realised. As twilight fades, and in those latitudes it fades rapidly, the stars are surrounded with haloes, and the southern cross resembles a constellation of comets ; but all are soon lost in darkness. Then the winds, which have hitherto been more than usually still (for the dew of the evening brings a little breath even in the utmost intensity of the heat), begin to blow their little signal blasts from every point of the compass in turn; yet the leaves are, if possible, more still than ever, and it is pitchy dark. But there comes a gleam of light, which envelopes earth and air, and, ere the mind recovers its surprise, crash go the elements, as if a thousand thunders of the loudest voice were concentrated into one peal. Then, flash after flash, and peal after peal, as if the night of final destruction had arrived. And the commotion is on no local or stinted scale; for well nigh "from Darien to the vexed Antarctic main," the Andes on their eastern slope are in one continued glare of lightning, and one voice of thunder, amid which the fire of the volcano is not seen, or the sound of the earthquake heard. Then are "the windows of heaven opened," and amid the glare of the lightning, and the bellowing of the thunder, the clouds, as it were, tumble headlong, till the earth receives one continuous cascade from the sky, the section of which is many hundreds of miles in area, and Niagara itself is but the emptying of a bottle in comparison.

This is an arousing for all the creatures, from the highest roosting bird down to the boas, and the sounds of terror at the present danger, and of joy at the plenty which this violent outbreak of nature is sure to bring, are blended together in so many notes and keys, that the creatures appear to be as much in chaos as the elements, and it is wriggling, and crawling, and running, and climbing, and flying, all to save the life. Nor is it any wonder; for before man can venture to look abroad from his hiding place, every ravine has its cascade, every hollow its lake, and each of the larger rivers rolls onward as a sea, as if they had mustered their powers to give battle to the ocean. Such is the turn of the tropical season, which raises the great serpents of America from their temporary inaction, and sends them high in the trees, or distant to the banks, to begin the season of activity.

Besides the three sections of boa which have been mentioned, there are other two, which are somewhat different in the characters of their heads, do not attain the same dimensions, and are not so formidable. One of these, an American species, is the *Boa hortulana* of Linnæus. It has horny plates on the muzzle, and the jaws furrowed with a groove which passes under the eye, and terminates in a slit a little behind that organ. The other is a native of the east, and is less closely allied to the typical species: it is the *Boa viperina* of Shaw. It has the body with a sort of crest or keel along the back, and very much compressed. There are no furrows along the jaws or under the eyes, but the plates on the muzzle are a little raised in the centre, something in the form of double wedges, with the one point in advance and the other to the rear.

The three sub-genera which have been separated from all the sections of the boas, and not included in the colubers, are Scytali, Erix, and Erpeton, of which some account will be given under these titles.

BOBARTIA (Linnæus). A genus comprising three species of perennial herbs, introduced from southern Africa. Class and order *Triandria Monogynia*, and natural order *Irideæ*. The flowers of the bobartia are not only curious, but very beautiful, as all the order are to which it belongs.

BOCCONIA (Linnæus). A family of two species of evergreen shrubs, natives of the West Indies. Class and order *Dodecandria Monogynia*, and natural order *Papaveraceæ*. Generic character: calyx of two sepals, deciduous; stamens seated below the germen, filaments short, anthers linear, and erect; style short, cloven; capsule on a foot-stalk, pod-formed, crowned with the style, one-seeded, two valves opening below.

BŒHMERIA (Jacquin). A genus of various character, comprising fourteen species of shrubs, under shrubs and herbs, chiefly from Nepal, and the West Indies. Class and order *Monœcia Tetrandria*, and natural order *Urticeæ*. Generic character: male flower—calyx four-parted, urceolus, none; filaments awl-shaped; anthers roundish, double. Female flower—calyx none; scales clustered, oblong; germen inversely oval; style elongated, filiform, feathery; akenium with the persisting style. These plants are only useful in botanical collections, none of them possessing any known useful properties.

BOG MOSS is the *Sphagnum vulgare* of cryptogamic botanists. It is the most useful of all the mosses for packing fruit, or delicate plants, and is usually found on bogs, or in wet woods.

BOG RUSH is the *Schœnus* of Linnæus, a genus of five species, four of them foreign. Class and order *Triandria Monogynia*, and natural order *Cyperaceæ*.

BOLBOCERAS (Kirby; *Odontæus*, Zeigler, MSS). A genus of lamellicorn beetles (*Scarabæus*, Linnæus), separated by Mr. Kirby, in the Linnæan Transactions, vol. xii., from the Latreillian genus *Geotrupes*, from which it chiefly differs in the structure of the antennæ, which are eleven-jointed, the three terminal articulations forming a very large compressed and suborbicular club, of which the central plate is concealed by the two outer ones, which enclose it as in a box. The mentum is entire in front, one of the jaws is entire and the other with two teeth, and the legs are inserted at equal distances. The males of these insects are distinguished by a long and erect horn upon the crown of the head. The type of the genus is the *Scarabæus mobilicornis* of Fabricius; it is about one-third of an inch long, and of a castaneous black colour. It occurs, but rarely, in various places near London. Latreille was informed by one of the sons of the celebrated ornithologist Le Vaillant, that frogs and toads are very fond of these insects, and that he had obtained many specimens by opening the bodies of some of these reptiles. This species varies in colour, and some authors have considered the *Scarabæus testaceus* of Fabricius merely as a variety, but Mr. Stephens regards them as distinct: his reasons, however, founded chiefly upon the development of the horns of the head and thorax appear to us to be inconclusive, as the same kind of distinctive variations occurs in other cornuted beetles, as in *Siagonium quadricorne* (see Zoological Journal, No. 9, and Kirby and Spence, Introduction, vol. iv. p. 166). It is a curious circumstance, and one which requires considerable investigation, as bearing upon the analogies of cornuted animals amongst the higher groups, that amongst the males, which sex alone is furnished with these appendages, there are generally to be observed two kinds of individuals, the larger ones being much more robust and armed with the most fully developed spines or teeth, and the smaller ones having the armature of the head and thorax remarkably small, no intermediate specimens being found amongst them, whence it has been supposed that the latter specimens are neuters. In the insects in question the reputed variety, *Scarabæus testaceus*, exhibits another mark of inferiority in its pale colouring, which is generally, amongst insects, regarded as a mark of immaturity. The genus in question is widely distributed, being found in every quarter of the globe. Dejean enumerates sixteen species.

BOLETOBIUS (Leach). A genus of coleopterous insects belonging to the family of the rove-beetles, *Staphylinus*, Linnæus, and to the sub-family *Tachyporides*. Its head is elongate, the antennæ slender, the palpi rather long and filiform. The species are prettily marked with blue-back, varied with red or yellow. They are of small size, not exceeding a quarter of an inch in length, but are extremely serviceable in the economy of nature, from their habits of feeding upon decaying boleti and fungi, whence the generic name. They form a portion of the genus *Tachinus* of Gravenhorst's work upon this family. Mr. Stephens enumerates eighteen species, of which the *Staphylinus lunulatus* of Linnæus is the type. It is a pretty insect of a red colour, with the head, breast, and base of the abdomen black, the elytra blue-black, with the base and margin of the tips red. It is a common species in various parts of England.

BOLETOPHAGUS (Fabricius; *Eledona*, Latreille). A genus of heteromerous beetles, belonging to the family *Diaperidæ*, of which it forms a separate section. The body is ovoid, very unequal above, and deeply striated in the elytra; the margins of the thorax are toothed; the antennæ are terminated by a perfoliated mass of three or five joints, and the inner side of the preceding joints is acutely produced. The head of the males is often armed with horns. The species reside in fungi, Boleti, &c., in a decaying state. Dejean enumerates six species in his Catalogue, first edition, of which one only is found in England, namely, the *Bol. agricola* (or rather *agaricola*, from feeding upon agarics). It is of small size, being only one-eighth of an inch in length, and of an obscure black colour. Another of Dejean's species, *Spinosulus*, Latr., has only three joints in the club of the antennæ, and forms the genus *Coxelus* of Zeigler.

BOLETUS. A family of fungi very often seen growing out of the decayed parts of trees. The boletus is distinguished from the mushroom by a very striking difference: the under side of the first is crowded with circular cells, that of the latter by diverging gills. The boletus grows to an immense size in the humid woods of the tropical countries; assuming the most fantastic and frightful forms, but of no known use. One of the family, the *B. ignarius*, is manufactured into a substance which serves for tinder.

BOLTONIA (L'Heritier). A genus of two species herbaceous perennials, from North America. They are syngenesous plants, and consequently in the natural order *Compositæ*. They are both occasionally met with in flower borders.

BOMBACEÆ. Cotton-tree family. A natural order of dicotyledonous plants, containing fourteen or fifteen genera, and about fifty species. It is closely allied to the *Malvaceæ* or mallow tribe, and by some authors is considered merely as a section of that order. It differs however, from the malvaceæ, in the calyx not being truly valvate, and in the tube of the stamens being divided into five bundles. The order bears a strong affinity to the *Byttneriaceæ* and *Chlenaceæ*.

The essential botanical characters of the bombaceæ are: sepals five, cohering in a truncated or irregularly-cleft tube, sometimes provided with bracteæ; petals five, regular, occasionally wanting, and then the inside of the calyx is coloured; stamens five, ten, fifteen, or more; filaments united at the base into a tube, which is adnate with the base of the petals, dividing at the apex into five bundles, each of which has one or more one-celled linear anthers; ovary of five carpels, either distinct or united; styles equal in number to the carpels; fruit variable, capsular or indehiscent, provided with five valves, bearing the dissepiments in the middle; seeds often enveloped in wool or pulp.

The plants belonging to this order are shrubs or large trees, with showy flowers, found in hot tropical regions. They are natives of South America, the East and West Indies, and Africa.

The wood which they furnish is generally light and soft, and they are propagated by cuttings and seeds.

Like the mallows they are mucilaginous, and do not possess any deleterious properties.

Bombax is the genus whence the name of the order is derived. *B. pentandrium* or *Eriodendron anfractuosum*, the cotton tree, is a large tree which occasionally attains the height of one hundred feet. It yields a kind of gum which, when combined with spices, is used in India in bowel complaints. The fruit is oval and larger than a swan's egg, having a thick woody covering, and containing a quantity of short dark cotton, inclosing many roundish seeds the size of peas. These seeds are eaten by the inhabitants of the Celebes islands. *B. ceiba* has a spiny trunk, and is one of the tallest trees in both Indies.

Bombax.

Its wood is used for making canoes. When the trunk decays it becomes the nest of the Macaca beetle, the caterpillar of which, when properly prepared and dressed, is esteemed by some people a great delicacy.

The Durion of the Indian Archipelago is a most delicious fruit, the product of one of the plants belonging to this order. This fruit is at first disagreeable from its fetid odour, whence the plant gets the name of *civet durio*, but it soon becomes a favourite article of dessert.

To this order belongs the *Adansonia digitata*, baobab or monkey's bread, the largest known tree, whose trunk has been found ninety feet in circumference. The particulars in regard to this tree and its uses, are fully detailed under the article ADANSONIA.

The genus *Helicteres* receives the name of screw-tree from its curious spiral seed-vessels. *Cheirostemon*, or the hand-plant of Mexico, has its name from the five bundles of stamens being thick, coloured, and turned on one side so as to resemble a paw with five claws. *Ochroma*, and the genus of the order, is so called on account of its yellow flowers. *Ochroma lagopus* is a large tree with diverging branches, and leaves more than a foot long. Its wood is so light as to serve for corks to nets. Its capsules contain a soft down, which is used in the manufacture of English beavers. The seeds of several of the species included in this order are enveloped in long hairs, like those of the true cotton. They cannot, however, be used in manufacture, owing to the want of adhesion between the hairs. The hairs are quite smooth, not rough and feathery like those of the cotton plant. The woolly matter furnished by the *Bombax ceiba, Chorisia speciosa*, and several other species, is used for stuffing chairs and cushions.

Any medical properties which the plants of this order possess seem to depend solely on the mucilage which they contain.

BOMBARDIER BEETLE. Under this name the species of the coleopterous genus *Brachinus* are known. These insects, whose generic character will will be found under their generic name, possess a very remarkable power, enabling them to defend themselves

Bombardier Beetle.

against the attacks of their enemies. The British species are of a rather small size, being under half an inch in length, of a blue-black colour, with the thorax of a red or yellowish colour. In general, they conceal themselves beneath stones; but when they are disturbed, one is surprised to hear a noise resembling the explosion of a musket in miniature, accompanied by a considerable discharge of bluish smoke from the anus. Many of the carabidæ have the power of ejecting an acrid and caustic fluid, but in the brachinus this is so extremely volatile, that it evaporates immediately on coming into contact with the air. It is, moreover, of so pungent a nature, as to irritate any part of the body upon which it may happen to fall, tinging the skin with a dusky mark, which remains for several days, and causing a most violent pain if it happen to touch the eyes. Indeed, according to M. Leon Dufour, who has studied the structure of these insects with particular care, the odour of this vapour has a striking analogy with that exhaled by nitric acid, and is caustic, reddening white paper. The insect, notwithstanding the assertion of Mr. Millard to the contrary (Outlines of British Entomology, p. 221.), not only possesses the power of causing this discharge when handled, but is able to repeat it successively for a considerable number of times,—Solander, who first observed it, says twenty (Mem. Acad. Stockholm. 1750); and Mr. Cooper, the celebrated R.A., counted thirteen discharges in rapid succession (Stephens' Illustrations Brit. Ent., I, 35). The discharges, however, become less violent, and afterwards, instead of smoke, merely a brown or yellow fluid is emitted, as if the more elaborately concocted liquid had been consumed. The insect may be made to play off its artillery at any time, by scratching its back with a needle; and by bending the segments of the abdomen, it is able to direct the smoke in any direction. It is in self-defence that these discharges are generally made, since, like many of the smaller carabidæ, the bombardier beetles are preyed upon by the larger species of the same family. When pursued, therefore, and on the point of being seized by its enemy, it has recourse to this stratagem, by lying in its pursuer's path, which advances with open mouth to seize it, and by immediately discharging its ammunition. Confounded by the scent, and unable to see from the smoke, the enemy draws back until it has recovered from its effects, when the pursuit is renewed, and a second discharge takes place, and which is continued, either until the brachinus has gained a place of safety, or the pursuer is enabled to seize its prey, which it immediately destroys by tearing off the head.

M. Dufour has given a very minute account of the internal structure whence this explosive fluid is produced in *Brachinus balista* (Annales du Musée, vol. xviii, p. 70, and Bulletin des Sciences, Soc. Phil. July 1812) and which consists of a double apparatus, according to Messrs. Kirby and Spence (whose abridged account we have thought most suitable), one on each side in the cavity of the abdomen, both formed of two distinct vessels. The first, which is the innermost, presents itself under two different aspects, according as it is contracted or dilated; in the former case it is a whitish irregularly rounded, soft body, apparently glandular, placed under the last abdominal segments, communicating at one end with the reservoir, and terminating constantly at the other in a very long and slender filament; in the second case, or when it is dilated, it resembles an oblong, membranous diaphanous sac, filled with air, then occupying the whole length of the abdomen, and appearing free except where it communicates with the reservoir. The second vessel or reservoir is a small spherical brown or reddish body, constant in its form, internally hollow, placed under the last dorsal segment, precisely above the rectum, and opening by a small pore into the anus, so that the tail of this little beetle may be regarded as a battery mounted with two pieces of cannon, which our alert bombardiers fire alternately without intermission until all their ammunition is expended.

The generic name is derived from the Greek, and signifies to make a noise; and in allusion to this property some of the species are named, fumigatus, crepitans, sclopeta, causticus, explodens, bombarda, exhalans, &c.

BOMBAX (Linnæus). The silk cotton tree belongs to the class and order *Monadelphia Polyandria*, and natural order *Bombaceæ*. Generic character: calyx nearly bell or pitcher shaped, abbreviated, irregularly from three to five-cleft; petals five, overlapping each other at the base; filaments united in bundles; anthers adnate or versatile, sometimes kidney-shaped, two-celled; style simple; stigma headed, lobed; capsule woody, five-celled, five-valved; cells filled with silky cotton; dissepiments central, seeds several. In addition to what has been observed of this tree in a preceding article, we may notice further, that it is found in South America, in Africa, on the Indian peninsula, and all over the same degrees of latitude to the eastward as far as China. The silky substance contained in the capsules, has been tried by both spinners and hatters for their respective purposes, but it wants tenacity of fibre, and is therefore useless for the fabrication of any durable material. Thin mattresses are however stuffed with it in India, and for which the silk cotton is so far eligible, that it is exceedingly light. Notwithstanding the tree is generally found between the tropics, the leaves are deciduous, that is, falling after the seeds are ripe, and renewed immediately after the flowers come forth in the next season. The leaves are compound; some species, as the *B. ceiba*, have five leaflets, others seven, all proceeding from the point of the common foot-stalk. This last species presents one of the most magnificent spectacles when in flower that possibly can be conceived. This tree is plentiful in the southern provinces of China; it grows like, and very much resembles, the largest walnut trees of England. In the month of March, and before the leaves appear, the tree comes into flower; every twig of the widely extended head bears a large tulip-like scarlet flower, remaining in perfection for a week or two—the first flowers on the points of the shoots being succeeded by others from the sides. As a proof of the plenty of these trees in the neighbourhood of Canton, most of the coffins required for the mortality of the vast population of that city, are made of the slabs of the bombax, or silk-cotton tree as it is called by the English, and *moc-main* by the Chinese. These coffins are soon made; a butt is chosen corresponding to the size of the defunct; four slabs are sawed off at right angles, the square centre is used for other purposes, and the four slabs are fastened together again to form the rude coffin. The timber is light, and of inferior quality. The genus is nearly allied to the *Eriodendron* of Decandolle.

BOMBYCILLA (Waxwing). A very peculiar genus of birds, belonging to the *omnivorous* division of the order *Passeres*, in Cuvier's arrangement, nearly allied to the CHATTERERS (*ampelis*), and also to the ROLLERS (*coracias*), but having sufficient distinct and peculiar characters for entitling them to stand in the systematic arrangement as a separate genus.

The generic characters are—the bill strong, short, rather compressed, but with a slight bend downwards at the tip of the upper mandible. The tomia margined but without any notch. The nostrils at the base of the bill, of an oval shape, and without any valvular or protecting membrane, but in part covered with feathers projecting to the front. The feet have three toes before and one behind; the outer toe joined to the middle one at its base; and the tarsus as long as the middle toe. The foot is thus much more of a perching than a walking foot. The wings are long and pointed; the first and second quills being the longest. The most peculiar character of the bird, and that which has procured it the name of *waxwing*, is the way in which the ends of the secondary quills are terminated. These have the tips of their shafts extended into little discs of soft horny substance, which appears as if that part of each feather had been dipped in sealing wax; but of what use these little balancers are to the birds in their flight, or in any other part of their economy, is not known. But this loading of the points of the feathers must render the wing a little stiffer against an oblique strain at that part; and this may be necessary, as the birds are very discursive in their habits.

As there are only two species of the genus,—the Bohemian waxwing (*B. garrula*) and the Carolina waxwing, (*B. Caroliniensis*), we shall combine what general observations we have to make on the habits and economy of the genus with our notice of the first of these species.

BOHEMIAN WAX-WING (*B. garrula*). Neither of these epithets are very applicable. The birds do appear in Bohemia, but they appear there only as visiters; and they might with equal propriety be named after any of the countries near the Baltic, and more especially after Sweden, where they are found in greater numbers, perhaps, than in any other part of Europe. As little is the word *garrula* descriptive of them, for they are rather silent than otherwise; and the name appears to be continued from that of chatterer at the time that this genus was confounded with the true chatterers (*Cotinga*).

These birds are never long in one place; but they are discursive rather than migrant, and upon the continent they do not resort annually to the same places, or at the same times of the year. Of their nesting places or resorts where they breed not much is known; and they are accordingly one of the genera which the continental naturalists are very often in the habit of "sending to Siberia," to construct their nests and perform their incubations. That many birds resort to Siberia, and also to the northern parts of Russia, as well as to the Scandinavian peninsula, during the summer months, is not only probable, but certain; for the summer there is proportionally as warm as the winter is cold, and it sets in so late that by the time there is temperature sufficient to entice a bird to the country, there is light sufficient for it to find its food during the greater part, and even the whole of the twenty-four hours.

In these northern places, which are either not inhabited at all or very thinly so, and which, being flat, are humid in the yearly part of the summer, abound much more in the food of birds than places further to the south, where the climate is upon the whole milder, and the seasons much more uniform. Insects and the smaller ground animals, which hybernate in the earth below the reach of the frost, which penetrates to a much smaller depth in proportion than when the earth is not protected by a covering of snow, are not only very numerous in those parts, but there is a more ample provision of food for birds than one would be apt to suppose. Even the mammalia, such as the bears (see BEAR), which remain in these high latitudes during the winter, have a tendency to accumulate more fat than the races, or even than individuals of the very same race which winter in warmer climates—so admirable are the constitutional tendencies of all creatures tempered to that state of the elements under which they have to exist.

But this law of adaptation in nature runs through all those productions in which the vital or the growing action has to be preserved through a dormant period of severity, whether that severity arises from cold, as in the climates more immediately under consideration, or from drought, as in tropical countries. In these northern latitudes, the trees make more perfect and also what we may, without impropriety, call "fatter" buds than they do in temperate climates; and they evidently do so because the germ or more active part of the bud requires the protection of a more thick and close hybernaculum, and because the more rapid action which these buds make when the summer calls them at once into action, with the intervention of little that can be considered as spring, demands a greater store of prepared materials. Thus there is upon these plants two crops of food for the tree birds—one of the hybernating bud on the early shrub; and the other of the seed when it is ripe, or of the pulp of the berry in other cases. The evergreens, the pines for instance, form no exception to this; for though they retain their leaves during the winter, their buds are as well prepared, and as closely moulded up as those of the trees, or rather the shrubs (for there are few deciduous plants which deserve the name of trees in those latitudes) which are denuded of their leaves.

This peculiarity of the polar forests forms so important an auxiliary in the history of those birds which resort thither, and the wax-wing of the Eastern continent is in its very irregular wanderings so intimately connected with the seasonal character of those forests, that this seems to be the fittest opportunity for offering one or two short remarks on them;—and this is the more necessary that the habits of these birds have never been very satisfactorily explained, and this apparently for no other reason than that the seasonal characters of those places to which they retire when they quit the more cultivated places, have not been considered along with them. This indeed has been the grand fault or imperfection of the study of nature in all its kingdoms and departments: one has attended to the animal kingdom, or even to one department of that kingdom; another has attended only to the vegetables; and a third has confined his observations and his investigations to the climate and the seasons; but no one has brought them together, and stated the manner in which it should be done for the proper and satisfactory understanding of any one of them, the general analogies which connect the three, or the general law which they all obey. They have, as hinted, "sent the bird to Siberia," and so got rid of any further trouble with it, as is the object of sending to Siberia in other cases. But they have not told us what the bird does in Siberia, or what entices it there; for it is enticed, not forced, and goes there in virtue of the *ukase* of nature, and not of any human autocrat. Now, why it should go to Siberia is the grand point of the case, the one upon which information is especially desirable, because it is in this that we discover the true character of the bird; and as we need the character of Siberia, in order to determine that, we make out the entire case; whereas if we content ourselves with merely stating that the bird goes there, we have only half a case, which we are of course unable to use as an analogy, and so the labour which we have taken is lost.

It is easy to answer, generally, that the bird goes to Siberia evidently because Siberia is the place best suited to its habits; but it is in the characters which so suit it that the information lies. Now many of the birds which summer in the arctic lands are insectivorous, or otherwise animal feeders; but the greater number of these are ground birds, and many of them have habits wholly or partially aquatic. Still, there are others which are in these northern climates for a larger portion of the year, which are chiefly vegetable in their feeding, and which are rather tree birds than perching birds; and they do not resort so regularly to the temperate latitudes as the others. The crossbills belong to this class, but they (see BIRD and CROSSBILL) have their bills of so peculiar a construction, that their locality in these northern places can be much more easily ascertained than those of such a bird as the wax-wing.

That the birds which resort to those regions in the summer to consume the vast surplus of life which is in and near the waters, should not seek their way there till the summer is considerably advanced, and that they should quit them again early in the autumn, we can readily understand, as the frost is long in giving way and returns early; and during its continuance the more aquatic grallidæ are frozen out (much longer of course than the swimmers, and longer still than the divers) and the insects perish or disappear. We know the habits of those birds in other countries, and thence we infer, with a reasonable degree of certainty, what it is that entices them to the north; but the wax-wings and other tribes analogous in habit, and on that account probably much more analogous in their general characters than their present places in the system would lead us to believe (for the place of the wax-wing in the system is far from being natural or satisfactory), make their appearance so irregularly in the southern parts of their range, and, though they appear there in considerable flocks, are so much fewer than they are in places further to the north, and in the immediate vicinity of those polar forests, or combinations of forest and marsh, which have been mentioned, that they may with much more propriety be said to be driven from the polar countries than enticed to them. And thus, before we can have any satisfactory knowledge of their characters, we must know something about the general economy of nature in those places.

Now, as we have mentioned that all the ligneous plants of those polar climates, whether they come under the denomination of trees or of shrubs, and whether they be deciduous or evergreen, form fatter buds, or buds containing more farinaceous or albuminous matter than those of milder climates. Those which grow to trees are for the most part evergreens, of the natural order *Coniferæ*, and generally speaking of the pine family; and their leaves worn all the winter are of great importance to every kind of life, on account of the shelter which they afford. Indeed where these evergreens are not found (for the deciduous plants are few in number, and they appear only in low and sheltered places), the storms when winter sets in, and the winds when it breaks, are so violent that the surface is scourged to barrenness, and there is hardly food even for a bird; so that in those high latitudes the pines are, in an eminent manner, the protectors of life and the preservers of fertility—such fertility as is to be found there.

And it is well worthy of observation, how very beautifully the coniferous trees of those regions are adapted for abiding the frosts, and protecting all those living creatures of which they are the shelter. Their roots have not a tendency to penetrate very deeply into the earth, for the soil is usually but thin in those places; but they extend to a very considerable distance laterally, so as to afford a broad, and therefore a stable base; and the bole of the tree rises in one straight cone, gradually tapering to the top, and thus increasing in strength as there is more strain upon it from the action of the wind. The branches too, have the same tapering and spiry out-lined ; and the leaves though closely set, and thus forming a thick shelter, are in their individual forms narrow and needle-shaped, so that they offer little resistance of surface to the wind ; and they are stiff and smooth, so that the wind takes but little hold on the surfaces which they present. Those of more lowly growth again, such as the junipers, which are a little more branched in their general form, are still spiry in their outlines, and their timber is both tough and flexible. The fruit, too, upon those plants, of more than one season's growth before it comes to maturity, affords food when that of the more seasonal bushes is gone ; and thus, what with buds, what with the seeds of fruits, what with berries, and what with young shoots (for those of the pine are eatable by man, and even agreeable to the taste), the vegetable feeders of those dreary climates,—though dreary only in the winter months, for in summer, they are the lightest and most gay on the surface of the globe,—find food when all the animal feeders, except those which depend on the sea, or feast on the flesh of their fellow birds, must retire to the south.

There is no question that the Bohemian wax-wing (for we must call it "Bohemian," however faulty the name may be,) belongs to those vegetable feeders ; and as it is much better winged, and more discursive in its range, than the cross-bills, the crested wrens, and some other races which inhabit the pine forests closely for the greater part of the year, we may suppose that it annually takes its range of all the kinds of vegetable food which present themselves in the succession of the seasons.

When it comes into Britain it is only in the winter, and during very severe storms; and then the birds do not appear as stragglers, but in large flocks distributed over a considerable part of the country, as if the whole colony had, by a storm still more severe, been driven *en masse* from a more northerly habitation. In 1810, they were numerous in some parts of the island ; none made their appearance for about twelve years afterwards ; and there is no account of their appearing in any considerable numbers ever since, though a few have occasionally been observed. When in this country their food is chiefly those wild berries which remain on the trees in winter, and become more mellowed and also more farinaceous after they have been touched by frost ; such as the berries of the common hawthorn and the mountain ash. Of course the birds perch when feeding upon these, and when with us they have been usually seen on the wing or on the perch, and rarely upon the ground.

In the countries immediately south of the Baltic, they are much more frequent and numerous ; but even there they are not so plentiful as in Sweden, where they are represented in such flights as absolutely to darken the air as they pass. This very numerous appearance in the southern part of the Scandinavian peninsula, very naturally leads to the conclusion that they are dispersed in the more northerly parts of the same country during the breeding season. From these particulars of its locality, and especially from its appearing in Bohemia only as a visitant (for there is no account of its having remained to breed in that country), it would, perhaps, if there were not some objection to the changing of a name however inappropriate, be better to call this species the *common* wax-wing (*Bombycilla vulgaris*), and it might not perhaps be amiss to alter the specific denomination of the other to American (*Americana*).

The common wax-wing is a very beautiful bird, of handsome shape and richly coloured. The male is about three ounces in weight, and between eight and nine inches long. The female is rather smaller.

Bohemian Waxwing.

The flesh of both birds, when in good condition, is highly esteemed. The bill is black at the tip, passing into pale whitish straw colour at the base ; the nostrils covered with slender black feathers which incline forwards. A portion round the eyes, and the chin and throat, are deep velvet black. Forehead and top of the head reddish brown ; the feathers on the crown being long and silky, and forming a sort of short crest, which is loose and pendent, and more rich in the colour, and inclining to purple, than the short feathers on the forehead. The neck, upper part of the back, and breast, are of a peculiar colour, which is very soft and beautiful, but not easily expressed in terms of any single colour having a name ; it partakes of brown, purple and grey, blended into an entire tint, and blended so equally that one cannot easily say which of the three predominates ; and it is not mottled, even in that minute way which produces these colours which change in different lights, but one full colour showing always the same. This colour is continued upon the scapulars and lesser coverts, but of a darker shade and partaking less of the grey. The greater coverts are black with white tips. The primary quills are black, with the outer webs white, and a bright spot of rich yellow on the white part of each near the end. The secondaries are grey, with white tips to the outer webs, and seven or eight of them have their shafts enlarged at the ends (beyond the webs) into red discs, which have very much the appearance of sealing-wax. The lower part of the back and the rump are smoke-grey with a reddish tinge, the tail feathers black with rich yellow tips. The under tail coverts and vent feathers are reddish orange-brown ; and the belly and breast purplish-red of a very pale and somewhat brownish tint. The irides of the eyes are purplish red ; and the tarsi, toes and claws black.

The female has nearly the same markings as the male ; but it is smaller in size ; the yellow on the wings and tail is paler, and the wax-like appendages to the tips of the secondary quills are smaller and not so numerous.

The wings and tails of those birds, when spread out, have a very fine appearance, from the contrast of deep black, pure white and bright yellow which they display; and the richness is farther increased by the very peculiar appendages, which are quite solid and shining, and unlike any thing that forms part of the feathers of any other bird. The whole plumage is indeed remarkable for its velvety texture, and the glossless purity of its colours; and though the birds visit us but seldom, and at inclement seasons, when they do make their appearance there are very few of our birds, whether native or visitant, that display so much beauty; and therefore it is highly desirable that something more of their manners were known.

Wild and erratic as the wax-wings are in a state of nature, they are tamed without much difficulty; and they appear to be of a mild and gentle disposition. But although they are passive under the captivity of the cage, their nature cannot bear up against a restraint so cruelly contrary to their native habits; and they very soon fall victims to the senseless cupidity of their gaolers. The sufferings of most birds in that state should plead powerfully with all who can feel for animal suffering, for the abolition of a custom which inflicts pain upon a very beautiful and interesting race of creatures, without having even the consideration of pecuniary profit to plead in its defence.

American Wax-Wing (*Bombycilla Americana*). There is much difference in size and colour, and no inconsiderable difference of habit, between this bird and the wax-wing of the old continent; but it has the external characteristic upon which the name is founded, namely, the enlarged discs of a substance in colour and gloss resembling red sealing-wax, at the ends of the shafts of the secondary quills. Besides, though the habits of the bird are different, we must bear in mind that there are great differences between

American Waxwing.

the country which it inhabits, and that which is inhabited by the other. On the old or eastern continent the coniferæ which have pulpy or succulent cones, at least which have them so much so as to come under the denomination of *berries*, are few and thinly scattered. They are only, or chiefly, the common yew and the common juniper, the first of which is no where very abundant, and the second is merely a shrub; so that the autumnal feeding of the wax-wings is in a great measure confined to the berries of the vacciniums and other lowly shrubs of the extreme north. The birds depart at that season into the swampy wilds where these are produced; and as there is not there much to tempt the foot of ordinary enterprise to visit such places, and as the places are difficult and even dangerous, the birds remain in undisturbed possession; and neither the time nor the mode of their nidification is known. It is indeed by inference from what is known of the American species only, that we can arrive at even a guess at the general economy of the European wax-wings, though they sometimes present themselves to us in considerable number, and though the flights of them in Scandinavia are probably to the full as numerous as those of any other European birds. From what is known of the American wax-wings, we may conclude that the European ones breed late in the year, after the summer solstice, and when the berries on the northern morasses are beginning to ripen. And we have some collateral proofs, or presumptions, that such must be the case in birds which visit nearly the same localities in the breeding time, and in others which reside more permanently in the neighbourhood. Turnstones, and various other shore birds, which linger with us till the season is far advanced, breed in great numbers on the islands along the coast of Norway and Lapland, and though it is not proved that these are the identical individuals which linger with us, yet it is probable that they are, as they have not hitherto been found breeding in any nearer locality. The cross-bills again are said to breed in the polar forests in the winter, in that depth of the season when both earth and tree have a mantle of snow, and the birds are sheltered from the air and concealed from observation. The time of the year in which cross-bills appear as migrants in the south favours this theory; which is farther confirmed by the fact that all birds pair at that season when food is most abundant for themselves and their young.

It is in the American forests and the American wax-wings that we have the most satisfactory analogies; and though these are analogies of difference, not of similarity, they are not on that account less efficient for the discovery of the truth, for an analogy of contrast is often as good as one of coincidence, and sometimes better. Now, the evergreen coniferæ of America, with pulpy cones, or berries, extend through all the middle latitudes of that continent, that is, from near the confines of Canada, where they inosculate with the pine forests, following the swamps, while the pines are on the dry *barrens* (so called, because grass does not grow under pines), to the northern confines of the Floridas, where they begin to give place to the deciduous taxodium. These berry-bearing coniferæ are popularly called "cedars," but they are not; they are junipers, only having the habit of tall and spiry trees, and from this habit forming perhaps more closely covered forests in the swamps than are to be found in any other part of the world. On the first settlement by European colonists, these cedar swamps occupied a great breadth of the country eastward to the shores of the Atlantic, but they have since been nearly extirpated in the whole range between the Apalachian ridge and the sea, with perhaps somewhat more zeal than wisdom, as building-timber begins to be scarce and costly even in that land of former forests. On the west side of the mountains those trees are, however, very abundant still, and as they bear a vast multitude of berries, the number of birds which find their food upon them, when these berries are in season, is beyond all precedent which we have on this side the Atlantic.

There is thus no need for the same extent of northward and southward migration on the part of any of the forest birds of America as there is in those of the eastern continent; and in the case of the wax-wings, which seem tempered to much range of climate, the necessity of migration upon a meridian is almost entirely removed, by the abundance which they find in the berries of those junipers in the winter, and very early part of the spring, and in the hill berries, over a very considerable extent of latitude (over the whole range, indeed), as the season advances. Accordingly, the wax-wings there are found all the year in nearly the same latitudes, only they are among the junipers of the swamps when the berries of these are ripe; and when this supply fails they are forced to range in quest of other food.

The early part of the season, which is the time of plenty and of song with the birds of the deciduous groves, is with these wax-wings the season of want, or, at all events, of penury. By that time the berries of the junipers, which afforded so abundant a supply in winter and early in spring, begin to be exhausted, and the few that remain are dry and shrivelled, and contain little nourishment. The birds are in consequence obliged to make out their subsistence with insect food, and the insects which they eat are said to be beetles; but that species of food does not appear to be very congenial to them, as they are lean and in bad condition at those times when they resort to it; and it is not till the early berries are ripe on the hills, and the early cherries, and other small pulpy fruits in the orchards, that they begin to disperse over the country, and commence the grand labour of the year.

According to Wilson, than whom there have been few observers of wild nature more true in all the minutiæ, or more graphically delightful in the general effect, these birds are very lean and low-spirited in May, the period when most of the tenants of the groves are in the very strength of their energy and the fulness of their song. In June their favourite forests begin to ripen, they fatten apace, and before the middle of that month the building of the nest is begun. The nest is placed in the fork of a tree, wholly composed of vegetable matter, coarse grass on the outside, and finer within, and it is large for the size of the bird. The eggs are four, of a dull bluish white, tapering much toward the small end. The greater part of it is dropped over with small blackish spots, but there are some purple blotches on and near the thick ends. The incubation is understood to last for about twenty-one days, so that the young break the shell about the end of June. They are fed at the first upon insects and larvæ, but afterwards upon leaves and succulent fruits.

This midsummer dispersion of these birds cannot be considered as a migration, because some of them remain in the near vicinity of the houses, and also in the cedars on the swamps, which still afford them sufficient concealment for their nests, though not food; but there are many insects in those places for the young in their early stage, and a little later there are generally berries on the margin of the swamp. On these low-lying places this species of food is nearly exhausted by the time that the bilberries, and other succulent fruits on the hills, are ripe. The birds, with their broods, retire to those mountain pastures about the end of July or the beginning of August; and by the end of September their harvest on the hills is about over, and they return to the low grounds, the tree berries on which are then beginning to get ripe; on their return they assemble in small packs, but they are never found in such clouds as the common wax-wings are.

Thus, though these birds occupy a more southerly latitude than the wax-wings of the eastern continent, and one which is very different in its climate and vegetation, there is, making allowance for these differences, no inconsiderable resemblance in the habits of the two species; so that, from the known history of the one, we may, in part at least, infer the unknown part of the history of the other with regard to time and manner of nesting, number of eggs, and various other particulars. The fact of the eastern ones being more discursive in the winter months obviously depends on geographical causes—the depth of the snow sometimes cutting them off from all supply of food in their northern haunts, which is not the case in the cedar (juniper) swamps of the central latitudes of North America.

In the size, the wings, and the colours of the two species, there are considerable differences. The American bird is by much the smaller of the two, and it is less powerfully winged than the other. This may be inferred from the different characters of the places in which they reside, and the necessity which the eastern one is under of ranging to greater distances in severe weather. But the two species agree with each other, and differ from the chatterers (*cotinga*), with which they have been confounded, as being very silent birds, so much so, that the American species, which is the one of which anything is known during the pairing time, does not sing or make any more noise then than at any other season. The following is the substance of Wilson's description of the American bird:—

"Length, seven inches; extent of the wings, eleven; head, neck, breast, upper part of the back, and wing coverts, dark fawn—darkest on the back and lightest on the forehead; head with an upright pointed crest; line from the nostril over the eye to the head, velvet black, with a white line on its upper margin, and another extending from the lower mandible; the chin black, passing gradually into fawn, and the feathers remarkably close; wings deep slate colour, except the two secondaries next the body, which have their exterior webs fawn, and their inner ones white, six or seven, and sometimes the whole nine secondaries, with the enlarged wax-like appendages at the ends of their shafts. These do not appear on the young birds till the second autumn; they are common to males and females, though generally less numerous on the latter; and there are instances of their being on the ends of tail feathers also. The rump and tail coverts are pale blue, and the basal portion of the tail feathers is the same, but on these it passes into deep black, which is terminated by about half an inch of bright yellow at the tips. The belly and vent feathers are white. The bill is black, the upper mandible triangular at the base, rounded toward the tip, slightly bent there, and deeply notched; and the upper one is scalloped and slightly turned up. The inside of the gape (which, as well as the gullet, is wide) is orange, the irides are dark red, and the feet and claws black. The sexual difference in colour is: the tints of the female paler, the yellow on the tip of the tail not so broad, and the crest on the head less produced and elevated."

Some circumstances mentioned by Wilson tend to throw light upon the very irregular appendages in which the secondary quills of the wings of these birds terminate. He remarks, that he found those feathers which had not the wax-like appendages always rugged at their tips, and broken and ruffled for some part of their webs, but that the ones with the appendages were entire and unruffled. Thence it follows that these appendages act as a protection for the more delicate part of the feather, and this unusual provision for the safety of that member must, according to the universal law of nature, be made for the purpose of providing against an unusual exposure to injury.

This brings us very naturally to the principal habit of the birds; that is, to the character of the plants upon which they find the greater part of their food; these are, in both continents, the junipers and vaccinIums, both of which, but more especially the former, have the leaves very stiff, slender, and sharp pointed; and as the leaves are borne on the exterior surfaces of the trees, the spiry parts of which are not easily penetrated by any bird, and further, as the birds have to range the surface of the spiry tree while they collect this food, they are in a situation in which they cannot have a very firm perch by the feet, though their feet are well adapted for perching (and, by the way, should, independently of other circumstances, take them out of the class of omnivorous feeders). They must thus, in order to maintain their stability, always have the wings ready, and in general spread; and as in this spreading the secondary quills come into frequent, indeed almost constant, contact with the stiff, pointed, and needle-shaped leaves of the trees and bushes on which they find the berries, these little "fenders," as we may call them, at the end of the shafts, afford a very efficient protection to the webs of the feathers.

Thus we find, in these birds, an adaptation which is peculiar among the many and wonderful adaptations of which the feathered tribes afford instances. This adaptation accords with the vegetation of a very peculiar part of the world, whether we look to the eastern continent or to America; and therefore the wax-wings acquire an importance in the eyes of the student of nature to which they would not be entitled in their ordinary character of handsome and finely-coloured birds.

It is this circumstance which has induced us to consider them at greater length than we can, in general, afford to consider a genus of which the known species are so very few. But in those very typical birds which connect themselves strongly with localities that are fitted to the growth of only one remarkable species of vegetation, there is far more in the bird than a mere bird's history; and if we did not avail ourselves of the opportunity of opening a little the general history of nature, and showing the harmony of the parts, and their connection with each other, when the subject of which we are more immediately treating offers itself as a key, we should feel that we were failing sadly in our duty to the public.

In our continent the wax-wings are at home only in places situated far to the north; and though, in America, they range more southerly, that can be easily explained from the physical differences of the two countries, which carries the appropriate food of the birds into regions farther to the south. So far as discovery has hitherto gone, there are no birds of similar structure and character in the high southern latitudes; indeed, there is no vegetation adequate to their maintenance. The extreme south of Africa, and that of America, have more of a tropical character than, reasoning from the latitude, one would be led to expect; and though, in Australia, there are some families of plants, such as *Lissanthe*, which appear to answer, in some sort, to the vacciniums of the northern hemisphere, yet they are plants of different character, not so productive of berries, and the berries on them are not so succulent.

BOMBYLIIDÆ. A family of two-winged insects (Diptera) belonging to the section *Tanystoma* of Latreille, having for its type the genus *Bombylius* of Linnæus, with which in fact it nearly corresponds. It is characterised by the great length of the parts of the mouth, which are very slender, and united into a porrected proboscis. The body is thick, short, and very hairy; the head affixed in a low position on the thorax, the latter is very gibbose; the wings are horizontally extended on each side of the body, with the halteres exposed; the antennæ are short, and inserted near together; they are composed of three joints, of which the last is the longest, and thickened, terminating obtusely. The legs are long and very slender. These insects are very active, flying with the greatest rapidity. They hover over flowers without settling upon them, introducing their long proboscis alone, in order to extract the honeyed fluid which they contain, and which forms the sole food of these insects. Their transformations are unknown; Latreille, however, presumes that they are parasitical in the nests of other insects. The perfect insects are to be met with in fine weather, and during their flight they make a humming noise like that of the drone flies. They delight to take their station in the sunny corner of a lane or other similar place, where they hover hawk-like for a great length of time without moving from the spot; on approaching them they dart off and re-commence hovering at a little distance. They are nearly allied to the *Anthracidæ*.

The insects comprised in this family are not numerous, they are of small or but moderate size, and are for the most part exotic. The genera are *Toxophora*, *Xestomyza*, *Apatomyza*, *Usia*, *Phthiria*, *Bombylius*, *Geron*, *Thlipsomyza*, *Ploas* and *Cyllenia*; of these the genera *Bombylius* and *Phthiria* are British. The former has the proboscis very long, the palpi distinctly visible, the second joint of the antennæ very short, and the third or terminal, joint long The body, which is short and thick, is covered with hair, which gives these insects the appearance of bees, whence they have been named bee-flies. The genus comprises seven or eight British species, of which the *Bombylius major* of Linnæus is one of the commonest species. It is about one-third of an inch long, and covered with dirty yellowish hairs; the outer half of the wings is dusky, the remainder hyaline. Another species inappropriately named by Linnæus, *Medius*, (since it is larger than the *B. major*) has the wings marked with small dark spots at the junction of the nerves. It has been figured by Mr. Samouelle in his Compendium, pl. 9, fig. 10, who has increased the confusion by calling it *B. major*. A third species, *B. minor*, Linnæus, is much smaller than either of the foregoing, with clear wings. The genus *Phthiria* has a much narrower body, and shorter proboscis. The type is the *Bombylius pulicarius* of Mikan, figured by Mr. Curtis in the last number of his British Entomology, for October, 1834.

By Geoffroy these insects were confounded with the genus *Asilus*, with which they are allied in some degree; and as the article upon that group was accidentally omitted in its place, it may be convenient, for the sake of pointing out the differences between the two families, to introduce it in this place.

Asilidæ (Leach). A family of insects of the order *Diptera*, the type of which is the Linnæan genus *Asilus*. These insects, which are very voracious, have the proboscis exposed, but not longer than the head, with very small terminal lips; the body long, the wings recumbent upon the body, and the antennæ composed of three joints. They are to be found in fields, gardens, and the borders of woods, towards the middle of summer. They fly rapidly, especially in the hot sunshine, and make a loud buzzing noise. They prey upon other insects, which they seize whilst on the wing, by means of their fore legs, and extract their fluids by means of the four fine lancet-like pieces contained within the mouth.

The larvæ reside in the ground; they have the body long and twelve-jointed, a scaly head furnished with two moveable and bent hooks; they are destitute of legs, but make use of the hooks of the head to seize hold of the substance upon which they are placed, so as to enable them to draw their body along. They undergo their transformations in the situations in which they have lived whilst larvæ, where they change to nymphs; yet although they quit the skin of the larvæ, they do not form a cocoon in which to change to pupæ. The duration of their existence in this state, as well as in that of the larvæ, is unknown. The family comprises the genera *Laphria*, *Asilus*, *Ommatius*, *Dasypogon*, *Dioctria*, and *Gonypes*. Of all the genera, with the exception of *Ommatius*, we possess British examples. The indigenous species of *Asilus* are numerous and very ravenous; one of the finest species is the *Asilus crabroniformis*, so named from its resemblance to the hornet; we have met with it in Battersea fields. It is represented in Samouelle's Compendium, pl. 9, fig. 9.

BOMBYX (Linnæus). A genus of lepidopterous insects, forming, in his system, the second of the eight divisions into which the *Phalenæ*, or moths in general, were divided, and characterised by the wings being incumbent, and the antennæ feathered; the first of these divisions comprised the *Attaci*, (which see). The investigation of this order of insects has, however, been greatly advanced since the days of Linnæus; and although Mr. Haworth, in his celebrated work, the "Lepidoptera Britannica," united the Linnæan *Attaci* and *Bombyces* into one genus, *Bombyx*, yet more recent authors have not only kept them apart as genera, but have separated the *Bombyces* into two families, namely, the *Arctiidæ* and *Bombycidæ*, in the latter of which the genus *Attacus* has been placed; and in the latest works upon this subject, a third family has been separated from the *Bombycidæ*, under the name of *Notodontidæ*, composed of the *prominent* moths, &c. These three families, together with that of the moths termed swifts and goat-moths (*Hepialidæ*), form a great division of the nocturnal *Lepidoptera*, to which the ordinary name of feathered full bodies is applied by collectors, from the large size of the body, and the feathered antennæ.

In Mr. Stephen's work on British Entomology, they form a section which he has termed *Lepidoptera pomeridiana*, in consequence, as he states, of many of the *Bombycidæ* commencing their aerial excursions in the afternoon, when they may be observed flying with great velocity, and describing large undulated tracts in their course. These four families may thus be briefly characterised.

Family 1. *Hepialidæ*. Antennæ generally moniliform or setaceous. Spiral tongue obsolete.

Family 2. *Notodontidæ*. Tongue (maxillæ) evident, but very short.

Family 3. *Arctiidæ*. Tongue evident, but not elongated.

Family 4. *Bombycidæ*. Antennæ bipectinated. Spiral tongue obsolete.

It will be seen from these characters, that the second and third families are separated by very slight distinctions, and we accordingly find entomologists at variance as to the limits of the groups. Our arrangement corresponds with that of Mr. Stephens, with the addition of the exotic genera inserted in their proper situations. We shall here only observe, that the footmen moths (*Lithosiæ*), which Latreille places amongst the *Arctiidæ*, are removed by Mr. Stephens to the *Lepidoptera nocturna*, and that in his last work, the puss moths (*Ceruræ*) were formed by Latreille into a distinct section, to which he gave the name of *Aposura*, (tail without feet) from the larvæ having no anal prolegs.

The families *Hepialidæ* and *Notodontidæ* will be described in their alphabetical places, but the article on the *Arctiidæ* having been accidentally omitted, it is here inserted.

Arctiidæ (Leach). A family of Lepidopterous insects, separated from the great Linnæan division *Phalæna Bombyx*, and nearly corresponding with the section of nocturnal moths, termed *Pseudo Bombyces* by Latreille, with the exception of the prominent moths (*Notodonta*) which, with a few others, have been formed by Mr. Stephens into his family *Notodontidæ*. The species introduced into this family are of very diversified habits and structure, and general characters alone can be assigned to them. The antennæ are generally more or less strongly feathered, especially in the males, the bodies somewhat robust, and the wings large and entire; when at rest, they are either deflexed or placed in a horizontal position. The spiral proboscis, so striking a character of the *Lepidopteræ*, is here so slightly developed, as to be incapable of performing the duties of a tongue, and is indeed occasionally completely obsolete. The palpi are also generally of small size.

The extremity of the body of the males is generally tufted, and that of the females covered with a woolly mass, which at the period of oviposition, is detached from the body, and serves as an envelope for the eggs. The caterpillars feed on the external parts of various vegetable productions; they are generally very hairy, and often ornamented with coloured tufts of hair along the back. The chrysalides are generally enclosed in a web.

In this family there appear to be several distinct groups, each of which is divisible into various genera.

The first of these divisions has the wings proper for flight on both sexes, the tongue almost rudimental, and the larvæ elongate, and not forming tents. Here belong the genera *Hypogymna* (the gipsey moth), *Psilura* (the black arches), *Dasychira* and *Demas* of Stephens (or the tussock moths).

In the second division the females are destitute of wings, and the caterpillars have large tufts of hairs on the neck. The only genus in this division is *Orgyia* (the vapourer moths).

In the third division the wings are more or less transparent, and the tongue distinct, scarcely longer than the head. Here are to be placed the genera *Lælia* and *Leucoma*, or satin moths, *Porthesia*, Stephens) *Arctia* of Curtis), or the brown and yellow-tailed moths, and some other genera.

In the fourth division the wings are thickly covered with scales, and the tongue, as in the last division, to which belong the ermine moths, *Spilosoma*, Curtis, the tiger moths, *Arctia*, Schrank and Stephens, and some other less interesting genera.

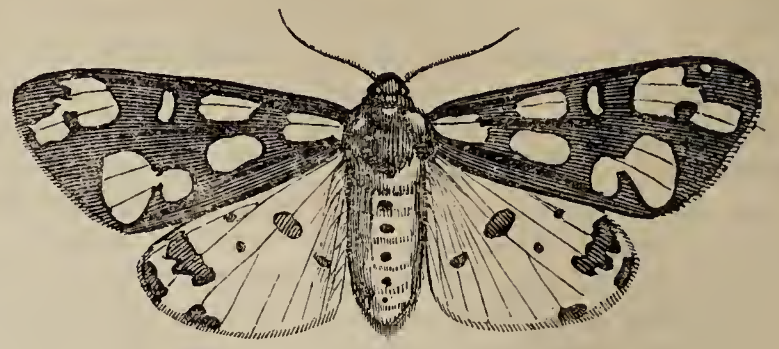
In the fifth the larvæ resemble wood-lice, without legs, and the antennæ of the perfect insects are simple, consisting of the two singular British genera, *Heterogenea* (Knoch), and *Limacodes* (Latr. *Apoda*, Haworth).

In the sixth the larvæ reside in portable cases of their own construction, the moths are destitute of a tongue, and the antennæ strongly feathered in the males; the wings appear to be clothed with hair rather than scales. There are three genera. *Psyche* (Schrank), *Fumea* (Haworth), and *Penthophera* (Germar).

In the last division (which are most nearly allied to the next family, *Lithosiidæ*, in which it is placed by Mr. Curtis), the antennæ are but slightly pectinated, the wings broad, and the tongue longer than in any of the preceding divisions. It includes the muslin moths (*Nudaria*, Haworth), as well as the scarlet tiger moths (*Hypercompa*, Stephens).

The natural history of many of these moths, which are amongst the most beautiful of the nocturnal lepidopterous insects, is very interesting, and will subsequently be detailed under the heads of the more prominent genera. Great confusion has originated in the generic nomenclature of the different groups of these moths, more especially in the works of Schrank, Stephens, Ochsenheimer, and Curtis. We have, however, adopted the views of the two former authors, by giving to the tiger moths, which appear to be the types of the family, the generic name of

ARCTIA (*Eyprepia*, Ochsenh. and Curtis. *Chelonia*, Godart). A name indicative of the hairiness of the caterpillars, which in some parts of England are thence termed woolly bears. The beautiful insects comprised in this genus were amongst the first to attract attention of our boyhood to the study of insects, and the most casual observer of nature cannot have failed to notice them from their common occurrence. The body is robust, and the abdomen transversely striped with different colours; the prevailing tints of the upper wings are rich brown, with white markings, and of the lower bright crimson, with shining blue-black spots. The caterpillars of the common species, *Phalæna Bombyx Caja* of Linnæus, are solitary, of a dark brown colour, thickly clothed with hairs arising from fleshy tubercles in the middle of each ring of the body, the hairs at the sides being reddish. They are hatched in autumn, and come forth in the spring, feeding upon various plants, especially lettuces and chickweed, and change to chrysalides in June, the moth appearing about the end of July. This species, which is the garden tiger moth, is very common. The cream spot tiger (*Arctia villica*) is smaller and less common. The small tiger (*Nemeophila plantaginis*), and the ruby tiger (*Phragmatobia fuliginosa*), which seldom exceeds an inch and a half in expanse, are rare near London, but seem to be more common in the north of England.



Cream-spot tiger.

The remaining family *Bombycidæ*, comprises some of the most valuable of the insect tribes, since the silk-worm is the larvæ of one of the species. The tongue in this family is either very short and flat, not spiral, or entirely obsolete; the wings are either horizontally extended, deflexed or reversed, and the antennæ are strongly pectinated, especially in the males. The want of an oral apparatus is the more remarkable, because some of the species are amongst the largest lepidopterous insects. Their habits are diversified and very interesting. The larvæ are naked, with sixteen legs. They spin a cocoon of pure silk. The pupæ are destitute of minute hooks on the sides of the body. The family comprises three primary divisions. 1. Those with horizontally extended wings, furnished with eye-like hyaline spots, consisting of the genera *Attacus* and *Aglia*. 2. Those with entire wings, and with the palpi not advanced in front, comprising the silk-worm moths, to which we restrict the generic name of *Bombyx*, the egger and lackey moths, (*Lasiocampa* of Schrank, but not of the Regne Animal) *Eriogaster*, *Clisiocampa*, and some other genera, and 3, those with porrected palpi, and denticulated wings, consisting of the lappet moths, *Gastropacha*, *Dendrolimus*, and the drinker moths, *Odonestis*.

The history of *Bombyx mori*, the silk-worm, will form a separate article under its English name, and the more remarkable of the other genera will be found in their respective places.

BONAPARTEA (Ruiz and Pavon). A rush-leaved herbaceous plant, native of Peru. Class and order *Hexandria Monogynia*, natural order *Bromeliaceæ*. It is a plant of no beauty, hardly deserving a place in the hot-house.

BONATEA (Willdenow). A handsome orchideous plant, native of the Cape of Good Hope. The flowers are said to be splendid.

BONNETIA (Schreber). A genus of one species of an ornamental tree, native of Trinidad. It belongs to the class and order *Polyandria Monogynia*, and to the natural order *Guttiferæ*. Its specific name being palustris, would indicate that the tree affects wet ground; and from its connection with other genera of great importance, implies that it may be possessed of valuable properties not yet sufficiently known.

BONUS HENRICUS (Linnæus). *Anglice*, Good Henry, is the *Chenopodium bonus Henricus* of botanists, a common plant found growing in rubbish about old buildings. Why it should have obtained such a name is not easily surmised; unless it be that it sometimes furnishes the cottage table with a dish like spinach, when no other greens, perhaps, can be had.

BOPYRUS (Latreille). A curious genus of crustaceous animals, which is parasitic upon prawns, causing a large swelling upon the sides of the bodies of those animals. The body is oval, flat and soft, having an elevated line beneath, with various transverse impressions; the abdomen is narrower than the body, flattened, and with similar impressions; there are seven pairs of legs placed at the side of the body, but very short and bent. The body is also furnished beneath with four pairs of longitudinal plates, serving as a sort of oviferous pouch. The type is the *Bopyrus squillarum* of Latreille (*Monoculus Crangorum*, Fabricius). It is one-third of an inch long, and must be very obnoxious to the prawns, which it infests; one, however, only attaches itself to each prawn, but it is found in this situation at all times of the year. It is a vulgar opinion among fishermen, that these parasites are young soles, which notion was even recorded by Deslandes in the Memoirs of the Royal Academy of Sciences of Paris, in 1722, and remained unrefuted for half a century, when in 1772 it was satisfactorily disproved by Fougeroux de Bondaroy. The supposed male is exceedingly minute, and of a very narrow form. This parasite belongs to the order *Isopoda*, in which it forms a distinct section, named *Epicarides* by Latreille.

BORAGE is the *Borago officinalis* of Linnæus. It belongs to *Pentandria Monogynia*, and to the natural order of which it is the type, viz. *Boragineæ*. Generic character: calyx five-cleft; corolla rotate, limb cut into five lobes, throat with a vaulted margin, on which lanceolate filaments are seated; anthers incumbent, oblong or lanceolate, and posited together; fruit turbinate, plain at the bottom. There are six species of borage, two of them are British annuals, the others are from the Levant. The officinal borage is a common kitchen garden herb, being used for various purposes, as well by the cook and butler as by the apothecary. The juice yields nitre; and on this account, perhaps, its medicinal virtues are considered salutary. It is cultivated by sowing seed on a small bed of fresh digged ground; thinning out the seedlings to six or eight inch distances, and keeping them free from weeds. The young leaves are an ingredient in dressed salads; and the young flowering shoots are thrown into the drink called "cool tankard." The seeds, which are shed in the autumn, rise on the same spot in the following year.

BORAGINEÆ. Borage family. A natural order of dicotyledonous plants, containing about thirty genera, and nearly three hundred species. This order, from the rough leaves of most of its species, sometimes receives the name of *Asperifolia*. It is nearly allied to the *Labiatæ*, from which it is distinguished by having regular flowers, five fertile stamens and a round stem. Its essential characters are: calyx monosepalous, regular, with five divisions, persistent; corolla hypogynous, monopetalous, regular, five-lobed; stamens five, inserted on the corolla; ovary four-celled; ovules pendulous; style simple, terminated by a two-lobed stigma; nuts four, distinct; seeds without albumen.

The plants included in this order are herbs or shrubs with varied stems, flowers in spikes, racemes or panicles, and alternate leaves, which are generally rough. They are found abundantly in the temperate latitudes of the northern hemisphere. Many of the species are natives of Europe, very few are found in arctic regions, and scarcely any within the tropics. In North America they are less abundant than in Europe. The borragineæ are in general mucilaginous and emollient. Sometimes they possess astringent and narcotic qualities. Some of them are weeds which are never cultivated, while others, such as some species of *Echium* and *Symphytum*, are valued on account of their beauty. They are propagated by cuttings, divisions, or seeds. The chief genera of the order are *Borago*, whence the name of the order is derived, *Anchusa*, *Lithospermum*, *Echium*, *Pulmonaria*, *Symphytum*, *Myosotis*, *Cynoglossum*, *Lycopsis*, and *Asperugo*.

Boraginea.

Borago officinalis, common borage, is found pretty abundantly among rubbish and waste ground in Britain, although scarcely considered indigenous. Exhilarating qualities were formerly attributed to this plant, and with the alkanet, roses, and violets, it was reckoned one of the four cordial flowers. It possesses emollient, diuretic, and sudorific qualities. Its leaves are considered in some countries as refrigerant and cordial. A syrup is prepared from them in France, which is used in pleurisy and inflammatory fever. The plant has an odour like cucumber, and communicates a peculiar coolness and flavour to any beverage in which it is steeped. With wine, water, lemon and sugar, it forms an ingredient in the favourite English drink called "cool tankard." It has been employed in cutaneous diseases. Its diuretic qualities are owing to the nitre or saltpetre which enters into its composition.

The roots of the *Anchusa tinctoria*, alkanet or dyer's bugloss, are imported into this country from France and Germany in a dried state, for the purpose of being used in dyeing. The alkanet is a native of Europe, and is frequently cultivated in Britain. Its roots have a bitter taste, and their bark yields a reddish-brown matter resembling resin, which is used for giving a red colour to oils, ointments, plasters and salves. The corks of Port-wine bottles are sometimes stained with it by way of deception. To alcohol it imparts a carmine-red colour, which by evaporation changes to blue, and then to green. This root is also used in compositions for rubbing and giving colour to furniture made of mahogany. Wax dyed with it and applied to the surface of warm marble, tinges it of a flesh-colour, which sinks deep into the stone. The small roots are best for dyeing. *Anchusa sem-*

pervirens, or evergreen alkanet, is found in waste ground and among ruins in many places, both in England and Scotland, and is often cultivated in gardens on account of its beautiful blue flowers.

Lithospermum arvense, Corn growwell, or *bastard Alkanet*, is also a native of Britain. The bark of its root abounds in a red dye, which imparts a fine colour to wax and oils. The country girls in Sweden and the north of Europe, are said to stain their faces with it on days of festivity. The seeds of the *Lithospermum officinale*, from their stony hardness, were formerly supposed to be useful in calculous disorders. The roots of *Anchusa virginica, Lithospermum tinctorum, Onosma echicoides*, and *Echium nitrum*, are used by dyers.

Echium vulgare, common viper's bugloss, is one of the most beautiful of our indigenous plants. Its flowers, which grow in a spike, are at first of a reddish-purple, and afterwards of a brilliant blue colour. *Echium plantagineum* is used in Brazil in the same way as the borage is in Europe.

The leaves of the *Pulmonaria officinalis*, common lungwort, are used as a demulcent in coughs, spitting of blood, or catarrhal affections. *Lymphytum officinale*, common comfrey, grows frequently on the banks of rivers, and in watery places in Britain. The plant abounds in mucilage, and may be conveniently substituted for the althea or marsh mallow. It is used in bowel complaints, hæmoptysis, and pulmonary catarrh. The leaves give an agreeable flavour to cakes and panada. The young stems and leaves, when boiled, are employed as articles of food. The root is emollient, and has a somewhat astringent taste. A decoction of it is used by dyers, to extract the colouring matter of gum-lac. *Myosotis palustris*, great water scorpion-grass, is a very common, but at the same time a very beautiful weed, and is well known to every one under the name of *Forget-me-not*. The plant is considered as an emblem of friendship in almost every part of Europe.

Cynoglossum officinale, common hound's tongue, is found native in Britain. The plant is soft to the touch, has a dull green colour, and emits a disagreeable odour. The root and leaves are said to possess narcotic properties, but they are seldom used in medicine. The leaves are sometimes boiled and applied to painful swellings, in the form of emollient, anodyne cataplasms. The extract of hounds-tongue is made into pills with opium.

BORASSUS (Linnæus). Is one of the most remarkable of the palm tribe, called specifically flabelliformis, from the edges of the leaves being furnished with dangling threads, resembling those instruments of torture called *cat-o'-nine-tails*. Class and order, *Diœcia Hexandria*, and natural order, *Palmæ*. Generic character: a branched spadix issuing from a common spatha; male flowers aggregated; calyx three-cleft; corolla of three petals on footstalks. Female flowers solitary, calyx of three sepals; corolla of from six to nine petals; stamens abortive, and connected below; stigmas three; berry, tripyrate, pyrenes inversely egg-shaped, involved in fibres. This palm is a native of the East Indies, and is a magnificent vegetable; the stem, and regular figure of its fronds are imposing, though not so useful to mankind as some of its congeners, it nevertheless yields both a sugar and a vinous spirit from the pith of the trunk.

BORBONIA (Linnæus). A genus of evergreen ornamental shrubs introduced from the Cape of Good Hope. Class and order, *Monadelphia Decandria*. Natural order, *Leguminosæ*. Generic character: calyx near five-cleft, segments nearly equal and rigid; corolla, exterior hairy, standard marginate, keel obtuse. Pod, often one-seeded, and pointed. This tribe are neat green-house plants, easily preserved and propagated by cuttings.

BOREUS (Latreille). A genus of small but remarkable insects, belonging to the order *Neuroptera*, and family *Panorpidæ*. The prothorax is large; the females are wingless, and the abdomen in that sex is terminated by an exserted conical ovipositor; the males have rudimental wings. The only species is the *Panorpa hyemalis* of Linnæus, figured by Panzer under the name of *Gryllus proboscideus*. It is found throughout the winter, under moss in the north of Europe, as well as on the Alps, where it is observed running about on the snow itself, as we learn from the account given by Dalman in his Analecta Entomologica. This insect is about a quarter of an inch long.

BORKHAUSIA (Böhmer). An extensive family of annual and biennial herbs, mostly natives of Europe. They belong to the natural order *Compositæ*, and bear small yellow flowers.

BORONIA (Smith). An interesting genus of New Holland shrubs, with handsome flowers and foliage. Class and order, *Octandria Monogynia*, and natural order *Rutaceæ*. Generic character: calyx, four-parted or cleft; corolla four long petals, which soon wither; four short stamens standing opposite the petals, those intermediate being abortive; filaments round the germen, incurved, thickened at top, anthers heart-shaped, fixed by the back; style simple, stigma capitate or quadrate; capsule four-lobed, four-berried, each berry two-seeded.

Boronia.

BORYA (Willdenow). A family of North American shrubs belonging to the natural order *Euphorbiaceæ*, of no beauty. The late Sir James Smith altered the name to *Bigelovia*.

BOS (the Ox). A genus of ruminant mammalia which is generally distributed over the globe, in one or other of its species, and altogether, perhaps, the most useful to man in the whole range of animated nature; and for that reason, one the knowledge of which is peculiarly valuable.

Some notice has already been given, under the word BISON, of one of the groups, or subgenera, into which the genus is divided. That group, however, in its two existing species, as there described, has always belonged to wild nature; and though the flesh is esteemed, and the skin is valuable, as is the case with all the ruminantia, and with this genus of them in an especial and pre-eminent manner, the bisons have always been creatures of free nature, the strength of whose necks has not been subjected to the yoke, nor have they been trained, except in a very partial manner, to obey the voice of man as their master. But the two groups which remain to be noticed, and to a brief account of which we shall devote the present article, have been domesticated.

The characters of the genus have their average or typical representation in the common ox, with which every one is familiar. The skull in all the species of this genus is strong in the anterior and upper part, with the front convex, flat, or concave; the horns are circular in their section, but variously formed and of different sizes in the different species. They are produced upon cores of bone, which are always more or less porous, and said in some of the races to communicate with the nostrils, through duplicates of the frontal bones. The true horn consists of a sheath produced upon this core, which receives a new layer on the inside every year. It is naturally smooth, but as the animals advance in size, the markings of the different layers toward the root of the horn give it a slightly annulated appearance. The horn is produced from the epidermis of the forehead, and not from the bony cone; only the last produced layer is attached to the epidermis; and if the horn is accidentally broken off it is not produced. The muzzle is broad and square, or appears truncated, and it is usually of a black colour; but the colour of the tongue and inside of the mouth varies. The ears are of considerable length, and project from the head. The body is rather long, but at the same time stout; the legs are stout; and the hoofs broader in proportion than those of the other two-hoofed ruminantia. Most of the species are gregarious, and some of them naturally congregate in large herds. The males, especially in the more gregarious species, fight desperate battles of gallantry; and in the pairing season, they are very pugnacious. They show their hostile disposition by tearing up the earth with their horns, and scraping and pawing it with their feet; at these times they bellow with a deep and hollow sound; but when the males attempt to low, their voices generally fail, as if they were hoarse. The voices of the females are more shrill; but they are not heard at so great distances as the deep bellowing of the males. When the passions of the males are excited, their eyes have a glaring and fiery lustre; and their passions are apt to be excited by circumstances which do not affect other animals. Blood spilt on the ground excites them very much; and so does any thing which is of a red and glaring colour. The young of all the species may be, to a certain extent, tamed; and some of them will even follow the hunters by whom the mothers have been killed, but the males of none of them can be said to be reduced to a state of great obedience, especially at that season when they are under sexual influence.

Generally speaking, they are inhabitants of the plains, and of plains where vegetation is moderately rich; and as they are heavier in the body, they are less fleet and discursive than the other ruminantia. They subsist chiefly upon green vegetable matter; the grasses, some leguminous plants, and the leaves of various deciduous trees, but they are not so fond of the latter as some of the other genera of the order. Their mode of eating differs from that of all other grazing animals. They do not nibble, but bite rather slowly; and as their upper lip is not prehensile, they use a peculiar licking motion with the tongue to gather in the grass which is divided by the bite. None of the genus are carnivorous; but they gnaw bones and other hard substances, and it is said that in some places the domesticated ones can be made to eat fish. Though there are considerable differences of appearance, habit, and geographical locality, in the various groups and species of which the genus is composed, it is understood that all, or nearly all, may be made to intermix in breeding.

The domesticated ones are remarkably yielding to circumstances, and readily take a very distinctly marked character, from differences of climate, pasture, and treatment. This plastic nature is of great advantage to those by whom they are reared, as it enables them, by crossing the breed of one place with that of another, to improve any particular quality that they may desire,—such as size and strength, if they are intended for labour; superior quantity or quality of milk, if for the dairy; and facility of fattening and flavour of flesh, if intended for food.

With the exception of the single species of bison mentioned in a former article, there is no evidence of any of the genus having at any period inhabited the American continent; and there are no vestiges even of that species in South America. This, however, is not owing to any want of adaptation in the climate, or the spontaneous productions of that country, to the habits of the animals; for those which were introduced by the European colonists have multiplied to an extent unknown in any other part of the world, so much so. indeed, that they are often captured for the skins only, and the flesh left to feed the vultures.

On the eastern continent, the native races in the wild state, have in all probability very much declined, though from the confusion which long prevailed of one group with another, their progressive history is not the most satisfactory. Fossil bones of all the groups are, however, met with; and some of them in deposits which we must suppose to have been formed long before the existence of any historic records of the places where they are found. Besides the bison, as already noticed, the groups are the common ox and the buffalo.

THE OX GROUP. Of all the genus these have been the most celebrated; and they are, in all probability, the first animals which man brought into a state of domestication. They are understood to have been originally natives of the middle latitudes, the plains by those rivers of central Asia, the banks of which are now, in many places, encroached upon by the deserts. This original locality of the group is inferred from its favourite pastures, rather than from any peculiar climatal adaptation; for, in consequence of that obedience to climate to which allusion has been made, the ox can bear a greater range of latitude than most animals; and it thrives as well in those which are rather high, and also in places, such as Australia, where there is not a vestige of any of the genus ever being native, as in the places where the bones are found in fossil state. It would be vain however, to attempt tracing the history of this animal, or attempting to determine the native locality of the race from which civilised nations originally derived that species which is now, and has from time immemorial been, of so much value to them.

Nothing tends more forcibly to prove the early period at which the ox was appropriated by man, and the advantage derived from the appropriation, than the association of that animal with religious rites and astronomical allusions. That the bull was the object of direct worship among the ancient Egyptians, and that it continues to be so to this day among the Hindoos, is well known. It had also large typical honours among the Greeks and Romans; and even with the Jews, under the Mosaic ritual, this animal was the most costly sacrifice. There are traces of very high regard for these animals among all the nations of the eastern continent; and among some of them the names of cow and calf are the terms of fondest endearment which the people apply to each other. This would lead us to suppose that the domestication of the ox was, if not the cause, at least one of the earliest and most efficient means of civilisation; and, if the expression may be allowed, there is a disposition to the society of man in the animals of this group, which is not so apparent in any other. The ox does not, it is true, voluntarily offer his neck to the yoke, and the female of the group does not come spontaneously to be milked; but the gregarious propensities of these animals, which is peculiarly strong, leads them to associate readily with almost any other animals, which have no disposition to offer them direct injury.

They are also much more constant to their localities than the lighter members of the order; and these are the very localities which are most enriching to man as a visitant, and a resident, and a cultivator. We have a remarkable instance of their superiority in this respect, in the contrast of the ranges necessary for cattle and sheep, in those parts of our own country, which cannot be profitably brought under the plough, or which, at all events, have not been so brought. If the country is to be thrown profitably into sheep walks, the cottages must be removed over a very considerable breadth, so that the sheep may have free range; and the sheep nibble the leaves of the shrubby plants as well as the grasses, and have a tendency to reduce the country to that bare and bleak state which suits best with their own healthy condition. A moist climate, and humid and soft soil, are also ill suited for these animals; as the water lodges in their fleeces, and makes them heavy and fatiguing to the animals, which heats them, and as the heat is carried rapidly off by the evaporation from the fleece, their strength is exhausted, and they are subjected to diseases of the lungs. Their feet, too, from the comparative narrowness of the hoofs, sink deep into soft and boggy ground. This also fatigues them; and besides, the moisture acts on the frogs or soft parts of the hoofs, which are altogether of less consistent structure than those of the ox tribe, and they are seized with "foot rot," or mortification of the lower part of the foot. Nor is it the weakly sheep which are subject to these casualties; but rather those which are in the best condition, and on that account the most apt to feel the weight of the rain in their coats, and to sink deep in the soft ground. They are also, altogether of more delicate constitution, and less able to bear severe weather than the ox tribe.

These last do not range so widely in their daily feeding, they are less disturbed by human habitations, or by the presence of other animals on the same pastures. Rains injure them but little in comparison, as their coats throw off the water, so that it does not load and fatigue them as it does the others. Their feet are broader in proportion to the weight of their bodies; their hoofs are of more compact and firm texture, and not liable to be rotted, or otherwise injured, by humid pastures. They are indeed partial to such places, as they prefer the grass when there is some moisture upon it; and accordingly, their chief feeding times are in the morning and the evening, and in the heat of the day they retreat to the shallow waters, and stand in these, chewing the cud with much apparent satisfaction. Sheep, on the other hand, continue to nibble all day long, but they are apt to suffer if they remain on their pastures after the dew of evening is formed.

The ox tribe is much less liable to disease of any kind than sheep are, unless it be diseases which are brought on by a deficiency of food, or food of an improper quality. The true grasses are their most natural and proper food, and they are always in the best condition in places where those grasses are native. This circumstance alone would point out the middle latitudes as their natural geographical habitats. They also readily eat the leguminous plants, and the smaller species which are found on dry pastures, or indeed any of the species when dry, are not unwholesome for them; but when the rich clovers, in a state of vigorous growth, and when wet with rain or dew, are taken into the stomach, they ferment and give out so much gas, that the paunch is in danger of bursting, which is of course fatal to the animal. Even this, however, does not appear to affect the system with disease, and thus it is no argument against the general healthiness; for an incision made into the distended paunch, if so made as not to injure the other viscera, suffers the gas to escape, and all is well.

Thus the ox points out to man those places where it is most advantageous to settle and begin the labour of cultivation, which may be considered as the primary foundation of all improvement. It was probably, indeed most likely, for this reason, that the bull found so honourable a place in the mythologies of all the civilised nations of antiquity, and in the sacrifices under the ceremonial law of the Jews, and for the same reason that he found a place, and the peculiar place which he holds, in the signs of the Zodiac.

We have seen a fanciful parallel drawn between those signs, and the progress of man in civilisation, which though probably not literally true, is yet worthy of being repeated. The Ram (*aries*) was typical of the primary or pastoral state, under which only single families, or small septs of people, could live in communion with each other; and there could not only be no communion of opinion, or unity of purpose among people in such a state, but they must have been at continual war with each other about the invading and the defending of their pastures. So far as we can glean from what is recorded in Holy Writ of the patriarchal ages, when there seem to have been as many kings as hamlets in Syria, this appears then to have been the condition of that portion of the world. The Bull (*taurus*) was emblematical of settlement and culture; and this appears then to have been the condition of Egypt, and the richer parts of the world; and we find that down to a considerably advanced period of their history, the Jews, whenever they fell into idolatry, usually had recourse to the symbolic calf as the idol. The Twins (*gemini*) were expressive not only of the fertility and consequent abundance which followed the domestication of the ox and the practice of agriculture, but of the brotherhood, or the union of man with man for purposes of mutual advantage, which was the immediate consequence. The subsequent part is considerably more fanciful, as when men are once civilised, the objects of their pursuit become so numerous, that no one subject can be emblematical of the whole. The Crab (*cancer*) is considered as indicating the firmness of that brotherhood, the establishment of which is typified by Gemini. The Lion (*leo*) the strength of men when so united. The Virgin (*virgo*), the elevation of woman in the scale of society, which has always been in proportion to the degree of civilisation. The Balance (*libra*), the institution of commerce, after considerable bodies of men had found it their interest to live at peace with each other. The Scorpion (*scorpio*), the ambition for discovery and for conquest, which has marked a certain stage of the history of all civilised nations and races. The Archer (*sagittarius*), the wars to which this ambition led. The Goat (*capricornus*), the passage of the mountains (which the goats inhabit) and the consequent extension of knowledge or conquest beyond the original valley. The Water-carrier (*aquarius*), the passage of the confining river or strait; and the Fishes (*pisces*), the launching of the ship upon the open sea, and the subsequent progress of discovery till man circumnavigated the globe, laying the foundation for universal intercourse, and for the enjoyments of the whole products of the earth by the whole of the earth's inhabitants.

The fable here may be fanciful, but the application is correct, and the whole affords a very good instance of allegoric reasoning. It will be seen that the bull or ox in the fable, is the point from which union, and the strength and effects of union among men, are dated; and the same is true in the real history of human improvement.

We do not say that the ox has been the sole cause of the localising, and consequent civilisation of man, because the first steps of civilisation, in any other way than from the example of those already civilised, are not upon the historic record. Nor can we expect that they should, for the existence of a record is itself an indication of rather an advanced state of society. Of the certainty of the matter,—of the first impulse to all those comforts and enjoyments which we possess over the wild men of the woods,—we must therefore remain in ignorance; but the subject is one upon which it is both pleasant and profitable to conjecture, inasmuch as our very guesses as to how civilisation, and civility between man and man were begun, not only put us in the way of spreading their progress, but reprove us sharply if we fail in the performance.

Now we can find in the natural habitats of the ox, more incentives to activity of mind, and variety and versatility of thought, than in the wood of the hunter, or by the shore of the fisher, and as these are still the best means of promoting improvement, we may naturally suppose that they were the most likely means of its commencement.

Where nature shows no change, man remains in the same state. The Bedouin of the African desert, and the native of Australia, have remained in the same condition time out of mind; and in all places where people have continued for ages without any improvement, we may naturally suppose that they remain so, not in consequence of any effect of climate or other physical action upon the body, but from want of stimulus to the mind; for we have the evidence of history in all climates, from Iceland to the Equator, that if this stimulus is supplied, man may be equally energetic under any parallel; and that, if the intellectual part can be sufficiently roused, it will soon teach the body to triumph over physical circumstances, unless in those extremes of cold or of drought, in which there is nothing upon which ingenuity can act. Nay, even there, it is the absolute extreme only which is desperate; for in the centre of the Indian desert, we find an inhabitant who cultivates his water melons, and digs hundreds of feet into the earth for water; and on the northern shore of America, in the region of winter, where no metal can be touched without affecting the hand in the same manner as fire does, we find the Esquimaux dwelling in the snow, and finding his food upon the ice. Still there must be a stimulus, and it is doubtful whether, in the first instance, the stimulus of necessity is sufficient, because, though an urgent one it carries a blight, a withering of all hope along with it.

The natural climates of the ox tribe, are those in which there is the most rapid and the most agreeable variety of seasonal action,—there is the most to be observed, and man is able to be at all times and seasons, most observant of it. There are various reasons why man, when he lives in the thick forest, or in the fastnesses of the craggy mountain, should remain unchanged. The vegetable world is the best calculated to rouse his attention, as the changing vegetable remains in its place, and allows him to command and examine it in all its states, while with most animals, it is but a sight and away. But the vegetation of such places changes little during the lifetime of man; and as the mountain, the rock, and the waters, which change not for centuries without some convulsion of nature, which must drive man from that locality, are the most conspicuous objects, they have still a greater tendency to chain down the mind to permanent routine. The oak in the forest stands for centuries, and there are many species of longer duration. In the extremes of latitude, where the *two* seasons are the most marked, either by heat and cold, or by humidity and drought; and where spring with its blossoms and autumn with its frosts, do not mark half the year with the energy and the fruits of nature's action, there seems little in the appearances of nature around which can stimulate man to be up and doing. The pine forests of the north are, if the expression may be allowed, "dismally everlasting;" and they tend to choke all other vegetation, the appearance of which is calculated to give interest.

Those who have what is called "a painter's eye," that is, who have a feeling of the beauty of scenes, complain of the dull and gloomy monotony of pines, in all situations where they are not relieved by other trees. But the feeling which is capable of deriving either pleasure or pain from scenes, always goes deeper than mere external appearances; and, though the party may not be aware of it, there is always something mental,—some feeling of relation in addition to the affection of the sense. It is on this account, that the trees in question are not pleasant;

the connections which they suggest to the mind, are those of dulness and death.

The perennial green of the tropical forest, has much the same influence upon the mind. No doubt it has its alternations of wet and dry, just as the polar one has of heat and cold; but it has these only, without the spring and autumn, and their succession is so rapid and so violent, that man can hardly take notice of the changes, and cannot at all profit by their appearance. The perennial leaf, too, makes the feeling of the same dull character as in the opposite extreme; and, as in the other case, man has no hope but just to leave the world at his death in the very same state in which it appeared to him at the first opening (for, in such places we must not say *use*,) of his eyes.

To those who look only for the common descriptions of animals as they appear to the eye, and as they might be better understood by one glance at the living animal, or even at a figure of it, than from the most elaborate piece of writing that could be put in words, these remarks may appear lengthy and out of place, in an article having the name of a single genus of animal for its title. But such remarks have been so much neglected by even the best writers on natural history, that they have no names in the vocabulary of the sciences—no titles under which they can be separately treated in an alphabetical arrangement, and they are at the same time so much more important than even those other subjects which have names in every book, that we feel not only justified in introducing them, but bound to introduce them, upon every favourable occasion. To know the details of one subject, as fully and accurately as possible, is very proper and very necessary as far as it goes; but it is a very small matter compared to that of being able to know the part, and the view of nature which shall be to us both book and instructor, which will not only take all the heaviness of taskwork out of our attempts to learn, but make the grand function of the mind—the acquiring of knowledge, go on in the same way as the grand functions of the body; that is, not only without interruption to any of the others, but furthering every other in proportion as it is in itself vigorous.

This seems an obvious, as well as an admirable view of the acquiring of knowledge; and one can hardly imagine how it can have escaped all those who have hitherto written on the subject. In the common business of life, the body has a part to perform, and so has the mind. The relations of them to each other vary with the occupation—as the body more in him who works as he is directed, and the mind more in him who directs the working of others. Farther, the exercise in this way is, up to a certain degree, healthy both to the body and to the mind.

Now, we all know that the business of life, whatever it may be, goes on the more energetically and successfully the more healthy that the body is—that is, the more freely and completely that all its natural functions, such as digestion, or the circulation of the blood, are performed. Now, with the knowledge of the universality of this fact, it seems passing strange that there should be, not only a prejudice against the analogy, but a direct denial and denouncement (sometimes not a very temperate denouncement) of it in the case of mind! The healthful function of the mind—the process of thinking, knowing, planning, and inventing, can no more fatigue the mind, or divert it from the performance of its part in life, than the healthy exercise of the bodily functions can so fatigue or divert the body. Indeed, it cannot so much, or even at all; for, though we are in the habit of speaking of mental fatigue, or distraction, just as we are in the habit of speaking of mental disease or derangement, yet the mind is equally incapable of the one and the other. Sleeping or waking, the mind is always thinking; only the idle thought perishes, effectless and useless, like the obscure dream of the sound sleeper, which, because it touches not the sense, leaves no trace on the waking mind—or rather on the mind after the body has awakened. See Dream and Sleep.

This view of the subject is of the greatest importance, and the neglect, or rather denial and resistance of it, cuts mankind off from more of the usefulness and pleasure of life than all other causes put together. The man who thinks the most, is capable of acting the best and the most also; and so conversely, he who is the most active in his body, is also the best capacitated for being active in his mind. It is sometimes said that men injure their bodily health by study; but it is quite a mistake, unless what is vulgarly called "brown study" be meant—that in which the mind stands still, and holds the body in inaction along with it.

Thus, whether we speak of the interruption given to business by thought, and the acquiring of (a habit of) knowledge in those who are not professedly students, or the injury done to health by the sedentary habit of those who are, we are equally in error, and thus express ourselves either on account of our ignorance of what knowledge is, of the nature of the human structure as a compound of body and mind, or of both. The healthful state of the whole man, that in which it can best perform that which it has to perform, whatever that may be, is the state in which those functions of the body and of the mind, which may singly be called the life of each, and together, the life of the whole man, are all performed with equal energy. If the one is really active, it will not allow the other to be idle; and when a man of action becomes studious to the neglect of his business, or a man of study to the injury of his health, we may be sure that it is mental dissipation or indolence, and not mental labour, which is the real cause of the mischief; and as there can be no indolence of weakness or of fatigue in the mind, as there may be in the body, we may be sure that another step of the analysis would bring us to the want of stimulus—to a perverted doting and dreaming upon that in which there is not sufficient excitement.

This would bring us back to the natural pastures of the ox tribe, as the places of the earth most eminently fitted for stimulating the human race to civilisation at the first, and to the animals themselves; as, from the readiness with which they can be domesticated, and their varied uses when this is accomplished, one of the principal means of forwarding that civilisation which their pastures are so well calculated for beginning. But there is still one general point, upon which we shall venture to make a remark or two, before we go on to any thing partaking so much of detail as even the account of this numerous and important genus of animals; and we do this the more readily, that what we have to say has, besides its importance in the general subject of knowledge, and the means of acquiring it, a very strict bearing upon natural history.

It is not the simple appearance of objects to the senses, as portions of mere matter, and without change either of place or of state, which is calculated to stimulate the mind to thought, and the body to action. Thus, when we look at the portraits of animals, however faithfully painted, or at their skins in a museum, however well preserved and accurately set up, if there were no more in them than the eye sees, they would give us no more pleasure, and please us no longer, than so many spots of colour daubed on a wall. If we could not, in some way, connect the specimens which it contains with life and living action, the sight offered by the finest museum in the world would not afford a fairer sight than the window of a draper's shop to one of a nation that do not wear clothes. A very striking, and by no means an uninstructive instance of this, occurred in London some time ago, in the case of two red men of the woods—two young chiefs of a very partially civilised tribe of North American Indians. They had come so far to see the world, and they spoke the English language, and conformed in great part with the costume and the manners of the country, so that they were very far above the first step in civilisation; but as those who took upon themselves the office of conducting them through the streets, were pointing out to them all the finery and wealth which are there displayed, they turned away with perfect indifference from all the grandeur and the riches, and expressed their wonder that *men* should waste their time, and occupy their attention, with such trifles. But when they passed the window of an eating-house they were in raptures, and burst out into loud encomiums on a country where a man "could eat whenever he was so minded."

The conduct of these Indians was true to the state of their knowledge, that is, to the relations of usefulness which were suggested by the objects which they saw. They were not aware how many of the people of this country depended upon those articles which they despised for a share of that food which they beheld with so much admiration. But those Indians were human beings, true to the common feeling of human nature; and there is a very valuable lesson to be derived from their case—namely, that it is to no purpose that we show the object, be it what it may, if we do not explain the use, or make sure that the person to whom we address ourselves is acquainted with it. In natural history the lesson is peculiarly apposite; for if we merely show the animal, the plant, or the other object, be it what it may, and remain silent as to the action and the use, those whom we attempt to teach will turn away from us with the same indifference as the Indian chiefs, and direct themselves to something which is palpable to the senses, as contributing to some purpose.

And if man is naturally placed where the objects around him, whether on the earth, in the waters, or in the atmosphere, show no change, they hold out to him no incentive for thought, and there is nothing to rouse him from ignorance. If nature is to be an instructor, there must be natural actions seen in the beginning, the middle, and the end, and the shorter the time in which this takes place, the lesson which it affords is the more valuable. On this principle (and it is a universal one) we may conclude, that if man had not seen the plant of the temperate climate, or the middle latitude, spring up and reach its maturity in the course of a season, or of so brief a period of time that he could carry the whole of the facts along with him, he would never have become a cultivator; but it is in the native pastures of the ox division of the genus bos that this is to be procured in the highest perfection, and therefore it is in these that, as we may safely conclude, civilisation had its beginning.

But the ox not only thus leads man to the regions where he has the proper stimuli to cultivate, but it, more readily than any other animal, assists him in the cultivation. The bison may be, in some sort, an exception; but that stage of a country which is the best adapted for cultivation is one from which the bison retires; yet even the bison, especially in the American species (see the article Bison), shows no dislike to the society, or at all events to the neighbourhood, of man. The young bison will follow the hunter who has deprived it of its parents, which is perhaps the strongest attachment to animal society, without reference to its own species and kind, which we find in any wild animals.

There is another property of the genus bos, and especially of this division of it (of which the domestic ox may be regarded as the type), which must have rendered it peculiarly advantageous to the human race in their early migrations, and of which we have very remarkable proofs in those cases of extensive colonisation of distant parts of the world by European settlers which have taken place in more modern times:—Of all animals, the ox is, next to man, the most plastic to climate, and hence domestic oxen are divided into more varieties or breeds than any other animals. If removed into countries analogous to those which many may suppose were inhabited by the bison, and in which the remnant of that division of the genus is still to be found, and exposed to the severity of the weather, the ox acquires a shaggy and bison-like character; and if, on the other hand, it is removed into climates resembling those in which the buffalo is found native, it takes more of the appearance of that animal.

There is not, perhaps, change enough produced in either case for enabling us to say that all the divisions into which this most interesting genus is broken have resulted from climate, but there is as much as renders our separation of the genus into species doubtful and unsatisfactory; for though we find what we may consider as specific distinctions in the external appearance of the form of the frontal bone and the number of the ribs, yet there are physiological coincidences in all the species, so far as has been observed, which are of equal, if not greater, importance than these. The different species have bred together in many instances, and they probably would do so in all; but there are no mules among those hybrids which are barren to each other, though they breed back to the pure blood of either parent, as there are, without exception, in the hybrids between the horse and the ass. [See the article Ass.] Now, if there be any meaning (that is, any physiological meaning) in the word "species," surely that which can continue itself, without the calling in of any other race, and can do this from any one pair, is unquestionably the best foundation upon which a species can be built. In describing, and knowing by description, the external characters, or rather appearances, of these animals, the names of the divisions of species may be admitted, but we cannot be too careful lest we thereby break down the physiological unity.

This double classification, or rather the taking care not to be led away by it, is a very important matter in the useful *study* of natural history, not only as it prevents those views about the origin of animals, into which they who examine no farther than the external differences are in constant danger of falling, but as it is of real and practical use to those who use the animals for domestic purposes. Every well-informed grazier knows that he may obtain any shade of character that he pleases between the widest extremes that are to be found in the domestic varieties; and thus he can breed for the table, the dairy, or the draught, with equal facility. So can he also breed for the pasture, both as to climate and to kind of food. Thus, in whatever part of the country there is food and necessity for one of those animals, that animal can always be the one most profitable in that particular locality, and this extended over the whole country renders grass and grazing profitable to the very maximum in a national point of view. All this may be done with a very moderate degree of knowledge, if that knowledge is of the right kind. The breeds must be known in their qualities and in their effects upon each other in crossing, both of which are matters of simple observation; and if there be added a knowledge of the local causes, the climate, the food, and the treatment, and the extent to which they influence the character of the breed, then the grazier has only to act according to his knowledge to obtain the most certain and profitable result. But the foundation of the whole is the fertility of the produce of these crossings.

It is worthy of remark, that this general fertility, and the advantages which result from it, are conspicuous in proportion as the animals possess the other qualities which facilitate their domestication, and also those which render them useful in the domestic state. It is in this, and not in what has been called the sagacity, and sometimes "an inferior kind of reason," that the nearest approach to man on the part of the other animals consists. When we take up the hypothesis of the "inferior reason," we at once get upon dangerous ground, and are mired if we venture a step. But here we are not only quite safe, but upon an elevated rock, which commands a wide view of the beauty and utility of nature—such a view as is of itself sufficient to convince us how bountifully we have been treated, and by whom. The sagacity of the dog has not only been selected as the nearest approximation to thought in man, but the dog has sometimes been called the means of civilisation, or, at all events, the stimulus to it, while the ox has been put aside with the brand of stupidity, and the sheep with that of silliness. Yet it is this very stupidity and silliness, or rather that which has been so called, not very wisely, which forms the value of these foremost of all animals in an economical point of view. The natives of New Holland, when first discovered by Europeans, had dogs, but they had neither clothing nor habitations. They cultivated no plant, and their traditional history did not go back to the whole lives of their immediate fathers, nor did their knowledge of geography extend beyond the hill or the flood which bounded their immediate horizon. As they were savage men, their companion was a savage dog; but still they had it, and it was the only wholly placental animal, except some very small ones, to be found in their country.

Man is, as we have had repeated occasion to remark, of all living creatures, the best fitted for enduring varieties of climate, in respect both of heat and cold, and of drought and moisture. This is more an animal than a mental adaptation in man, and therefore it is one in which the analogy of the other animals, so far as they agree or disagree with man, may be admitted without the least impropriety. The approximation toward this may be taken as the leading ground of the fitness of animals for domestication, as it enables man to take them along with him in all his migrations. And no one can refrain from noticing how perfectly the number and value of the uses of animals to man, and also their obedience to his culture, in fitting the breed to the place and the purpose, accord with this pliancy to climate. The ox stands foremost in pliancy both to nature and to art; so does he in utility. Alive, he gives his strength for labour; and dead, his body for food: and, as civilisation advances, there is no part of that body which may not be turned to some useful purpose. No doubt he is, as a labouring animal, better adapted to the more early, than to the more advanced, stages of civilisation; and in Britain, and some other places, the race is bred almost exclusively for the dairy or the table. But, if we take the working world, in all its breadth, we shall find that there is, even at the present time, more of its agriculture and its carrying labour performed by the genus *bos* than by the horse. The ox is slower-footed, but he is more enduring, more easily fed, and, from the structure of his feet, capable of travelling along paths for which the horse is not at all adapted as a beast of burden. In all the hot countries, where, from the violence with which the rains set in, and, generally speaking, from the poverty of the people, roads cannot be made and kept up in the same style as they are with us, the genus *bos*, under some name or other, is the animal for the plough, the team, and the load; nor are there wanting some places where the same animal is used for the saddle.

Thus, in whatsoever point of view we consider this genus, we find it interesting in the highest degree—so much so, that its history and the history of civilisation are so blended together, that we cannot study the one properly, without studying the other along with it. The same causes tend, however, to that difficulty of separating the species in a satisfactory manner, which has been noticed; and thus render the details of the history as unsatisfactory as the general view of it is interesting. We treated of the true bisons in a separate article; however, it does not appear that they have had much (if any) influence in civilisation. Their history in the eastern hemisphere is too distant and dark for leading to any thing satisfactory; and though the American bisons were exceedingly numerous on the first discovery of that animal, and are still so in some parts of that country, it does not appear that they ever led the natives to settlement and culture, or were received by them in any other light than that of prey for the hunter. There are more species of the eastern continent, principally, if not exclusively, of the central and southern parts of Asia, in the eastern division of that quarter, which are frequently classed with the bisons, from some of their external characters (chiefly); but these have not the locality or the appearance of the true bisons; and most, if not all of them, have been in part at least, domesticated. These we shall, in the very short notices which we are about to give, include in the same section with the domestic ox, but without asserting that such an arrangement is right, or admitting that it is wrong;—for as we have endeavoured to show, there is not much science in the subdivision of the genus.

THE COMMON OX, WILD BULL, or URUS (*Bos taurus*, *Bos urus*, of authors). Whether the native stock of the domestic varieties still exists, or whether (as is more likely) these have accompanied civilisation from the East, is a point which cannot be ascertained with any degree of satisfaction, as they contain enough of resemblance, and also of difference, to make the conclusion plausible either way. This species belongs to the living world, only as a very doubtful, and certainly a contaminated remnant, as in the countries where it is said to be found, the domestic breeds were introduced before they were fenced in by enclosures, or any attention paid to the difference of breeds and their characters. We trust however to be able, in the course of our observations, to show that the only variety of *Urus* of which there are specimens existing in an apparently wild state, is in truth nothing more than a small portion of a living and well-known domestic variety, which has been allowed to run wild under peculiar circumstances. Cuvier, with his usual sagacity, says nothing about this original race, in the *Regne Animal*; but as we have the popular writers against us, *totum armentum*, we must proceed cautiously, and guard our steps.

The characters usually given of this species are; the forehead, or front, square and flat, or even a little hollowed in the centre, instead of being arched, as in the bisons; the occiput also flattened, and the union of these two parts forming a ridge at the top of the front; the horns, originating from the lateral angles of this ridge, are round in their section, and they curve outwards, upwards, and forwards; the ridge at the upper part of the front (in the male), thickly set with curly hair, but without any very distinct mane along the ridge of the neck, or beard on the chin and throat; no bump over the interscapular part of the spine, but a dewlap pendent between the fore legs, which becomes enlarged and of firmer texture in the autumn, when the animals are left exposed to the weather; only thirteen pairs of ribs; the tail rather long, furnished with a brush at the point, and the basal part for some length seated in a groove; female with four inguinal teats, arranged in a square upon the udder, which is more enlarged than in most of the other species. The period of gestation (in the domestic species) is nine months; and the female arrives at fertility in a year and a half, and the male in two years. These are also the characters of the domesticated race, in so far as animals which are so much broken into varieties can have general characters.

Of the wild ones there are, or rather there are said to have been, two varieties, if not three. One of larger dimensions is found only in a fossil state, though if we can credit the accounts of the ancients, it appears to have been in existence about the time when the people of the then civilised world began to invade the forests of central Europe. It appears from the localities in which its remains are found, to have been the immediate neighbour of the bison, and it is possible that the one may have been confounded with the other.

There are black *uri* with white chins, and without the shaggy appendages of the bisons, mentioned at a later period of European history; and these are said to have been smaller than the fossil *uri*, and with the horns differently formed. But no very great stress can be laid upon such accounts. The antiquities of natural history are the most vague of all antiquities, though the whole is sufficiently tinged with that character. Somewhere not very far from the place where the remaining bisons are still said to be found, is the locality assigned for these black wild cattle. But we ought to bear in mind, how man had chased man, and civilisation dawned and set in these places, or their near vicinity, between the time when the Romans first established themselves on the Danube, and that at which these wild cattle are said to have been seen. Further, we should bear in mind, that many (indeed most) of the adventurers by whom these creatures were invaded, were from the East, where they had lived wandering or nomadic lives, and subsisted in great part upon these cattle. From these circumstances, it is at least as likely that these had been the descendants of herds now domesticated, as that they were a native race in these localities. Even now, if by any combination of circumstances, the histories of the colonisations of South America and Australia could be as completely lost, as many centuries of that of much of Europe is, future naturalists would be very apt to describe cattle as natives of these countries, and especially of South America, where the unhunted ones have become so numerous, as to reach, or even exceed in abundance, the native bisons of the north of the same continent.

The species of which there are the most recent alleged accounts as being in the wild state, is the *white Urus*, or wild bull (*Urus Scoticus*); and even its history is abundantly vague. Report says that, at one period of British history, and that not a very remote one, these animals ranged at large in the natural forests of the north of England and the south of Scotland, though less is said of their appearance in the opposite end, or even in the centre of either country, where both climate and pasturage were at least as favourable for them. That there have been a few of them at scattered points since people began to observe, or at any rate to record their observations on natural history, cannot be doubted. But these remains of a supposed ancient race are found only in the parks of a few of the great proprietors, which are generally artificially formed and planted; and none are said to have been observed even in the wildest woods, which, in a state of nature, even where these consist of deciduous copse-wood, and abound in grass of the most kindly description, forming the least "inviting" for the proprietary cattle, which are most nearly in a state of nature. Now that any part of the genus *bos*, which in all its species, and in all other parts of the world, keeps aloof from the haunts of man, and fades before the progress of civilisation, if not domesticated and thus made part of the system, should be so wholly changed in one small locality, or rather in a few detached spots of that locality, as to have got into inclosed plantations, and to remain and breed there, and there only, while it has, from time immemorial, vanished from places more in accordance with the usual habits of the genus, is such an anomaly that it cannot be received upon the testimony of any tradition.

We do not, however, question the fact of its having been lately, or being still at the places in question; but the doubtful point, and one to establish the affirmative of which there is no satisfactory evidence, is that it is native in those places. Analogy is against such a position: it is well known that deer in a native state were, up to a comparatively recent period, numerous in many of the wild woods of the island; that they are now thinned; that the artificial parks which contain deer, and even the hill forests, such as that of the Duke of Atholl, between Blair and Badenoch, have been stocked by artificial means; and that the remains of the red deer have taken up their final abode in the very wildest part of the island, the north-western part of Invernesshire, where, from rough mountain and interspersed marsh, the surface is peculiarly uninteresting to human travellers. These are as much natural fastnesses, though of a different character, as those in which the remainder of the bisons have taken up their final abode in central Europe. It is, therefore, unreasonable to conclude from analogy that, if there had been any actual remains of a wild breed of cattle in Britain, they would have been found in the wild plains, and not as ornamental stock in the parks of the great. There must therefore be "some mistake," about the white cattle, and the sooner that it can be removed the better.

That the colour of these animals is nearly entire (it is not wholly so, as they all have the muzzle and the tips of the horns black, and those at Burton Constable have the tips of the ears and tail black also,) is not a proof that they are an original race, which has never been broken into varieties by domestication; for when domesticated cattle, with broken colours, continue for some generations exposed to the weather all the year round, they return to an entire colour, varying in a number of shades from black to dun; and hence the cattle which are bred in the Scotch highlands, have the colour generally unbroken, and black is so much the prevailing shade, that they are known to dealers by the general name of "black cattle."

Before, therefore, we can rationally conclude that the white cattle are a native race that has never been domesticated, and not a domesticated race which has run wild, we must examine what there has been in the progressive history of the places in which they are found, that may bear on the one conclusion or the other. For as this genus of animals has had a powerful influence upon the progress of human society; and as all natural action is in so far reciprocal and mutual, we may very naturally suppose that the state of human society, and the change which that has produced upon the country, must have had a considerable influence upon the character of the animals.

Now both England and Scotland, for some distance from the border, have been for a long period previous to the union, in a very different state from the more remote parts of the countries, and even from a portion upon the confines. The two nations were very often at open war with each other, and they were never cordial friends; and the inhabitants of the border, who consisted of a considerable number of expelled men from each country, were the friends of neither, and the pretended partisans of the one or the other, according as they found it more suited to their own predatory habits. Their "forays," or inroads, were carried on chiefly for the purposes of plunder; and as the portion of Scotland near the border was a poor country, and the court, and army such as it was, were too near for rendering frequent forays into the Lothians safe, unless for larger bodies of men than the border robbers could muster, for people of that description never can combine to any great extent, the depredations were most generally carried on in England; and in that country there necessarily was a considerable space within the border, where men cultivating the arts of peace could not dwell in safety. The better part of this would naturally get overrun with wood or with coppice; and the same would also be the case with a part of Scotland, though to a less extent. Cattle formed the principal booty in these predatory incursions; these cattle had to be driven through the pathless and uninhabited parts of the country; and as the marauders had often to make hasty retreats, and not unfrequently abandon their plunder and defend themselves, it is natural to suppose that the cattle might not unfrequently escape into the wilds; and many of them might remain and breed there till they returned to the entire colour from constant exposure to the weather. This seems the most rational mode of accounting for the existence of the wild cattle in these localities; at least this hypothesis would require to be encountered by very forcible argument before that of an aboriginal breed, in favour of which there is neither proof nor probability, could claim that implicit credence which it has pretty generally received from those who have written on the subject.

We may farther remark that the usual accounts of these animals do not assert that they are aboriginal in the artificial parks; but that they were obtained much in the same way, as no inconsiderable portions of the estates of those who became their owners, that is, they were gotten from the religious houses when those were broken up at the Reformation. This part of the history, if authentic, and there is much more probability on its side than against it, is decisive of the whole case of those white oxen; and not only so, for it renders the whole hypothesis of the *species* (and it is only a hypothesis, not only doubtful, but evidently fabulous). The monks and others, connected with the religious establishments, brought fruits and flowers from Italy for the ornamenting of their gardens; and it is natural to suppose, nay it is impossible not to suppose, that they brought cattle from the same country to stock their parks and dairies; and that such has been the fact, and the origin of those cattle, is placed beyond all doubt, by the cattle of the finer parts of Italy, especially those of the valley of Arno, being white from the time of the ancient Romans, and remaining so at the present time. They are an excellent breed, and highly prized in the West India islands, to which numbers of them were once sent, if there are not so still. It is probable that all those breeds of cattle which have much white in them have been obtained by crosses with those Italian cattle obtained in the manner above stated; and this is rendered more probable by their being more delicate than those of a darker tint. This origin of the white cattle, does not in the least invalidate the ground of their being sometimes found in the woods, or even remaining there as strays from the marauders; for the religious houses were always favourite objects of attack.

The annexed figure, which represents an adult male, after he has attained that age at which the hair on the ridge of the neck becomes prominent and shaggy, will give some notion of the form and bearing of these animals.

Wild Bull.

These animals are of much smaller size than what may be considered their parent stock in the plains of Tuscany; but this, as well as their greater energy of character, can be very readily accounted for from their being exposed to the air all the year round in a severer climate. Breeding "in and in" in an upland district where the woods were thin and the pasture bare would, in no very long time, reduce the largest breed of cattle to the average stature of the natives, if they could be kept alive and in health till the change were brought about; and it is well known that with equal feeding, small and exposed cattle are the most active and pugnacious.

If the remarks which we have made on this supposed original variety of the domestic ox are true, and we trust we have carried along with us the reader's conviction that they are, the peculiar manners of the white cattle in those parts of Britain where they are found become of no more value there but as they show the change which one variety of the species which has been long domesticated in a climate remarkable for its mildness undergoes, when it is allowed to run wild in one which is less favourable; and really, all that we can discover is so like what takes place with cattle of any other colour, black, brindled, brown, or dun, that it is not worth mentioning. The animal gets smaller, more shaggy in the hair, and a little wilder in disposition; there the whole matter ends; and as the same thing happens not to all the varieties of the common ox, but to the genus and (in a greater or less degree, according to their susceptibilities to climate,) to all animals, it teaches nothing.

This however is not all, for the existence of any such animal as the *urus*, whether white or black, within the period of authenticated history—that is, as *a living animal* within that period—becomes exceedingly problematical; because, as we have already shown, the black *urus*, which is described as having been seen (or heard of) in south-western Russia some time by gone, if it had any real existence there at all, is much more likely to have been a remnant of domestic nature turned over to the wild state in the course of human revolutions, than a fragment of wild nature which had survived there. As for the urus of earlier wastes, again, if we are to suppose it any thing else than the ox become shaggy and violent in an inhospitable climate, the most probable conjecture is that it had been the bison—the *aurach, uarach*—the rough or shaggy animal.

Thus in our attempts to trace the genealogy of the domestic ox, even in those varieties with which we are most familiar, to any wild animal in a state of wild nature, we are forced from the living world to the grand charnel-house, the earth; for we might as well attempt to trace the human inhabitants of any particular part of the world, up to the present time, without the assistance of any historic record, as to trace to wild nature, an animal of which we know nothing save in a state of domestication. In such an inquiry, even unlettered man can give us no clue to his history. Ask the native of Australia whence came his ancestors, and how men who now know, of their own invention, no other means of navigating the waters than astride a log of timber, how their fathers contrived to stem the dangerous tide of Torres' Strait, to say nothing of the Indian Ocean or the Pacific, and you will find that his knowledge of the matter does not reach the time of his grandfather. Neither will the external appearance, the manners, nor even the language of those very rude tribes help us out; for where thought and knowledge are limited to that which is personally observed, there are as many languages as there are families. Now, if this be the case with man before the dawn of science—who is, notwithstanding, still man, and shows no lack of capacity where he is placed under favourable circumstances, we cannot presume that it will be better in the case of animals, which cannot, under any circumstances, be so educated, even to the smallest extent, and of which the one generation cannot leave a single iota of instruction to that which is to come after.

As to the bones again, they are even more silent in all manner of instruction; and how the races which were lost before the record of history began, may have differed in habit from those which they resemble in skeleton, or how the earth which is now their pasture, may have differed from what it has been at any known time, we are, and we must remain, completely in the dark. Therefore, though the history of the domestic ox is, of all animal histories, the one most desirable to be known, it is one of the most difficult upon which to obtain any satisfactory information. But it is fortunate that the difficulties with which the progressive history is thus beset, do not in the least stand in the way of our reaping the full economical benefit of the animal. Indeed it is the early domestication of the ox, and that plasticity to climate and culture, that render him so valuable to man, which are the chief, if not the sole cause of the difficulty. We shall now notice some of the most remarkable of the Asiatic species or varieties; but to enumerate all, or even a slight approximation to all, would be a very long, and not a very profitable task.

The general shape of the Brahminy bull, which is the sacred bull in most parts of India, and especially in the valley of the Ganges, may be understood from the figure. In Benares, and those other cities which are crowded with the more wealthy and devout Hindoos of high caste, these animals are exceedingly numerous, thronging the streets, and the courts, and areas of the temples. They are fed to the utmost profusion, and they are very fat, indolent, and inoffensive. When left without these attentions they are smaller and much more active, but they have been so long domesticated, or rather under the protection of the people, that there are many varieties

Indian Bull.

in appearance. When they are fat, the hump on the shoulders and the dewlap are very much produced, and in all conditions they have the skin of the neck furrowed with transverse wrinkles. Their general colour is dun, passing into blackish on the upper part, and whitish on the under. There are many varieties of these hunch-backed ones in India, but it is not easy to say which is the original race, or whether those which are found wild be in a state of nature, or have been left in the changes of society which the country has undergone. These humped oxen have the voice less deep than the others, and the form of the hind quarters and the insertion of the tail are different from the European varieties.

The Gayal (*Bos gavæus*) has sometimes been considered as a bison; but it has few or none of the characters of the true bisons. These are light and agile animals for their size, and have great part of their power thrown into the neck. The gayal, on the other hand, is a heavy and clumsy animal; and the neck, especially the part of it next the head, is small an feeble. The only character which it has in common with the bisons, other than those which belong to the whole genus *bos*, is that of fourteen pairs of ribs; and, although our domestic oxen, and the varieties of other countries which most resemble them, have only thirteen pairs, yet fourteen is not a constant, and therefore cannot be regarded as properly a typical character of the bisons. The Eastern one has fourteen, but the American has fifteen.

The full grown male of the gayal is nine feet and a half long, and exactly half as much in height. The body is rounded and rather clumsy in appearance; and both the middle of the back and the setting of the neck are depressed, which gives a hump-like appearance to the interscapular portion of the ridge; but there is no true hump; yet, in consequence of this ridgy appearance, the animal stands four or five inches higher on the fore-legs than at the crupper, and the hinder part of that curves downward to the tail, which is slender and not very long. The front is square, broad and flat, the insertions of the horns being ten inches apart. The horns curve slightly outward and upward, while the ears, which are nearly of the same length as the horns, and slender in proportion to their length, droop down till their direction is nearly the reverse of that of the horns. The eyes are rather small in proportion to the size of the animal. Both sexes have a small tuft of white curled hair between the bases of the horns, which curls down upon the forehead. The dewlap is large and pendulous, and makes the portion of the neck next the head appear more feeble than it really is; it also gives an apparent depth to the chest, out of all proportion to its width. The abdomen is large, but contracts toward the groin, as if the body were slightly compressed by a girdle there. The udder of the female is small. The legs are thick and stout; the principal hoofs broad, and the false ones much larger in proportion than those of the domestic ox. The hair is very short, with the exception of that on the forehead, already mentioned, and a small bunch on the end of the tail. The colour is brown in various shades. The characters and also the habits of this animal resemble the ox more than they do the buffalo; but it breeds indiscriminately with either.

It is chiefly found upon the south-western and southern slopes of the secondary hills to the Himalaya, and on those to the south of the Burhampûtra. When in the wild state it is rather a woodland or jungle animal; but it is domesticated in large herds by the people to the eastward of India. It does not extend into the dry districts.

The Yak (*Bos grunniens* of Pallas) is not very accurately named by that naturalist, as its voice is a sort of subdued and broken low rather than a grunt. This is the mountaineer of central Asia, being found in the Himalaya and Altai ridges, and in the connecting ones, and their spurs eastward as far as China. It has been classed with the bisons, and in the northern extreme of its geographical range, it is understood to trench closely upon the habitat of the eastern one; but it is an animal domesticated to a very considerable extent; and its characters are more peculiar than those of many others of the genus. It has the same number of ribs as the bisons, and the forehead is a very little arched; but the resemblance between them extends little farther.

In the more elevated portions, it is rather a small animal, not above three feet and a half in height at the shoulder, and seven feet in length; but in its more fertile pastures it attains a larger size. In the form of its head there is a slight resemblance to the buffaloes; but the character of the horns is more that of the ox. They are lateral in their insertion, and do not advance toward each other on the frontal ridge as in these animals. One of the most peculiar parts of it is the tail, which is covered all over with long hair like that of the horse, only the texture of the hair is much finer. Their tails are in much request both in India and the Turkish Empire. In the former they are used for fanning off the flies, and among the Turks they are used as insignia of rank. They take a fine dye, the stumps are often richly and beautifully ornamented, and they have a very flowing and graceful appearance. When a bashaw of so many tails is mentioned, it means the number of the tails of the yak which he is allowed to have carried when he rides in state.

As has been already hinted, the varieties of the genus bos are exceedingly numerous, and they range over a very great extent of country both in latitude and in longitude. For the reasons which have been already stated, there is no possibility of exploring their progressive history and progressive geographical distribution in any thing like a satisfactory manner. But, so far as we can judge, mankind do not appear to have made any even very moderate advance in civilisation without pressing one variety or other of the genus into their service; and, therefore, we may expect to find traces of them wherever improvement has at any time been, whatever may be the condition of the place and the people now. If we are to take their central locality, or what we may designate their original head-quarters, somewhere about the north or north-west of India, where also there are more of the cultivated plants which are common to all civilised nations found in the wild state than perhaps at any other spot on the earth's surface, we should say that they have extended northward both in Asia and in Europe to the confines of the polar regions—to those places which once were perhaps the favourite abodes of the larger bisons, and of the northern elephant of a still earlier time. They have extended westward to the Atlantic both in Europe and in Northern Africa; and they have been carried by later adventurers across that ocean, till they have stocked both the northern and the southern part of that continent with more valuable animals certainly than any which it contained when the knowledge of it was first added to eastern geography. They have extended southward into Central Africa; and in Asia they have reached the larger islands which lie most contiguous to the shores of its middle and its eastern peninsula. But it is doubtful whether they reached those places during the time that they were wholly in the possession of that dark race who are called the "Oceanic Negroes;" and even the Malays do not appear to have carried them on their distant voyages; for there is no trace of them in the remoter isles of the Great South Sea; neither were they known in Australia, till it became an object of European settlement.

In the present state of the world there is not perhaps any one of the species or varieties, which are more properly designated oxen, to be found wholly in a state of nature, and not to some extent or in some way under the dominion of man. In proportion as those which more clearly appear to be of the same stock, whether that stock is to be considered as the production of natural circumstances wholly, or more or less modified by culture, have been the more readily spread over different climates, and among people of different habits, they are found to differ the most in the individuals, both in colour and in all their other external appearances; and in proportion as any one species or variety is more confined in its locality, or has the locality over which it ranges more uniform, whether in its own physical circumstances, or in the habits and degree of civilisation of its people, we uniformly find that all the individuals are the more constant to one general type. But their characteristic history is as extensive as their uses to man are valuable, so that we must leave them, with whatever reluctance, and briefly notice the section which contains the buffaloes properly so called.

The Buffalo section. The animals which form this section, though they have the general characters of the genus bos, have a considerable number of points of distinction; and they belong to a different geographical position. They are animals of the eastern continent only, and though, in what may be considered as the central zone of the genus, they are found both wild and domesticated, yet they do not reach the northern part, and in Africa they are found farther to the south than any of the others; and there are native species in those countries toward the farther extremity of that continent which the ox had never reached till carried there by European settlers. The three sections may thus be considered as, in their native distribution, lying in parallel belts along a zone stretching from north-east to south-west, the bison and the domestic ox being on the north side of the desert, and the buffalo on the south, though the localities of the ox and the buffalo mingle with each other on the banks of the great rivers by which the continuity of the desert is broken, as the Ganges, the Indus, the Euphrates and Tigris, and the Nile.

Domestication has, however, carried the ox into every place where the buffalo is to be met with, and even beyond it to the south in some places; and though the domesticated buffalo has been in fact carried into places which may more properly be considered as the localities of the ox, yet the interference in this way has not been nearly so great as in the other. This is easily accounted for, both from the haunts of the buffalo in a state of nature and from its disposition and habits, which render it far less fit for domestication than the ox. There is a slight approximation to the buffalo, both in haunt and in appearance, in some of those species or varieties which are oxen in their principal characters, and those are the varieties of ox found nearest the localities of the buffalo. The gayal, for instance, has a heavy and buffalo-like appearance, though it is not so expressive of strength as the latter animal. Now we mentioned that the favourite country of the gayal is the lower slopes of the Himalaya, toward the Indian side, and especially in the lower parts of the valley of the Ganges, in which places there is a most abundant vegetation, as the mountains pour forth innumerable springs which irrigate those places and keep them in a state of vigorous vegetation, at those times when the level plains in the same latitude are completely burnt up.

The gayals come to the border of the marsh in these places; the buffaloes enter it, and feed upon a much more rank and coarse herbage than any others of the genus bos. They eat the luxuriant but rough grasses with which the permanently humid spots in such a climate are always covered; and they seldom quit these naturally, even for those pastures which, during the rains, afford much more succulent food for grazing animals.

Though different in all essential respects as animals, the buffaloes and the elephants are neighbours, and often co-dwellers on the same grounds; and this holds in Southern Africa as well as in the lower valley of the Ganges, and along the banks of the other rivers to the east which discharge their waters into it, or into the Bay of Bengal. All animals are in part modified by the physical circumstances of the places where they reside; and however they may differ in genus, or any other division into which animals can be formed, if they feed on the same pastures, they acquire a sort of community of manners which mark them as the animals of that peculiar place rather than of any other.

This is so very general, especially in the mammalia, which, being more the tenants of the earth's surface than animals of any other class, are necessarily more influenced by the physical circumstances of that surface and of the air over it. So general is this character from locality, that it is found not only in wild animals, but in domestic ones, and even in man; and so powerful is the operation of those physical circumstances, that their effect is fully as conspicuously seen in the animals, as the circumstances which produce it are in general observation. Our observation of the productions of nature must always be comparatively imperfect, therefore, if we do not take this effect of locality along with us. Nor does it at all require great differences of latitude, or of climate as dependent upon latitude; for all circumstances which alter in any way the characters of a place, alter to the same extent all that are produced in that place, or that inhabit it; and in the case of the animals, those which are the most plastic to climate, and therefore the best for domestication, show it most conspicuously. Intercourse tends to lessen it, and those who are much in the habit of travelling, and who travel for business or for pleasure rather than for observation, are apt to become insensible to it, unless in cases which are very striking; but it is a power which should be carefully kept alive as the very foundation of knowledge, that is, of the intelligence which is the parent of knowledge, inasmuch as the whole of human knowledge, be it what it may, is either directly or it may ultimately be traced to a knowledge of differences. The chief difference between an intelligent man and a dull one is, that the former can see small differences and the latter cannot.

England is not the best country for seeing those characters produced by locality, because in England both man and animals shift about, and even the seeds and germs of cultivated plants are yearly changed from district to district, all of which changes tend greatly to the advantage of the country. But even in England there may be a difference traced between the inhabitants of any two valleys, and if those valleys open to different aspects or different seas the difference will always be more conspicuous; and if it be found more so in one, it will be found more so in all, whether natural or cultivated, if the latter have remained long enough to be affected by the local influence.

The buffalo and all the animals which inhabit the marshy or permanently humid places on the lower rivers of India, afford a remarkable instance of this; and the influence extends to the neighbouring plain. No matter for the class to which the animal belongs, for the locality is stamped upon its appearance; and to those who are well acquainted with the differences which known places produce, the animal of itself tells at once whence it comes. Even the cattle, as they approach these humid jungles, have the skin much exposed to the action of the air, and formed into folds in those places which are subject to much motion. The shape too has fewer angularities than in the inhabitants of dry upland pastures (this particular is remarkable in the human race). The whole body becomes heavier, more expressive of strength, but less of activity; the legs become stouter, and the feet broader. Thus from the bullock on the plains of India, we may trace a gradation through the gayal and the buffalo to the rhinoceros and the elephant. And it is worthy of remark, that the horns or armature of the head of the rhinoceros, though it is produced upon a different part, and has no core of bone, is formed of horn produced by the epidermis, and resembling, in the matter of which it is composed, the horns of the ox tribe. We could, therefore, easily fancy the rhinoceros to be a link connecting the herbaceous elephant with the herbaceous buffalo; and as being the last of the horned animals in coming down from the polar regions to the equatorial, just as the rein-deer of the eastern continent is the first.

There is one curious gradation in those horned animals, taking them from the rein-deer to the rhinoceros, which, properly worked out, might throw much light upon the relation between animal and climate; and thus be of great use not only in speculative natural history, but in the rearing of animals, and the increasing of their value in an economical point of view, without which natural history, pleasant though it be, is but a barren subject. And here we cannot help remarking that, however tedious the tracing of these general analogies may feel to those who look merely for the surface anecdote of natural history, and are incapable (of course because they are triflers in all matters) of entering into the spirit of them, yet it is because those analogies have not been attended to that natural history has failed in producing those practical results—those extensions of the dominion of man over the animals—those additions to the most productive power of wealth and comfort in all countries, which we have so much right to expect from it. We are aware that in this matter the prejudice both of the unlettered and the lettered vulgar is against us; but truth and reason are on our side, and in their train the analogies of all the sciences, in which the generalising of the observed facts and the tracing of the relations have evolved the law, which law once discovered speeds onward, as the beams of the sun, illuminating and warming as it proceeds, and turning even the pestilent fogs and vapours of the night into the immediate means of fertility and of health. We call upon the reader who is not accustomed to view natural history in this light, to think of what has been done for and by the science of astronomy. Mankind were star-gazing long enough before they began to attend to the analogies, and by their assistance to arrive at the grand law of the celestial motions; and what did they make of it? Why ridiculous blunders and superstitious fears and mummeries; nor was it till the ardent mind of Kepler, bent upon tracing the analogies or, as it was then called, seeking "the harmonies of the spheres," got hold of the observations of Tycho, as the proper instruments of his labour, that the several branches of the grand law of planetary motion were so much as named. This, however, was *the step*, and thenceforth observation ceased to be desultory, and became useful. Newton followed, and completed what Kepler had begun; and now there is not a man in civilised society who does not owe much of his personal accommodation to that giant effort of mind, neither is there one useful machine upon earth, no, not even the body of an animal, which does not work according to, and to a considerable extent in consequence of, the law of the heavens.

But if this has been the result of the discovery of one law, the centre of whose action (the sun) is at the distance of a hundred millions of miles, and which at most is but a law of dead matter, what may we not expect when science shall once fairly grapple with natural history, and the law of life shall be as well understood as the law of gravitation? There is no mystery in the one any more than in the other, save the mystery of ignorance, and, only 300 years ago, that enveloped the laws of motion far more closely than it at present does the laws of life. Gravitation is not matter, but it is a universal phenomenon of matter, and life is not matter, but animal life is a universal phenomenon of living matter. The two, therefore, stand in the very same predicament; and we have no more reason to despair in the one case than we had in the other. But as in the one instance so in the other, mere observing will not do; we must study all the relations, and they are far more numerous than in the other instance. This is the age of observation in natural history; our vigilant students are Tycho: may we soon hope for a Kepler to quarry the block, and a Newton to work out the statue.

The analogy which we have to mention is but a slight one, and cannot conduce much to the grand purpose; but on a subject where mere appearance has been almost every thing, and relation almost nothing, or the counterfeit of it (made by the idle fancy of the dreamer) less than nothing, the very smallest hint ought not to be lost. Now, in all these horned animals, taking them from the elk to the rhinoceros, there is an increase of the production of horny substance and skin, and a decrease of that of bone in the horn, and hairy covering upon the skin, as we proceed from the pole to the equator. The horns of the rein-deer and the elk are not true horns, but consist wholly of bone. The bisons have small horns; they are larger in the ox, and largest in those varieties which inhabit nearest the equator, as in the oxen of Abyssinia; they are larger still in the buffaloes, and in some of the species they form a horny plate of great thickness along the whole frontal ridge; and in the rhinoceros, the armature of the head consists wholly of horn without any bony core. So also the elk and the rein-deer have the bony covering remarkably close, but the skin of rather loose texture, and deficient in gelatine. The bisons, though their coat is longer, have it not so close, and their skins are more compact; the ox has the coat still thinner, and the hide firmer; the buffalo, at least the Indian one (and the one of Southern Africa is in a colder latitude) has the hair so very thin that it does not cover the skin, while the skin is the thickest among all the ruminantia; and the hide of the rhinoceros is almost naked, and nearly impenetrable by common weapons.

All animals which have the skin thus naked and thick are fond of walking in the mud and being in the water, and they are but ill able to endure the cold. The buffalo retains the obedience to climate which is characteristic of the genus to a considerable extent; but still it cannot face extremes of cold nearly so well as extremes of heat, and it is very partial to wallowing in the mud and swimming in the water. Farther, though the buffalo is a ruminant animal, it partakes of the sullen character of the thick-skinned tenants of its native jungles. It cannot be attached to man as the ox can; and though its strength and power of enduring the heat render it valuable for some purposes, it cannot be made the same general servant to man as the ox. When they are roused by danger, either to themselves or their young, buffaloes are very resolute in their attacks, and their style of warfare combines that of the ox and the elephant. They butt with the forehead, the large ridgy shields of bone upon which render the blow of an animal of so much weight very serious; they also toss with the horns, and it is when they succeed in the toss that they resemble the elephant; they kneel upon the fallen enemy before it can recover itself, and by the weight of their bodies press it to death. But an enraged buffalo, like an enraged elephant, is not satisfied with the mere killing of that which it attacks; it will return again and again, and gore and trample the remains till they are separated bone from bone. They retain this propensity even in the domesticated state, and when they observe any of the more formidable carnivorous animals, they rush boldly to the attack, and in situations where the beast of prey has no time to crouch and make his spring, the buffalos usually master him. Thus, it is only when a buffalo can be approached skulkingly, and generally when he is apart from the herd, that even the lion or the tiger will venture to attack him. When once the spring is taken, and the beast of prey has got his hold, he can master the strongest single buffalo, because those predatory animals always spring to a place where the prey cannot injure them, and they convert the very strength of the prey into a means of its own destruction; but if the herd are near and excited, the dead buffalo would be no meal for the lion or the tiger; the rest would instinctively set on him and finish him, just as the one of a pair of ravens will go in and finish a hawk, if the hawk pounces on its mate. Indeed, it is only when strongly pressed by hunger, and under circumstances very favourable to its purpose, that either the tiger or the lion will attack the buffalo.

Under ordinary circumstances, the buffalo is a quiet, and, to a very considerable extent, a manageable animal; but its chief use is as a beast of draught or of burden, or for its skin when dead. The milk can be used, but the flesh of the buffalo is rank and coarse, and thus it has not the same general utility as the ox to recommend it.

There are two species of buffaloes, the Indian, and the Cape, or South African. The former has been domesticated, spread over various countries, and of course broken into varieties, which differ from each other in the forms of their horns, and in several other of their minor characters, though they do so to much less extent than oxen. These varieties have often been described as species, and they have been called by different names, and names which are given to them in those countries where they are all natives; but popular language is a very unsafe guide in these matters. If an observer from Hindûstan were to make the tour of the districts of this country, and notice the varieties of an animal—a horse or a pig, for instance, together with the local names, he might return with his portfolio full of species and specific names, and much more must an observer in India be exposed to this deception. That there are wild buffaloes in India is not meant to be denied, any more than that there are wild and domesticated animals of other kinds; but the species is most likely the same in the buffalo, just as it is in the gayal and others. This is rendered more probably by there being considerable differences among the wild ones, especially in size, in development of the horns, and in boldness of character. The larger and more formidable ones are met with in the richer jungles, which may be considered as the best pastures; and it is very natural to conclude, that, from the superiority of their feeding and their being obliged to shift for and defend themselves from very formidable enemies, they must be much more ferocious than those which are under the protection of men, and have their spirit broken by labour. The white cattle of Tuscany are a very mild race in their pastures on the Arno, but their manners are very different in those places of this country where the remnants are left in a wild state. These have no doubt degenerated in size as much as they have increased in spirit, while the wild buffaloes of India are superior to the tamed ones in both respects; but the reason of the difference as to the size obviously is, that in the one case, the running wild, and in the other, the being domesticated, have been attended by a change of locality, of food, or of both, unfavourable to the animals.

Some notion of the general form and appearance of the Indian buffalo may be obtained from the following figure.

Indian Buffalo.

The Arnee, the variety which is found in the humid and luxuriant jungles, to the eastward of the plain of the Ganges, and also in similar pastures in various parts of the eastern peninsula—which peninsula has the advantage of the humidity of two currents of the sea, and is much more fertile than India, the greater part of which is watered only periodically by the monsoons—is much larger than that to the westward of the Ganges, and it is different in colour, though in animals of this genus colour is not a specific difference, but a difference arising from external causes, and greater exposure and inferior pastures are apt to change the colours of the genus. The height of this variety is said to be sometimes seven feet at the shoulder, and the chest is remarkably square and broad, forming in this respect a striking contrast with the gayal, though the colour of that animal differs, and its size is larger in rich and shady places. The hair upon this animal is said to be rather long, partially shaggy, and of a black colour, but it is so thinly scattered, that the skin, which has the epidermis white, appears through it. The face is broad and square, and the breadth continues with little interruption to the muzzle. The horns are truly gigantic, at least six feet long each in the larger specimens. They are wrinkled, triangular in the section, and when the line of the face is perpendicular, they bend outwards, upwards, and slightly forwards, but bend backwards at the tips. These appear very formidable weapons, and they are so in reality to some extent, but certainly not so much so as they appear. They are not offensive weapons for daily use, but rather defensive ones; and those animals, as well as all the horned ones, attack only as the best means of defence. They have no prehensile or tearing organs, like the carnivorous animals, and therefore, unless they can destroy the enemy, or ward off his attack by means of the horns, they must be vanquished. The muzzle in the buffalo is said to be the place at which the more formidable beasts of prey spring, in the same manner as a dog attempts to lay hold of a bull, and thus the horns are so placed, that they act most powerfully in guarding the muzzle. But in the ordinary and peaceful habits of the animals, the horns answer some very important purposes. These animals feed in the close jungles, where eyes are of comparatively little use; and though the ears, which are long and funnel-shaped, may be of service in enabling them to avoid hostile animals, or find friendly ones, they can be of no use in guiding a grazing animal to its food. Hence, the sense upon which they have chiefly to depend for their subsistence, is the sense of smell; and as the scent of their food comes in the air, and is not on the surface of the ground, as is the case with that of carnivorous animals which follow their prey upon the scent, they require to carry the nose elevated while they are ranging the jungles. In doing this, the horns act as powerful auxiliaries, as their weight assists in balancing the weight of the head when the line of the face is carried in a horizontal position, or rather with the muzzle more elevated than the ridge of the forehead. This is the general position of the head while they are walking in all the varieties of the Indian buffalo, whether wild or in a state of domestication. When it is so carried, they have not, of course, a very full or ready use of their eyes, and so, when they are alarmed, and make a halt, in order to have ocular proof of what may be the matter, the elevating of their great horns, especially if there is a herd of them, and they are very frequently in small herds, has a very formidable appearance.

Their horns are of use to them in another way. They are much in the water, not only for pleasure, when they seek to cool themselves, or wash off the mud in which they have been wallowing, but also for what may be called "business," that is, in crossing the rivers, and in making use of them for transport from place to place. There are seasonal changes in the pastures of these animals, even where they are the most favourably situated. The rivers flood when the rains are on the mountains, and when it is dry there they run low. These periodical changes cause a sort of periodical migration of the buffaloes, and in their descents especially they have recourse to the water, and float down apparently at their ease, till they arrive at those places which suit their habits. The manner in which they carry their heads in swimming may be seen by observing those which are represented in the water in the back ground of the figure above given. This aquatic habit is of much value to them when the season requires that they should change their pasture, as neither the places which they frequent, nor their own heavy bodies and short thick legs, are well adapted for long journeys upon land.

The *Arnee*, as found in the less humid and productive parts of India, is said to be much shorter than in the eastern jungles, though it is most likely the same animal—at least there is not any difference between them that can be considered as absolutely specific. These wild buffaloes of the plains of the Ganges (for it is said to be in the country places near that river where the greater number of them are found) are represented as being nearly as heavy as those in the eastern jungles, though lower. They are said to be nearly of the same colour, only the hair is shorter, and the skin not so white. They are further represented as being much more gregarious, and as appearing in herds of several hundreds, both on these marshy pastures, and when they are floating in the river. That they should be more gregarious in proportion as their pastures are wider, and there is less cover for the few enemies which they have cause to dread, is readily to be supposed. One animal may make its way through the jungle, but the passage of a herd of animals as large as the buffaloes would be rather a difficult matter. We find that, in the case of the antelopes, those which live in the forests are far more solitary than those which frequent more open places, and they are also far more bold and resolute.

The history of the wild buffaloes of India, like that of the wild oxen, wild dogs, and many other wild animals of the same country, is far from satisfactory; and it is of such a nature that the most careful inquiry which can now be made can hardly be expected to clear it up; and we never can enter safely upon the history of any one of its races, unless we keep the cause of those difficulties constantly in our view. India is not only a land of very violent natural action, as is proved by the facts, that much of it is worn to the granite, that some of the rivers flow through deep channels, even in the solid rock, for hundreds of miles; and that the lower parts of the valleys of others continue, for hundreds of miles in length, deposits of matter, evidently brought there by the waters, extending to the depth of several hundred feet. It is no exaggeration to say that the Ganges alone has, in the course of time, and without any other action than the common one of the seasons, washed down more matter than there is in all the British islands above the level of the sea; and while the Ganges has been doing this, the other rivers and means of change have not been idle. Land and water must thus often not only have changed places with each other, but have alternated on the same place many times over, and soil, with its plants and its animals, must have again and again been formed and swept away. Thus we may see in India, upon a tolerably large scale, changes and revolutions in the earth, and its productions and inhabitants, similar to those which, in countries where the common action of the elements is far milder, we can imagine to have been brought about only by some grand convulsion of nature. For, in India, they appear to have taken place without the agency of either earthquake or volcano.

Nor, if we compare the feebleness of man's resistance with what can be done by natural causes in such a climate, situated between the gigantic Himalaya on the one hand, and the ocean which stretches uninterrupted from Cape Comorin to the Antarctic sea on the other, can we consider that the changes produced by human means have been less in proportion. For nearly three thousand years, according to tolerably well authenticated history, or for four thousand years, if we are to believe the really not improbable history of the war of Mahabharat, India has been a prey to the sword of every conqueror, so that there is perhaps not a spot within it, even that pestilent barrier at the foot of the Himalaya, which says imperatively to man, "thou shalt not dwell here," which has not felt fifty alternations of fertile fields and lonely villages, with houseless jungles, in which not one memorial of man or his works remained. Those alternations take place with wonderful rapidity in India; and in the memory of many now living, much of the country immediately to the south of the Nerbudda, has been thickly inhabited and well cultivated, tenantless, and overrun by the productions of wild nature, and thickly inhabited and well cultivated again. In such a country, it were vain to speak with too much obstinacy of original races of animals, more especially if at all analogous to those which man has at any time had in a state of domestication. Nor can we confidently assert that such an animal as the Arnee may not be the remnant of a race once domesticated which took shelter in the jungles, in the same manner as many of the peculiar tribes of men that are found in the fastnesses of those forests and mountains are understood to be. This is a very necessary caution in the natural history of India, and we have availed ourselves of what appears to us the fittest opportunity of putting those readers who are not conversant with such matters in possession of it.

The *domesticated buffalo* of India has been pretty generally distributed over the south-western part of Asia, Europe as far as the Alps, and Africa to the northward of the desert. It is a large animal of nearly the same character and size as the average of the wild varieties, being about six feet and a half high at the shoulders, and eight and a half in length, but the size varies with the climate and treatment. The horns are not so much developed as in the wild ones; they are less triangular in their section, being rather rounded on the posterior side, though they have the angular ridge in front. The skin in this variety is dark coloured, and the hair short, like that of the wild ones on the plains by the Ganges; but it is said that those which have been domesticated to the eastward of the mountains which separate India from the countries sloping toward the eastern sea more resemble the pale skinned ones of the eastern jungles. When we say that the skin is white or dark, it must be understood of the epidermis only; because the hair is of nearly the same colour in all, and therefore we must suppose that so also is the true colouring matter of the skin, which is generally understood to be lodged in the mucous tissue, between the epidermis and the true skin, which last is muscular, and contains vessels. All therefore that we can infer from the lighter epidermis of these animals in the thick jungle, and the darker one in the exposed plain, is that this particular portion of the covering is in them peculiarly susceptible to the action of the sun and atmosphere; that this pale colour takes place something in the same way as it does in vegetables when they are *etiolated*, or blanched; and the deep colour comes on in the exposure, just as vegetables become green in the leaves when they are exposed to a moderate degree of light and heat, and are apt to turn to a more intense tint, such as red or purple, when they are more exposed and not killed by the exposure. The same consideration would lead us to suppose that the general development of the animal is diminished by the same causes which darken the epidermis, as not only the horns which, as more immediately connected with that integument, and as we may say, growing out of it, are smaller in those varieties which are dark, but that the general dimensions are inferior. The fact that the horns of these animals are considerably more developed in the moist and sheltered situations than in the exposed ones, is of some value toward a right understanding of those large horns which are often dug up in the marshes and woods (or rather in those places which appear to have been once humid and marshy woods) in Britain, and in other countries;—as the fact that the shade and the exposure produce differences in one race, affords a rational presumption that they may do the same in another, especially where the races are so nearly allied to each other in a physiological point of view, as those unquestionably are which belong to the genus *bos*. This view of the subject is so very new that we will not venture a positive opinion upon it; but it is worthy of serious attention to those who never find a horn of more than ordinary size in a peat-bog, without at the same time discovering a remain of a race of animals which has become extinct. The deepening of the colour in the cattle of our own country in exposed situations, appears to be part of the same law; and that the white cattle which have retained their colour for nearly two centuries, in a climate so much more severe than their native one, may be in great part at least owing to their having enjoyed the shelter of the woods. The change of colour in domestic animals is an exceedingly curious subject; it is one the investigation of which would in all probability throw much light upon the general principles of natural action; and there are no animals which present so inviting a field for it as the genus bos. But, unfortunately, this is a subject to which so little attention has been paid, that those who may study it must begin at the very beginning.

The life of the common buffalo is understood to extend, under favourable circumstances, to about four-and-twenty years; and the female is said to become fertile at four, and even to be so at twelve, bearing only twice every three years during the interim. The period of gestation is not very well ascertained, and it may vary with climate; but it is reported to last about ten months. At all events buffaloes are not so prolific animals as common oxen, and this is another point of inferiority, in a state of domestication.

The Cape Buffalo (*Bos Caffer*). We have left ourselves but little space for the notice of this species; and much is not necessary, as we have already adverted to the principal general points, and endeavoured to show in what direction the general analogies lie. A figure of this species is shown in the next column.

This animal, as may be seen from the figure, has the most formidable front in the whole genus *bos*; and its general aspect is shaggy and formidable. We need not describe the form of the horns, as that is exceedingly well represented in the figure; but we may mention that they are the most compact, and in their substance the heaviest of all the horns of ruminating animals, excepting only some of those of the antelopes. This animal is considerably lower than the Indian buffalo; but it is firmer, though shorter in the legs, rounder in the body; and though the beard and short mane give it a rugged appearance, the greater part of the skin is nearly naked of hair, exceedingly tough and firm, and of a black colour.

This is by far the most formidable animal of the genus. It has never been tamed, and the males are dangerous to come near; and, as is the case with domestic bulls, they are found much more dangerous when they run bellowing by themselves than when they are with the herd. In the dry season they frequent the woods and copses by the banks of the streams; though when the rains have brought vegetation upon the surface, they often come to the *karoos*, or plains; and, in accordance with what has been said of ruminating animals generally, they associate in much greater numbers there than when they are in the woods. When they are thus in numbers on the open pastures, they are not, unless when physiologically affected in the season, so apt to do mischief as when they are met with in the woods. One might perhaps explain this difference by saying that, in the open plains they are much more secure from enemies, as not even the lion himself, formidable as he is in Southern Africa, will venture to attack them there. Ambuscades are what they have most danger from, and it is in the woods that they are in danger from these. But as they have a very acute sense of smell, they can generally keep out of the reach of the enemy; and unless he has the advantage of the spring and the stratagem, he seeks other prey. All the genus have a dislike to red colours; and in the Cape buffaloes, this dislike is peculiarly strong, and puts them into a state of excitement, in which they are probably among the most dangerous of animals.

Cape Buffalo.

No attempt has, so far as we are aware, been made to tame the Cape buffalo. If that could be accomplished, he would be a very powerful animal; and he is more swift-footed than most of the genus, though he does not take to his speed unless when excited to it by the violence of his passions. There must be a way of dealing with him so as to get the better of his violence, which, bold and daring as it is, is only an instinctive means of self-defence; but the experiment would, if practised upon the adult animal, be highly dangerous.

How far those animals may extend to the northward of the Cape is not known, neither are we in possession of data sufficient for settling whether they are or are not the same race as the buffaloes of

India. There is no obvious chain of connexion leading from the one to the other; and there is a very considerable difference in the nature of their haunts, as well as in their appearance and dispositions. The Cape buffalo does like the waters, but he can subsist in much more arid places than those of the East. No conclusion can, in the present state of our knowledge, be drawn from it; but it is not a little singular that the gnu of Southern Africa should hold among antelopes nearly the same place in respect of shagginess, production of horn, and violence of disposition, that the buffalo of the very same part of the world holds in the genus *bos*. It is probable that there may be varieties of this species, or even other species of buffaloes in the interior of Southern Africa; and some museum specimens, or at all events painted representations, have been mentioned; but these we are not warranted in admitting into the catalogue of real animals. This genus is, for obvious reasons, one of the most interesting about which the attention of mankind can be occupied, and the analogies of its history are peculiarly worthy of attention; but the very same causes which render the knowledge of it so very desirable, heighten the difficulty of obtaining that knowledge in a satisfactory manner. Some notice of the musk bull, which has been improperly considered as belonging to this genus, will be found in the article Ovibos.

BOSSIÆA (Ventenat). A genus of ornamental Botany Bay shrubs belonging to the natural order *Leguminosæ*. Generic character: calyx of two lips, the upper one broad, round, bifid. Pod on a footstalk, flatly compressed, the margins thickened; seeds like beads. Several of these plants are elegant, and well worthy a place in every green-house collection.

BOSTRICHIDÆ (Leach). A family of insects of the order *Coleoptera*, and section *Xylophaga*, or wood-eaters, of Latreille. In the recent works of the latter author, the family is considerably restricted; but in his early works it comprised the *Scolytidæ*, a group of very destructive insects. As the arrangements of Dr. Leach and Mr. Stephens are founded upon the latter method of distribution, being, in fact, an adaptation of the classification contained in the "Considerations génerales" of the French author, we shall tread in their steps, observing only that the *Scolytides* are intimately allied to the wood-boring weevils (*Cossonus*), and that the *Bostrichides* are apparently allied to the death watches (*Anobium*, &c.) The family then, in its extended sense, is characterised by an oblong and cylindric body, the tarsi are simple, or with the third joint bilobed, the antennæ never with more than ten distinct joints (often with fewer), terminated either by a large solid mass, formed by the union of several of the terminal joints soldered together, or by three large distinct joints; the first joint is generally long and bent; the palpi are often very short, and the tibiæ are flattened and toothed at the edges. The family is divisible into two sections, 1st, the *Scolytides*, and 2nd, the *Bostrichides*.

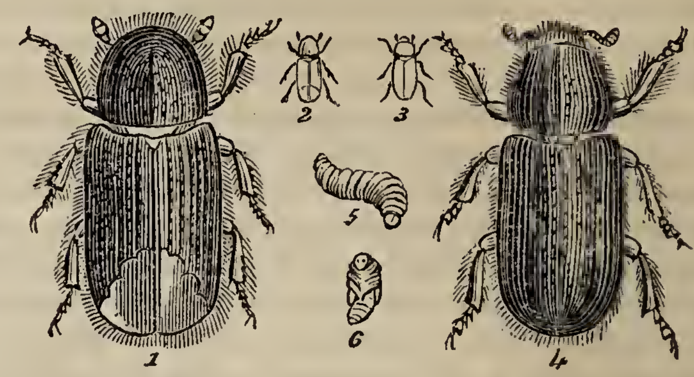
The *Scolytides* are distinguished by their antennæ terminating in a large compact oval club; the palpi are very minute, the body is convex and cylindric, and obliquely truncate at the extremity: the head is globose, with the front produced somewhat into the shape of a muzzle. This division comprises the genera *Hylurgus*, *Scolytus*, *Hylesinus*, *Tomicus*, and *Platypus*, all of which are British, and *Camptocerus*, which is an exotic genus. The ravages committed by these minute insects upon our standing timber trees is lamentable; indeed, it would probably be impossible to find any other objects of so small a size, capable of producing greater destruction. Probably there is no species of tree which is exempt from the attacks of some one or other particular species; moreover it does not unfrequently happen that several other species are found upon the same tree. It is to the ravages of one of these insects, that the elms, the pride of our metropolitan parks, have suffered so severely as to have caused a parliamentary inquiry upon the subject. This insect is the *Scolytus destructor*, distinguished generically by the compressed and rounded club of the antennæ, the truncate extremity of the body and the bifid penultimate joint of the tarsus; and specifically by its shining black colour, with the elytra reddish or pitchy, and the antennæ and tarsi of a pale reddish colour; the elytra are marked with longitudinal lines of raised dots. It is to be observed, that the destruction of the elms has not been attributed to these insects by several writers, who have considered them as consequent upon some previous indisposition in the tree, rather than as the actual cause of the injury. We must refer our readers to numerous papers relative to this part of the subject, contained in the early numbers of Mr. Loudon's Gardener's Magazine, observing only, that it is quite impossible to suppose that the facts subsequently to be noticed, can warrant any other conclusion, than that the insects must tend in a most material degree to the destruction of the trees, even if some already existing indisposition be admitted.

Who would believe, asks the German author Wilhelm, in his "Recreations of Natural History," that the little *Scolytus typographus* (another species nearly allied to the *Destructor*, but belonging to the genus *Tomicus*) is capable of totally destroying the finest fir trees, to which it restricts its attacks save in the last extremity? This insect has been long known in Germany, under the name of the black-worm. The great consistence of its envelope, enables it to withstand a degree of cold sufficient to kill millions of other insects. In the month of May, they make their way through the bark of the trees, beneath which they have passed the winter and acquired their full developement, and in certain favourable seasons they are so numerous, that in a warm evening when they take wing, they appear in swarms, and rise to a height in the air exceeding that of the trees; being carried away by the wind, and alighting at the distance of several miles from their native place. It is at the period of the emigration of these swarms, that the impregnation of the female takes place. On alighting, each couple goes in search of the rotten parts of trees newly felled, or, in default of these, they select perfectly sound and standing trees, in the crevices of the bark of which they commence gnawing a domicile, the situation of which is indicated not only by the powder which they produce, but by the noise which they make while at work. Latreille has observed on this part of Wilhelm's statement, that as the impregnation of the female has already taken place, it is probable that the male takes no share in the construction of a place for the deposition of the eggs. This indeed is a circumstance of such common occurrence amongst insects, although the reverse takes place in the majority of the higher animals, that the observations of Wilhelm have need of direct confirmation. At first a straight groove is perceived in the bark, on each side of which they burrow lateral channels, in which the female deposits sixty or eighty eggs ; each egg being placed separately in a small rounded cavity, which is then covered with saw-dust. After completing their labours, the parent-insects make their way again through the bark to the outside of the tree. At the end of fifteen days the larvæ are hatched, and immediately commence their work of destruction. They are small, soft, fleshy grubs, with short pointed legs, their body being divided into segments. Each of these grubs, starting from the place of its birth, constructs for itself a serpentine tubular gallery gnawed between the bark and the wood, and which, from the fanciful resemblance of these galleries to the letters of the alphabet, has given rise to the specific names of these insects, *typographus*, *micrographus*, *polygraphus*, &c.

Track of the Typographer Beetle.

These galleries never cross each other, but, by a remarkable instinct in the larva, run in diverging lines from the principal gallery, in which the eggs were deposited. Each gallery also increases in size, as it increases in distance from the centre, which is owing to the increased size of the grub. At the end of several weeks the larva attains its full growth, and changes into a pupa, in which state it is very tender and sensitive ; so that an unfavourable season destroys vast numbers in this state. And it is owing to the difference in the weather, that the duration of time passed in this state is increased or diminished. If the period of the full growth of the grub occur in summer, the insect passes through its various stages in the course of eight weeks ; but if the eggs are deposited in autumn, as many months are required for this purpose. Arrived at its perfect beetle state, it devours all the portion of the tree which remains between the wood and the outer bark, and finally escapes through the latter by boring a small circular orifice. If, therefore, a tree exhibits a number of these small holes, it is evident that the insects have escaped in their perfect state. Wilhelm states, that often times as many as 80,000 larvæ are engaged in the destruction of a single tree. The number seems immense, but when the minute size of the insects is considered (and they are much beneath a quarter of an inch in length), the statement may readily be credited. Another thing is equally surprising: even if the trees infested by these insects be cut down, floated in water, kept for a length of time immersed either in water or snow, or even placed upon ice, still the insects remain alive and unhurt.

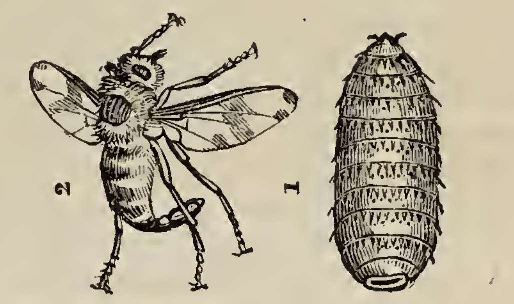
There are few of the large German forests which have not, at one period or another, suffered from the epidemic produced by the swarms of these insects, and which is there termed wurm-troekniss, and in the old liturgies these insects were mentioned under



their vulgar name of the turc. At the commencement of the eighteenth century, the Hartz forests were attacked, it reappeared in 1757, redoubled in fury in 1769, and increased until 1777 ; in the two following years it seemed to abate, but in the following year, after a hot summer, it increased to a most alarming extent ; the inhabitants were thereby menaced with entire ruin, by a total suspension of the working of the mines. The mischief arrived at its height in 1783, when it was calculated that on the Hartz alone, a million and a half of trees were destroyed by it. As the evil increased, the impossibility of applying remedies was augmented, since at this period the insects migrated in swarms, like bees, to Suabia and Franconia. A succession of cold seasons gave it a check ; but it re-appeared in 1790, and even in 1796 there was cause to fear for the few situations which had previously escaped. From these observations it was evident that the insects would not unwillingly attack sound and healthy trees, and Wilhelm observes, that the misplaced confidence which many persons entertained that the insects attack only trees already injured, and that their ravages are put an end to by the insects themselves, have cost many hundreds of trees. A small number of the bostrichi would not be sufficient to destroy a healthy tree, nor would they, except in favourable seasons, increase to an alarming extent; but it is always prudent, nay, absolutely necessary, to remove felled timber without delay, as the flowing sap is most attractive to insects. Carpenters also, for the like reason, should be prevented from erecting their sheds in or near forests. The trees once attacked, should be immediately cut down and barked, and the bark burned. Indeed, it is certain, that trees allowed to stand for a considerable time after they are dead, are neither fit for building, nor for fuel, nor for the manufacture of charcoal. The *Bostrichus ligniperda* instead of placing its eggs at each side of the principal gallery, deposits them all together, so that the larvæ work from a common centre, whence their burrows form a kind of star.

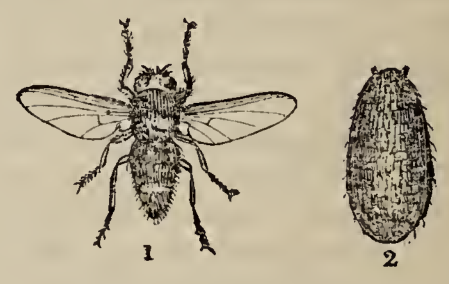
The second sub-family, *Bostrichides*, have the antennæ terminated by three large distinct joints, the palpi are of the ordinary shape, neither being minute nor conical. The tarsi have always the articulations entire ; here belong the genera *Sinoxylon*, *Apate*, *Bostrichus* and some others, to which Latreille adds the genus *Cis*, which Mr. Stephens places amongst the death-watches. The habits of these insects are somewhat similar to those of the other family, since they are constantly found under bark, in which they form cylindrical burrows, but they have never been observed to produce such mischief as the *Scolytides*.

BOT. The ordinary name by which the grubs or larvæ of certain species of dipterous insects, belonging to the family *Œstridæ*, or Breeze-flies, are known. The insects of this family are parasitic upon various quadrupeds, the larvæ residing and attaining their full growth within the bodies of these animals, inflicting great pain by their continued attacks ; and it is to be observed, that it is more especially those animals, which, from their domestication, have become of essential service to mankind that are infested, the cow, the sheep, and the horse, being in a more particular manner subject to these tormenting scourges, which change the little comfort which these useful slaves might enjoy during the summer months into perpetual torment. Considerable variation exists in the habits of the different species ; we shall therefore here restrict ourselves to those which attack the horse, and to which the term bot is generally confined, the larvæ of the species which prey upon the oxen and sheep being termed worbles, or wormalls. The history of these insects has been treated upon by several authors, Vallisnieri, Fischer, Reaumur, Linnæus, &c., but more especially by Mr. Bracy Clark, F.L.S., whose Memoir, contained in the third volume of the Linnæan Transactions (and which was subsequently published separately, with additions, under the title, "An Essay on the Bots of Horses and other Animals;" London, 1815, 4to.), has left little to be desired concerning the habits and economy of the different species. This gentleman (to whom the author of the present article is indebted for a series of specimens of these insects) was enabled, by tracing the flies through their various stages, to correct a curious error into which Linnæus had fallen respecting them. In the Systema Naturæ of the latter author, we find a species named *Œstrus Bovis*, but the description attached thereto is that of an insect which attacks the horses, whilst the habit of the species is given—" Habitat in ventriculo equorum, in boum dorso ;" (Vol. II., p. 969, edit. 12.) Thus it is evident that this distinguished author was entirely ignorant of the real *Œstrus Bovis*, and that the accounts which he had heard of that insect residing in the backs of oxen were considered by him to belong to the same species which he had also ascertained to reside in the stomachs of horses, "which," as Mr. Clark observes, "certainly never happens." If we, therefore, find such high authority as Linnæus stumbling over the habits and names of insects possessing such considerable claims to our interest, it is not perhaps to be wondered at, that the ignorant should equally fall into errors respecting them. Thus Blundeville, who wrote upon farriery in the reign of Queen Elizabeth, seems to have confused two different kinds of larvæ in his observation, "The second sort of worms have great heads and small long tails, like a needle, and be called *bots;* the third sort be short and thick, like the end of a man's little finger" (which we shall subsequently perceive must be our *bots*), "and be called *truncheons*." Dr. Johnson gives the ascarides as synonymous with bots ; whilst we find Shakspeare furnishing proof of the vulgar opinion current in his times, that these animals were produced from no other source than poorness of condition, an opinion resulting from the old and groundless doctrines of equivocal generation, which we have more than once alluded to. The ostler at Rochester, in King Henry the IVth, says, "Pease and beans are as dank here as a dog, and that is the next way to give poor jades the bots." That half-starved beasts must be more tormented by the half-starved bots in their stomachs endeavouring to obtain more food, is not improbable, and would render the poor jades still more jaded ; but that poverty, or bad food, would of itself produce these bots, is an assertion which we hope few at the present day would be credulous enough to believe ; since, although it is unquestionable that the generation of intestinal worms has always been a source of great difficulty, it is equally unquestionable that the bots arise from eggs deposited by a parent fly. Of these flies there are not fewer than five distinct species which are parasitic upon the horse. 1. *Gasterophilus Equi;* 2. *G. hæmorrhoidalis;* 3. *G. nasalis;* 4. *G. salutiferus;* and 5. *G. Clarkii.* These insects have much the appearance of drone flies ; they fly with great velocity, and make a considerable humming noise during flight. The instinct which they exhibit in selecting a proper place for their eggs is not exceeded in interest by any other insect. Of this, as exhibited by the *Gasterophilus equi*, the author of this article



Gasterophilus equi.

was a witness, in a meadow near Gloucester. We observed a large-sized fly hovering near a couple of horses, and having selected one of them, she approached it, still on the wing, her body being carried nearly upright in the air, with its extremity considerably elongated into a horny tube, which is extended nearly horizontally, and consequently nearly at right angles with the body. This fly chose the side and back part of the shoulder as her place of oviposition, but the inside of the knee and the extreme ends of the hairs of the mane are more generally selected, especially the former. Being anxious to capture this fly, we approached the horses, which had not exhibited the least signs of alarm ; but our approach disturbed them, and away they scampered. We, however, followed them, as they happened to take the direction in which we were going, and were not a little surprised to see that the parent fly, in her anxiety to place her eggs in a fitting station, had kept up with them, and which she continued to do for a considerable time, during which we drove these horses about the field. The mode in which the egg itself is deposited by the parent fly is thus described by Mr. Clark : "Suspending herself before the part where she designs to deposit her egg for a few seconds, she suddenly darts upon it, and leaves the egg adhering to the hair : she hardly appears to settle, but merely touches the hair, with the egg held out on the projected point of the abdomen ; the egg is made to adhere by means of a glutinous liquor secreted with it. She then leaves the horse at a small distance, and prepares a second egg, and, poising herself before the part, deposits it in the same way. The liquor dries, and the egg becomes firmly glued to the hair. This is repeated by various flies, till four or five hundred eggs are sometimes placed on one horse." Here two circumstances are observable; first, that, unlike the œstrus of the oxen, this fly instils no terror into the object of its attack; and, secondly, that as the grub when hatched, does not, like that of the ox, gnaw its way into the body of the animal, it is essential that the instinct of the parent fly should be exerted to the utmost, in the selection of those precise spots where its offspring will be secure of obtaining the means of conveyance into the stomach of the animal. Now the accomplishment of this exploit, for so we may well term it, presents an example of that reasoning faculty, as we may almost consider it, which certain animals amongst the lowest ranks of the creation exhibit in an extraordinary degree. That this is the case will at once be perceived, when it is stated that these eggs are placed only in those precise spots which the horse can lick with its tongue. After remaining in this situation for four or five days, the eggs are sufficiently ripe to bring forth the larvæ on the slightest application of warmth and moisture. "At this time," continues Mr. Clark, "if the tongue of the horse touches the egg, its operculum is thrown open, and a small active worm is produced, which readily adheres to the moist surface of the tongue, and is from thence conveyed with the food to the stomach. If the egg itself be taken up by accident, it may pass on to the intestinal canal before it hatches, in which case its existence to the full growth is more precarious, and certainly not so agreeable, as it is exposed to the bitterness of the bile. I have often with a pair of scissors clipped off some hairs with the eggs on them from the horse, and on placing them in the hand moistened with saliva, they have hatched in a few seconds. At other times, when not perfectly ripe, the larvæ would not appear, though held in the hand under the same circumstances for several hours, a sufficient proof that the eggs themselves are not conveyed to the stomach." We have seen that during the act of oviposition no alarm is created by the fly, nor is this the case subsequently, although the contrary is stated in "Insect Architecture," p. 409. Mr. Clark, indeed, expressly states that it is owing to the irritations of "*other flies*, such as conopes, tabani and muscæ, who, by settling on the skin, occasion a horse to lick himself on those parts, and thus receive the larvæ on the tongue and lips, and a horse that has had no ova deposited on him, may yet have the bots by performing the friendly office of licking another horse that has." As, however, Mr. Clark has stated, that the eggs, when ripe, often hatch of themselves, and that the larva without a nidus crawls about till it dies, we should be inclined to consider that somewhat of the irritation above alluded to may be occasioned by the motion of the grub amongst the hairs of the body. Of the great numbers of these insects which we have stated are deposited on the body of a single horse in the egg state, few arrive at the perfect state, being subject to numerous casualties, so that probably near a hundred are lost for one which becomes a fly; first there is the chance of these eggs being washed off by wet; others are hatched and not taken up by the mouth; others, when in the mouth, are crushed to death; some may pass into the intestines of the horse; and when full grown and fallen to the ground many may be trodden to death, fall into water, or be eaten by birds. If however they escape the dangers which threaten their early existence, they make their way to the stomach of the horse, where, in a degree of heat far greater than that of the hottest climate, 102° Fahr., they attach themselves in clusters, especially about the pylorus, varying in number from six to a hundred, fastening themselves by the small end of the body, with the assistance of two small hooks, which are not found in such species as reside beneath the skins of various animals. Here their food consists probably of the chyle; and Mr. Clark is of opinion that they are not so very injurious to the horses as is generally conceived. After arriving at their full growth, these larvæ detach themselves and are passed with the fæces, when falling to the ground they seek out a convenient spot where they are changed to pupæ, and in about six or seven weeks the fly appears, during the month of August. It is to be observed with respect to these insects, that Mr. Clark, who has given a very minute account of the larvæ, as well as of what he considered to be the pupæ of several of the species, was not acquainted with the real pupæ. It is true, that, previous to becoming flies, the insect appears of a very different form to that which it possessed in the larva state, but this change of form takes place in the covering of the larva, which becomes shorter and hardens, forming, in fact, a cocoon, in which the real pupa is enclosed, as is the case with many other flies belonging to the same order. The *Gasterophilus equi*, whose habits we have thus detailed, is one of the largest in the genus, being about two-thirds of an inch long; it is of a dirty yellowish colour, with the back of the thorax, and a line of spots on the abdomen (which is of a redder colour) black, the wings are white, with a band and two small apical spots of a dark brown colour. The other species in the genus whose habits has been noticed, *G. hæmorrhoidalis*, resembles the former in the form and habits of the larva; but the economy of the perfect insect as to the mode of oviposition is very different. Linnæus, on the authority of Reaumur (who derived his information from Dr. Gaspari), describes it as "*mirè per anum entrans*," a perfectly fabulous statement, which has nevertheless been repeated by many authors, and which seems to have originated from confusing this insect with the forest fly, *Hippobosca equina*, which sometimes gets beneath the tail of the horse. With respect to the mode of depositing its eggs, Mr. Clark observes, "the part chosen by this insect for this purpose is the lips of the horse, which is very distressing to the animal, from the excessive titillation it occasions, for he immediately after rubs his mouth against the ground, his fore legs, or sometimes against a tree. At the sight of this fly the horse appears much agitated, and moves his head backwards and forwards in the air, to baulk its touch



Gasterophilus hæmorrhoidalis.

and prevent its darting on the lips; but the fly watching for a favourable opportunity, continues to repeat the operation from time to time, till at length finding this mode of defence insufficient, the enraged animal endeavours to avoid it by galloping away to a distant part of the field. If it still continue to follow and tease him, his last resource is in the water, where the œstrus is never observed to follow him. At other times, this œstrus gets between the fore-legs of the horse whilst he is grazing, and thus makes its attack on the lower lip; the titillation occasions the horse to stamp violently with his fore-foot against the ground, and often strike with his foot as though aiming a blow at the fly. They also sometimes hide themselves in the grass, and as the horse stoops to graze they dart on the mouth or lips, and are always observed to poise themselves during a few seconds in the air, while the egg is preparing on the point of the abdomen."

The *Gasterophilus nasalis* of Linnæus (Œstrus) is described by Mr. Clark under the name of *Œstrus veterinus*.

BOTANY is that science which includes the study and investigation of the vegetable kingdom. To describe and enumerate plants, to give to them their proper names, to mark their habits, physical differences and qualities, to arrange them into divisions by their organic structures, into tribes by their most ostensible characters, into families by their affinities and essential synonyms, and each individual of the families by its specific distinctions, is the business of the practical botanist.

Systematic botany was first projected by Conrad Gesner above two centuries ago. In the course of time the science was gradually improved, particularly by Tournefort and his cotemporaries; but it was reserved for the celebrated Linnæus to concentrate and reduce all that had been written before his time into his ingenious though artificial sexual system. Before the appearance of this new system, that of Tournefort was chiefly received and studied, and, though imperfect in many particulars, it had many excellencies, especially in preserving several of the true natural orders entire. Linnæus himself it seems felt the propriety of such an arrangement of plants, and had before his death made some progress in sketching a natural classification, but did not live to render it in any way complete. The idea, however, was not lost, but was approved and strenuously embraced by the indefatigable Jussieu, who, seeing the defects of the sexual system and the superiority of that of Tournefort, set about re-arranging the latter, and has by dint of great labour and extensive botanical knowledge, laid the foundation of a system which, with subsequent corrections and amendments of other botanists, comes as near to perfection perhaps as such an attempt can possibly be; for nature, notwithstanding she presents some very striking features of similitude in vegetable forms and structure, yet in general the diversity of external figure and conformation is so great and unlimited that many of Jussieu's groups must necessarily be small, and the number of the groups greatly increased in order to embrace every plant, and yet not depart from the grand principle on which the natural system is founded.

In presenting to the reader a general view of this interesting portion of natural history, it will be necessary, before treating of systematic botany, to describe the physical members of plants, that is, those different parts or organs which compose the vegetable frame, their apparent uses or functions, the character of their various membranes, their duration, decay, and reproduction, together with the nature and motion of the sap. In the prosecution of this detail, we shall have occasion to notice every grade of vegetation hitherto described, so that the reader may have as comprehensive a view of the whole as can be exhibited within the prescribed limits of a cyclopædia.

Before proceeding with a description of the various members of a plant, it is in the first place necessary to convey some idea of the membranes of which they are composed.

Vegetable membrane. This is one of the results of Almighty creative power, which, by the concentration or union of pre-created elements, called into form every plant whose seed or power of extension is in itself. This membrane is composed of innumerable distinct vesicles, variously arranged with respect to each other; each having a thin pellucid elastic integument, originally uninflated and inconceivably minute, but capable of being distended to a limited size, but in a definite order incident to the plant to which they belong, and in any direction. Leaning closely on each other, the cells are pressed into the various figures of spheres, spheroids, elongated cubes or ovals, forming the specific organic structure. There are also intercellular spaces which serve for the conduction of fluids or depositories of the secretions of the plant. Of this membrane every part of the vegetable is formed; it being capable of extension into filaments and fibres, fig. 1; spread out into tissues,

Fig. 1.

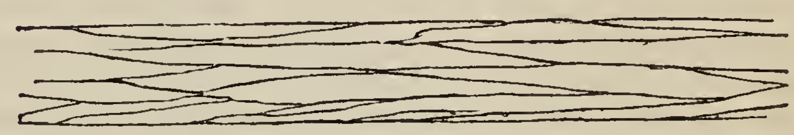


Fig. 2.

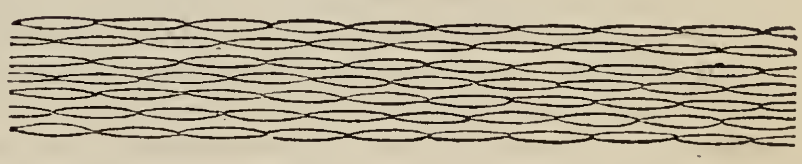
fig. 2; depressed into horizontal layers, fig. 3;

Fig. 3.



compressed into perpendicular partitions; or disposed in regular columns. When it is uniform in consistence and arrangement it is called *cellular;* when varied by being disposed in tubes, fibrous bundles, or other organic forms, it is said to be *vascular.*

In describing a plant it is usual to begin with the root, but as a seed or some dissevered part of a plant must exist before roots can be produced, it may be as well to begin with the description of a seed, because from it springs every other member which we shall have occasion to notice in the sequel.

Seed. Seeds are the oviparous offspring of plants. They are discharged spontaneously from the parent in a dormant state, except in some few instances which will be adverted to hereafter; but, with these exceptions, they may remain for ages uninjured. They contain a vital principle or embryo, which, when developed under favourable circumstances, is in all respects like the parent, unless art has interfered to change its form or qualities. When seeds are ripe they are shed from the capsules or from the other parts to which they were umbilically attached, and are then covered with one, two, or three integuments to preserve them till the season arrives, when other favourable circumstances conspire to produce germination.

A perfect seed is one of the most wonderful productions in nature! It contains a living principle within an organised body of cellular membrane capable of indefinite expansion. An acorn has been said to comprise the rudiments of every member of the largest oak. When placed in the soil, the fluids within are excited into fermentative action by the impact of heat, air, and moisture, in due degrees. Expansion of the membranes takes place, the outer coverings are burst asunder, the rostel of the awakened plantlet escapes away from dry air and light, descends in search of humid and gaseous elemental food, and fixes itself in the earth. Soon after the apex of the ascending axis shoots upward, pierces the surface, and expands in the air.

The vital embryo is attached to one or two lobes of nutritive matter, destined to yield sustenance to the infant plant while it is establishing itself in the ground. In doing this office these reservoirs of nutrition either remain undeveloped in a shell, as the cocoa-nut, within the surface of the ground, as the common bean, or are raised with and upon the ascending stem, as exemplified in the cucumber, the garden balsam, &c.; when thus developed they receive the name of seed-leaves (*cotyledons*).

Were it conducive to any useful information, a great deal of curious matter might be quoted here relative to the growth of seeds, from their first appearance in the seed-vessel (*ovarium*), until the time when they are ready to drop from it. Such investigations have been made by botanical physiologists, who, by the assistance of the microscope, have shown very satisfactorily the progressive generation, or rather gradual development, of seed, both before and after impregnation; but for such information we must refer to those authors who have written on that branch of botany called *Carpology*, and to the descriptions and figures of the seed-vessels hereafter given. Suffice to add here that the seeds of plants, like the ovæ of animals, are formed along with the vessels which contain them, and of course long before impregnation.

The general form of seeds is ovular or kidney-shaped; some remarkably compressed, others depressed, varying in size from an inch or more in diameter to an atom hardly perceivable by the naked eye. Some are provided with appendages for defence, others with spiral awns, or little hooks, or wings, to assist their dispersion. All are enclosed in a thin film of cellular tissue, and this protected by a covering of chaff, by a woody shell, or by a membranous or leathery coat of dense cellular matter. These again are frequently contained in pulpy, or fleshy, or rigid vascular husks. When discharged from these integuments they are of many different colours, as black, or white, or brown of various shades, purple, and some are beautifully scarlet, and used as ornaments. Almost all naked seeds have a mark or scar (*hilum*), sometimes prominent or depressed on the exterior, showing where they were attached to the seed-vessel or to its partitions (*dissepiments*), or to the receptacle of the seeds.

Although seeds, in all cases, are the real offspring or progeny of plants intended for the perpetuation of the species, and in this sense may be called also the fruit of plants, yet botanists have made a distinction between seed and fruit, and not without reason, because the latter is only the exterior covering of the former. The mark of distinction is this: whenever a stigma, or remains of its style, appears on the exterior of any production succeeding the flower, it is a fruit; but if no such mark or remains of a faded style be visible, it is a seed. By this rule, the common orchard apple, with the visible remains of the flower at the top, and the dry leathery capsule of the poppy, with its permanent stigma, on its apex, are both fruits; so the long husky pod of the common broad bean, and the delicately beautiful pendent globes of the cherry tree, are equally fruits. The very large and very small seeds of the second and third of these plants present no such exterior mark or appendage at all similar.

It has been already observed, that the internal substance of some seeds are either farinaceous or albugineous, and that these are destined for the support of the infant plant (as the chick is in the egg) before its roots are fully fixed in the ground. Such substances are entirely absorbed by the plant during the first stage of its growth, and in but few instances expanded as distinct bodies to do the office of leaves. Other seeds are entirely filled, with the cotyledons curiously folded up within the integuments, and when set at liberty by the bursting of the shell, or outer coat, they come forth in the air, expand, and seemingly act like real leaves. They are, however, only temporary appendages, as in most cases they quickly drop off.

The foregoing descriptions of seed relate only to those plants called dicotyledons, that is, such as have two seed-leaves, and monocotyledons, having but one seed-leaf. But there is another class of plants, called acotyledons, which have no seminal leaves, and consequently the structure or organisation of their seeds (*sporules*) are very different from those already mentioned. Instead of the resemblance to an egg, having an embryo enclosed by, or surrounded with, farinaceous or albugineous envelopes, as in the dicotyledonous plants, they rather appear to be viviparous particles separated from the mother plant, exserting roots or shoots indifferently from any and every part of them. But as these are only microscopic objects, their modes of germination, or rather the manner of their self-extension, is but imperfectly understood.

The Root. A root is first an undivided spur-like body, descending directly into the earth, either attracted by its moisture or solidity, or averted from dry air and light. The extreme point of a radicle is elongated chiefly by the protrusion of its centre, and in some degree by an increasing of its length, the exterior cuticle being left behind, while the internal part is momentarily progressing forward; the point itself being extremely delicate, would be instantly checked or withered if exposed to dry air. This constitutional delicacy may account for the prone direction of roots in the first place, or at the first setting off; because, as soon as they have gained a certain depth, they proceed laterally as readily as they descend. Indeed, a certain degree of influence of the air seems to be necessary to them: as the roots of some trees take a very extensive horizontal range, keeping at a very regular depth from the surface, however unequal this may be, even from one side of a ditch to the other, without varying much in distance from the air.

The roots of an air plant (*Aerides*) hung up in a moist hot-house, all tend towards the back wall, or to the nearest solid body. A growing plant bound to the periphery of a wheel, kept constantly in motion, directs all its roots to the centre or nave of the wheel. The attraction of the solids seems to be the cause of the inclination of the roots in both these cases. Roots are attracted by water, or by those elements on which they feed; manure laid on the surface will cause working fibres to rise; and in dry seasons they will descend deeper in search of moisture.

As soon as the first spur-like root issuing from a seed enters the soil, it emits small fibres from its point and along its sides; some of these become branches, which, in their turn, also eject fibres along their whole length; these are again divided and subdivided, until the whole system of roots is formed, and thus they continue annually extending as they are prompted by the demands of the head. The roots and head of the plant are *correlative*, and are always naturally proportioned to each other. No extension of the one can possibly take place without a corresponding extension and enlargement of the other.

The fibres (*spongioles*) are the real roots or mouths of the plant, by which they imbibe or extract nourishment from the earth; for, though it be perfectly reasonable to suppose that the spongy bark of the larger ramifications also imbibe alimentary matter, yet to the working fibres is the system chiefly indebted for the principal share of the nourishment required. These delicate bodies are beautifully organised, and well fitted to take up those gaseous and aqueous elements necessary to the plant; their syphon-like form, beset with hair-like appendices, enter into every cavity and interstice of the soil in search of food, which these convey into the body of the root; and it is observable, that they are more or less numerous according as the plant is more or less vigorous. In water, or in finely comminuted soil, they are much divided, and are ejected like tufts of hair from the ends of the principal divisions of the root.

Fibres can only be produced in the earth or water, or in any other humid medium. Proper roots are often produced in the air, as may be seen on the cherry-tree, the grape-vine, and many other plants, when placed in damp or shady situations. The Indian fig, or banyan tree, is celebrated on account of its tendency to produce and throw down roots from its branches, which, fixing in the ground, become stems to support a new birth of branches which rise from that part of the branch whence the root has descended. Such roots, however, produce no fibres, because, as before observed, they are too delicate to be exserted in dry air.

There is no question but that these roots, though destitute of spongioles, have the power of inhaling through their vascular bark those qualities floating in the air which are adapted to, and necessary for, the amplification of the plant.

Although the roots of a great majority of plants are produced below the collet, or base of the stem, they may also be produced from almost every part of the stem or branches, sometimes naturally, as above alluded to, or accidentally, as in the case of a fallen tree, or by art, as takes place in propagating by cuttings and layers. Of roots there are many modifications, differing chiefly in form, and probably in their manner of acting as recipients of food. Bulbous-stemmed plants have generally fleshy roots, with but few fibres, acting in the earth as the air-plants and other fibreless roots do in the air, viz., by absorption through the pores of the cuticle.

Some plants, as the peony, have, besides fibres, large fleshy appendages, which not only serve to fix them in the ground, but to serve as reservoirs of moisture during severe drought. It seems to be a general law of nature, that all plants assailable by drought are furnished with bulbous or tuberous stems, or appendages to enable them to resist its effects.

In botanical books, roots are designated by proper names viz., bulbous, of which there are three,—the scaly, the coated, and the solid; to which are added the duplicate, the articulate, and the caulinar. There are also tuberous roots distinguished from each other by their form, or by the manner of their connexion, namely the globular, the truncated, the spindle-shaped, the handed, the bundled and several others. The writers who first proposed such distinctions, evidently meant nothing further than that that part of the plant usually found in, or resting on the ground is the root; because an onion or a potato can no more be called the root than any other part of the stem which happens to be elevated in the air. The proper functions of a root are to draw nourishment from and fix the plant in the earth, neither of which are performed by bulbs and tubers without the assistance of real roots put forth from the body of the bulb or tuber, or from a member quite distinct from what is called a bulb or tuber.

With regard to the permanency of roots, they partake of the character of the plant to which they belong. Those of annuals die with the plant at the end of summer. The main roots of trees and shrubs are as lasting as the stem and branches, but the fibres produced upon them are more fugitive, in many cases dying at the end of the growing season, and renewed in the following autumn or spring. This is very apparent in the case of bulbs and many tubers: and it is worthy of remark, that there is much agreement in the times of appearance and disappearance of the leaves on the branches of a tree, shrub, or herbaceous plant, and the fibres on the roots; they are produced simultaneously and fall off together.

Compound plants, that is, such as perennial herbs and some sorts of shrubs, being formed of many divisions, have not a common root; each division has its own roots, and may be slipped off without injury. Every new addition of shoots or leaves is produced by a new set of working fibres.

Some parasitical plants, as the misseltoe, have no visible fibres; their attachment to the plant they live on, seems to be an union of the cellular membranes of both. Others, as many of the tropical orchideæ, appear to use the stems of trees as supports, but without extracting from them any aliment whatever.

The foregoing observations are intended to identify what are really roots from other parts with which they are sometimes confounded. Under-ground stems are often called roots; such as those of couch-grass, the potato, and other plants which increase themselves by under-ground runners.

The structure of roots is very similar, whether succulent or woody. They all have a central member, formed of longitudinal fibres bedded in cellular and vascular matter, but without any pith. This central body is increased by annual additions to its exterior, in the same manner as the woody axis of a tree is increased. It is also covered with various layers of cuticle or bark; but which are always thinner, softer, and more spongy than that which is exposed to the air. The roots of some trees, as the elm and white poplar for instance, appear to have the same structure (except in being pithless) as the stems, and moreover are also furnished with buds, which shoot and form suckers all round, and at considerable distances from the trunk.

Roots of trees are more durable than their heads; and this, perhaps, because they are less exposed to the vicissitudes of weather. Although they generally die soon after the stem is cut over, yet there are many exceptions, as in the case of the two kinds just mentioned; and there are some remarkable circumstances on record relative to the longevity of roots. It is well authenticated that the roots of a mulberry tree when grubbed up, were found fresh and sound, though the tree had been felled forty years before! And from what has been lately observed by an eminent French botanist, the roots of the silver fir not only live for several years after the butt is dissevered, but actually increase in bulk: thus showing that the vital membrane, or that layer which is always seated between the bark and the wood, retains the power of enlarging itself, although there are no shoots to excite it into action, or outlet save its own expansion.

Attending to the development of a seedling plant, we cannot fail to observe that there is a point between the descending and ascending members which seems peculiarly organised. Whatever enlargement or ramification of the axis takes place in the first stage of the life, below this point, are roots, and descend; and whatever is above, are shoots, and rise into the air. This point bears the cotyledons, or seed-leaves; it is the crown of the roots and the base of the stem. In bulbs it is called the radical plate, fig. 6; of herbaceous plants it is the crown, fig 7; and of trees and shrubs it is called the life-knot, or collet, fig. 8.

This member is constitutionally of the greatest importance in the system; all the other members of the plant may be destroyed or separated, without risk of killing the plant, if the collet only be preserved. In some cases it may be divided into many parts, each of which will become perfect plants. Every scale of the bulbs of the common white and orange lilies, if pulled off with ever so small a portion of the radical plate attached, will each, if placed in the ground, become entire plants. In all bulbs, many tubers, and all other herbaceous plants which have not under-ground stems, the radical plate or crown is the centre of vitality, from whence all accretion, whether of roots, stems or leaves, proceed. All the productions of former years arose from it, and have withered away; and all that shall be produced must spring from that slender body—the radical plate of a hyacinth or tulip bulb.

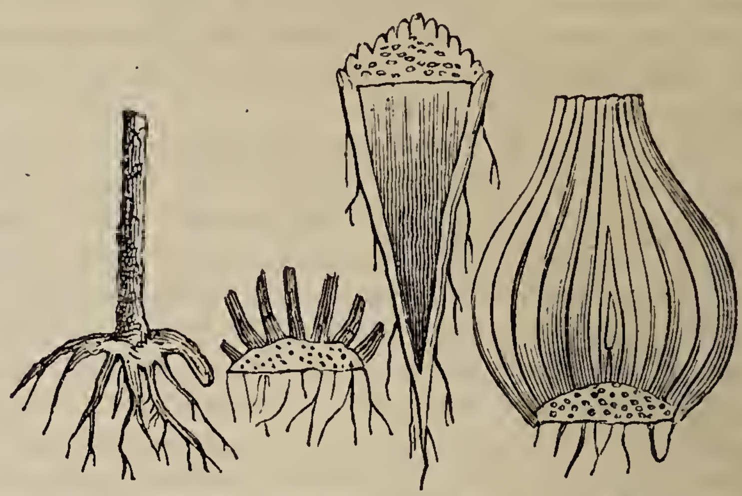


Fig. 8. Fig. 7. Fig 9. Fig. 6.

Sections of different Plants, to show the Collet.

If we examine this wonderful member we find it a homogeneous, solid substance; not granulous as we may suspect it to be, like the ovarium of an animal; but from its power or property of throwing off an endless train of perfect individual plants, we must consider it to be an aggregation of vital gems which are developed in the order of their position. The most central bud or gem generally takes the lead; but if this be damaged or checked by accident, or if it cannot appropriate the whole of the vigour derived at any one time from the roots, the next gem in order will be advanced, and perhaps one, two, or three of the lateral gems will be ejected, these when they do so appear, are called off-sets. In every year of the existence of a bulb we see the radical plate produce new roots, leaves, flowers, and seeds, all of which when the last are ripe, fall off, and are for ever separated from the mother plant. A successor in the mean time comes forth, occupies the space of the former, and is matured by the summer heat to be fully developed in the following year. In this way is the plant perennial, from its principal member being a source whence flows in infinite succession its annual products; and so it continues to do, as long as the plant remains in a sound and healthy state. Herbaceous plants in general not only produce an annual growth of leaves, flowers, and seeds, but also viviparous progeny parted off from the edges of the crown, which however is not thereby diminished, as is the case with the narcissus. Others, when they are surrounded by numerous offsets die off, leaving the space to be occupied by their offspring: of this description is the strawberry.

In many kinds of trees, especially those which have buds situated on, and which send up suckers from the roots, the collet becomes merged in the trunk and no longer conspicuous. In others it may always be identified as being more swollen than that part of the stem immediately above it. In the plant called elephant's tongue (*Testudinaria elephantipes*), the great body of the plant is only an uncommonly enlarged collet or ligneous tuber, fig. 9.

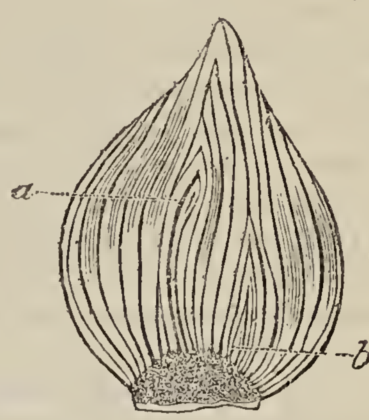
Of the Stem or Trunk. The stem or axis of a plant is that columnar body, which if above ground, serves to support and elevate the fructification. It assumes many forms and characters, as to bulk, structure, position, place and duration. It appears as a tuber a bulb, a scape, a culm, or as a woody column. It varies in size from that of a bristle to a trunk of many feet in diameter. In structure, stems are hollow or solid, jointed or simple, single or numerous. In position they are erect, inclining, prostrate or involving. They rise in the air, creep on the surface, or enter deep into the ground. They are succulent or woody: if the former, they are quickly perishable, if the latter, they are more or less durable.

Tuberous stems are exemplified in the iris and potato. The first is a stem, branched or single, partly beneath the surface of the ground, from which the real roots are ejected; and partly above the ground, the top bearing the leaves and flower stem. The second is a plant which, whether propagated from seeds or cuttings, has a system of fibrous roots on which the whole depends for support. The plant produces stems of two descriptions, one in the air which bears the foliage, flowers, and fruit: others in the ground, which, when they have shot a few inches from the root, instead of being lengthened out, stop—the point swells, and becomes a tuber of a larger or smaller size, according to the richness of the soil, or variety cultivated. When the seeds are ripe the whole plant dies, leaving the oviparous progeny perfected in the air, and viviparous offspring matured in the earth, to perpetuate the species. The tuber has a large farinaceous pith, covered with a thick coat of the like substance, and a thin exterior cuticle. Those integuments are studded with groups of buds or eyes, independent of each other, over the whole surface, and particularly at the point or crown. Each of these groups, when dissevered with a portion of tuber attached, become perfect plants, and again in their turn produce other seeds and tubers. A plant with such powers of reproduction, and in its native climate, must soon usurp the surface of the surrounding country, did not their numbers, by diminishing and robbing each other, confine them to very limited spaces.

There are many other plants similarly constituted, that is, such as produce stems in the ground, as well as in the air. Of these may be mentioned the Jerusalem artichoke (*Helianthus tuberosus*); the field bindweed (*Convolvulus arvensis*); the couch grass (*Agropyrum repens*), &c. There are also aquatic plants, the principal stems of which are extended in the mud, as the water lily (*Nymphea*).

It is worthy of remark here, that plants which have the property of increasing themselves by both seeds and offsets, produce the one in greater abundance, where means have been taken to prevent an increase in the other. Thus for instance, the potato denied its purpose of producing seeds by being deprived of its flowers, the tubers in the ground will be much increased, as well in size as in numbers. On the other hand, if the young tubers be removed from the plant as soon as they are formed, and none allowed to be perfected, the numbers of flowers and seed will be greatly increased. So rare or curious bulbs, which yield flowers, but do not ripen seeds in a climate foreign to them, may be forced to produce offsets by denying them the means of flowering, that is, by cutting off the upper half of the bulb. The same law of nature is exemplified in the English elm, which in this country bears no seeds: but to compensate for this defect, produces annually abundance of suckers.

A bulbous stem has the collet for a base whence the roots are produced; on the upper disk of the collet the leaves are seated involving each other round the centre, the exterior ones incrassated, abbreviated, and remaining for a longer or shorter period of time as a defence to the fructification before its expansion. The roots, leaves, stalk, flower and seed produced in this year are all deciduous, and fall off to be succeeded by the next division of the system, which will be developed in the next. As an example we may take the tulip, figured beneath.



Section of a tulip bulb in autumn—*a*, the flower of the following spring; *b*, the succeeding division of the bulb which is perfected during the summer.

In other bulbs, as the hyacinth, polyanthus—narcissus, there are always two or more divisions of the bulb coming forward together in different stages of their progress towards flowering: consequently these bulbs are always larger than those of tulips, or others of more simple character.

There are many modifications of this kind of stem. Some are very slightly bulbous, as the leek and blue African lily; others much expanded, as the Spanish onion and some of the Cape bulbs. The thick gouty stems of the crinum and aletris appear to be only the remaining bases of former leaves.

The internal structure of the bulbous stems is different, according as the leaves of the plant are placed with regard to each other. This may be rendered evident, by making a transverse section of the bulb: the outermost leaf partly or wholly embraces all the innermost, one of the edges overlapping the other, but without adhering, as in the leek; the onion having fistular leaves the coats of the bulbs are entire. This description of bulb is said to be *coated* (*tunicatus*). Another difference of structure is exemplified in the common white lily and other liliaceous plants; the exterior of the bulbous body being composed of thick fleshy scales attached to the radical plate: hence these are called scaly bulbs (*Squamosus*). A solid bulb has also been described in old books, and the tulip has been pointed to as an example, but this is an error: the tulip is a coated bulb; nor has there been any bulb of that description yet discovered.

A scape is a stem which springs immediately from the radical plate of a bulb, as the daffodil, or from the crown of a herb, as the primrose.

A culm is a hollow stem, either jointed, as most of the grasses, or simple, as some of the rushes.

The above enumerated stems are mostly succulent, and either hollow, or filled with a soft cellular pith, the exterior being formed of a fibrous cylinder, charged with parenchymous and vascular tissue, and covered with a thin transparent cuticle. The greater number rise erectly in the air or water; some creep along the surface of, and others enter deeply into the ground.

A ligneous or woody stem supports the branched heads of shrubs and trees, and is composed of three principal parts, viz. the pith, the wood, and the bark.

The Pith. This member occupies the centre of the stem, and constitutes the principal part of the bulk of the seedling, and of every young shoot. It is more or less filled with a spongy matter, easily permeable by fluids. There seems to be no action in the pith, except as a duct, after the first year; for, as it increases in age, it decreases in volume, and in old trees becomes almost obliterated. This central member is inclosed in a sheath, to which, if it be a dicotyledonous tree or shrub, the first concentric layer of wood is attached. In hollow stems, pith is only found at the articulations; and in jointed stems, which are solid, it is somewhat interrupted at each joint.

The above remarks refer to the stems of dicotyledonous plants; those of the class monocotyledoneæ have no regular pith, this being suffused throughout the whole body of the fibrous stem.

The Wood. The first layer of this principal member of a stem is simultaneously produced with the pith which it surrounds. During its growth it appears in three different states; at first, it is like thin colourless jelly, in which state it is called *cambium;* next, it gains a subsistence like gum, showing faint signs of organisation; and lastly, as perfect wood, called *alburnum,* having all the fibrous structure, cells, tubes, and consistence of timber. In this manner the diameter of all dicotyledonous stems are annually enlarged by concentric layers, the pith being in the centre of the whole. These layers of wood are composed of a mass of ligneous fibres, closely and longitudinally arranged, extending from the collet or base to the summit of the trunk, and to that of every branch of the spreading head. The fibres are embedded in dense cellular matter, the cells of which are placed horizontally between the bundles, and, being distended in the line of their position, give thickness to the alburnous layer.

As these layers are perfectly distinct from each other, there being no fibrous INTERJUNCTION, but merely cemented together by cellular matter and concreted sap, it is necessary there should be some common tie by which the whole column of concentric layers should be held together. This is accomplished by the convergent partitions of dense cellular matter, which reach from the bark to the pith in right lines through each layer. These perpendicular partitions are called "silver grain," and are those wavy lines so visible on oak timber when cut into pannels.

The number of the layers, reckoning from the pith to the bark, on one side of a transverse section of the butt or trunk, indicates the age of the tree exactly; for the layers never run into each other, nor do they increase or diminish after they are once imposed.

After the tree has passed its mature age, it at last begins to decay; the first imposed layers next the pith fail first; and this decay at the heart extends outwardly, till the trunk becomes a hollow cylinder, when the whole is laid prostrate by the wind. This happens sooner or later, according to the durability of the timber. Some kinds, from the light porous character of the wood, and aqueous quality of the sap, perish in a few years; others, from the density of the grain, and preservative quality of its concreted juices, resist decay for many years.

The Bark. The seedling rises from the ground with its coat of bark, consisting of a layer of green parenchymous matter, covered by a thin cuticle. This ever remains on the exterior of the greater number of trees, and is distended as the internal growth increases. Some few trees and shrubs, as the plane, arbutus andrachne, and others, discharge their bark every third or fourth year, but on the greater number the outer bark remains, and is either rent into longitudinal irregular furrows, or stretched horizontally. At the end of the second year, the second layer of bark within the first becomes visible, and takes the name of *liber,* a new layer of liber being formed within the former in every year during the life of the tree. The diameter of the tree is thus increased by a new layer of alburnum, or white wood, and a new layer of liber; of course they are always equal in number to each other. The liber, however, of many trees, is so thin, and of so open a fabric, that the layers cannot, without maceration, be easily separated from each other; but others, as those of the lime-tree, are so entire and tenacious, that they are easily separable, and woven into Russia mats.

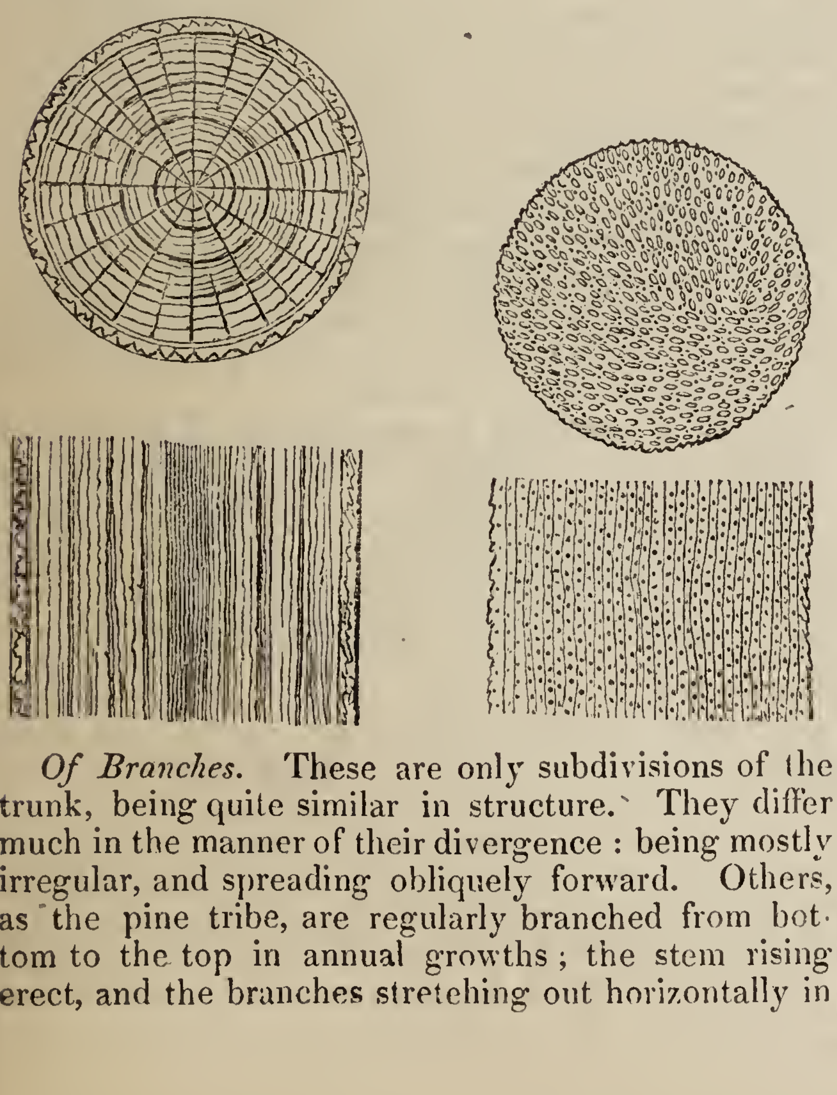
The new layers of wood and bark are the principal channels for the motions of the sap, it being always more copious in those members than in any other. Whatever the qualities of the sap of any tree may be, we generally find them more powerful and in greater quantity in the bark than in the wood; hence the many purposes to which bark is employed in medicine and in the arts.

The stems or trunks of monocotyledonous plants are very differently formed. Instead of additional layers of new matter being deposited on the outside (*Exogenæ*), the new accretion is formed, and proceeds from within (*Endogenæ*). This manner of growth is exemplified in the palms and other plants belonging to the same class, but the most familiar instance is that of the common asparagus. In this plant it will be observed (if we consider one division of it) that it has a system of thick fleshy roots, fringed with fibres, proceeding from the collet, or crown. From the centre of the latter the stem takes its rise, and is almost as large on its first appearance above ground as it is ever afterwards. Its development is evidently an elongation of its previously existing organisation, and surely not consolidated by any fibrous processes, which, during growth, descend from the branched head.

The stems of all the other orders of monocotyledoneæ are similar in their development. Whether we examine the peduncles of bulbs, the stems of the irideæ and musaceæ, or the culms of the gramineæ, we find they all gain elevation by an elongating process, and by the simple distension and subdivision of the cellular and vascular apparatus, without addition of any new matter save the incremental elements which they extract from the earth and atmosphere. Here it may be necessary to premise, that in considering or investigating vegetable structure in general, we should always distinguish the mere distension of the cellular and vascular fabric of plants from their elements. The former are rudimental, the latter accessory; the first pre-exist before enlargement, the last are imbibed during, and to assist enlargement.

The development of other monocotyledonous plants may be noticed here. There are two very remarkable constitutional differences; in some the fructification is terminal, that is, placed on the point of a central stem; but in the greater number the fructification is lateral, that is, issuing from the axils of the leaves. Of the first description is the common American aloe, which is constituted of roots, a certain number of leaves seated on the collet, and which are developed *seriatim* from the circumference to the centre, the last involving the fructification, which, when produced, and the seeds ripe, the whole dies. The second description comprises most of the palms; the evolution of these begins by the expansion of the first exterior leaf, which is usually the least of all that follows; a second succeeds, with all the rest in train, until all are expanded, or so long as the plant retains vigour to bring them forth. The petioles, or foot-stalks of the leaves or fronds, as they are called, remain attached to the collet, and in time acquire a woody consistence, and aggregately compose what afterwards becomes the stem. This is conspicuously the case in the genus *Zamia*, and in all the dwarf palms, which, though they continue to evolve fronds and flowers, never show any great elongation of their axis. In the case of the lofty-growing palms, the first evolution of their radical leaves is similar to the dwarfs; but with the consecutive development of their leaves, an elongation of the axis commences, and continues rising to the height of sixty feet or more. This altitude is gained slowly, the exterior of the stem being formed by the persisting bases of the leaves, and being connected with each other within, and with the collet, whence they all spring, form the stem. Thus it appears that the fronds are only expanded portions of the stem, the whole being one uniform body of longitudinal fibres, embedded in coarse cellular matter, hardening, and becoming more compact by age. On a cross section, there appear no consecutive layers or divisions of the structure to indicate periodical additions, like those of exogenous stems, and may be described as the *common* petiole of the foliage and flowers.

The annexed figures represent transverse and perpendicular sections of dicotyledonous and monocotyledonous stems.



Of Branches. These are only subdivisions of the trunk, being quite similar in structure. They differ much in the manner of their divergence: being mostly irregular, and spreading obliquely forward. Others, as the pine tribe, are regularly branched from bottom to the top in annual growths; the stem rising erect, and the branches stretching out horizontally in every direction; when branches are so disposed, they are said to be *verticillate.* In some cases the branching is regularly alternate; in others produced in opposite pairs, alternately crossing, in which position they are said to be *decussated.* The branching of trees constitutes their chief beauty: the lower and lateral ones are mostly inclined to droop at the extremities, and which in many sorts is most graceful. The pendent spray of the weeping willow, birch, and ash trees, are universally admired, being much more beautiful than the stiff and formal forms of the larch and Lombardy poplar.

The Leaves. The foliar expansions of plants are of several descriptions. The first to be noticed, are the scales or winter coverings of the buds, hence called *hybernacula.* They consist of dry membranous scales seated at the base of the bud, over which they are imbricated, and mostly deciduous when the bud bursts. They are in some instances covered with thick down; in others with gum, as the balsam poplar, or with resin, as in most of the order *Coniferæ.* Without such a provision as this, all the buds of trees and shrubs in the regions of frost would be destroyed; but such is the protection afforded by *hybernacula,* that they can bear thirty degrees of frost without injury.

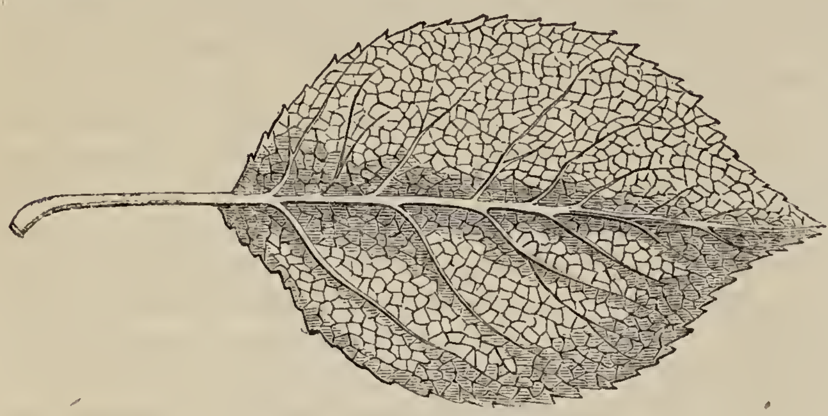
The *Stipulæ* are the next leaf-like expansion to be noticed: they are sometimes single, but very frequently double, and situate at the base of the petiole, or leaf-stalk, one on each side, shown beneath.

Stipulæ.

Sometimes they are united to the petiole, or changed into prickles, as in the berberry. In some of the grasses the stipulæ is single, investing the culm a little above the limb of the leaf, whence they are said to be intrafoliaceous; and when seated on the outside of the petiole, they are said to be extrafoliaceous. In some plants the stipulæ embrace the stem like a sheath; in others they invest the top of the shoot, as in the fig tree. Stipulæ generally fall with the leaves.

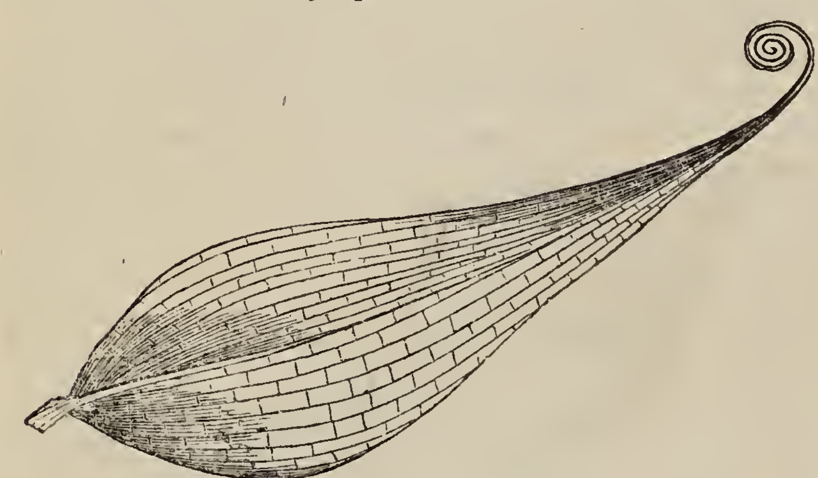
The proper leaves are the grand ornaments of plants; from their numbers, position, and delicacy of organisation, they are destined to effect some important office in the economy of the plant. They are, however, only temporary organs, being articulated with the surface of the bark, and always seated upon, or near the buds. Those of deciduous trees or shrubs drop or wither as soon as the summer growth is over. Some of both of those descriptions retain their leaves to the second or third year, hence they are called evergreens; and some of the pines and firs retain them for many years.

Leaves are generally furnished with a foot-stalk (*petiole*), though sometimes this member is wanting, in which case they are said to be sitting (*sessile*). The footstalk is either short or very long; somewhat grooved on the upper side, and convex below; it is produced into the web or disk of the leaf, where it forms the mid-rib (*costa*), whence branches like veins are sent off, traversing the whole disk. This disposition, and lateral branching of the mid-rib only, obtains in dicotyledonous plants: the leaves of the



Dicotyledonous leaf.

class *Monocotyledoneæ* have the footstalk more equally divided at the point where it enters the disk, and thence projected towards the point of the leaf in nearly parallel lines, fig. 14. The



Monocotyledonous leaf.

web of the leaf is filled up between the veins by cellular tissue, having a thin porous cuticle both above and below. The structure of the upper and under surfaces of the leaves are not alike; one is supposed to be furnished with excretory, the other with incretory organs. Water plants, whose leaves are constantly submersed, have no cuticle.

Leaves are either simple, as in the myrtle, or compound, as in the mountain ash. Compound leaves are distinguished into pinnate, bipinnate, tripinnate, ternate, biternate, triternate, and digitate.

A pinnate leaf is said to be *equal*, when the leaflets are opposite to each other on the footstalks; *alternate*, when placed one above another; *terminal*, when the primary footstalk has a single leaflet at its apex; *cirrhose*, when it is terminated by a tendril; *abrupt*, when it is terminated by a pair of leaflets; *interrupted*, when the alternate pairs are long and short; *articulate*, when the footstalk is jointed between the pairs of leaflets; and *decurrent*, when the leaflets have a membranaceous continuation down the foot-stalks.

A bipinnate leaf is when the footstalk itself is divided, and branching out into other footstalks, each of which supports leaflets corresponding to the simply pinnate leaf in all its modifications.

A tripinnate leaf is of the same description as the above, once more decompounded. The petiole being bipinnate, supporting leaflets as in the former modes.

A ternate leaf is so called, when the footstalk supports three leaflets, as is exemplified in the wood-sorrel.

A biternate leaf is when the common footstalk supports three others, each of which supports three leaflets.

A triternate leaf is only a further decomposition of the above.

A digitate leaf is when the common petiole supports several leaflets, diverging from a common centre at its apex.

Leaves are either radical, i. e. proceeding from the crown or radical plate, or caulinar, i. e. borne on the stem; and either sessile or petiolate, that is, either sitting, or having footstalks. A sessile leaf is sometimes *vaginant*, that is, sheathing, as in grasses, or *amplexicaule*, stem-clasping, as in many of the umbelliferæ; or *connate*, situate opposite each other, and united at the base, circumscribing the stem, as in the leaves of the honeysuckle. In some cases connate leaves form cups, which hold rain, probably for the supply of the plant, or they are *decurrent*, running stem, as sow-thistle.

The leaves are the principal organs of respiration, and contribute to the growth by their powers of absorption. Gaseous qualities are emitted as well as inhaled by them; and that they allow the escape of aqueous fluids is well known. As they aggregately present an extensive surface to light and all atmospheric influences, their action in the development of the plant is indispensable. As such, they are with great propriety called "the lungs" of vegetables. They are mainly instrumental in producing a constant flow of sap upwards, in consequence of their perspiring functions. In proportion to the quantity of foliage, in like proportion is the need of, and consumption of water. Indeed it is not too much to assume, that hydraulic action is their chief office: the amplification of the system could not take place without such agency, to excite intestine motion of the fluids, and thereby assist the enlargement of the various membranes. The health and vigour of every plant depends very much on the number and amplitude of the leaves. Defoliation, either naturally, or by art or accident, instantly arrests the growth, and the failure or diminished expansion of foliage, is a certain sign of debility. There is a numerous description of plants called succulents, which have few or no leaves, as the torch and melon thistles; but their stems are much dilated, presenting a large superficies of parenchymous exterior to the air and light; or they are profusely covered with spines, which no doubt, conjointly, do the office of leaves.

Green is the most general colour of leaves, but some are red, or purple, or yellow; some appear nearly white, in consequence of being clothed with short woolly or silky hair. They differ much in substance and structure; some are immensely thick and fleshy, as those of the genus aloe, others remarkably thin, as those of the beech. The texture of the surface is also very dissimilar; some are rough, prickly, and wrinkled, others smooth and glossy. In some leaves, the middle rib and its ramifications or veins are flat, on others remarkably prominent below.

The figure of leaves are extremely various, and sometimes constitutionally variable on the same plant, as in the genus acacia; in which the bipinnate leaves of some of the species are changed into a single oblong leaflet called *Phyllodium*, which is also altered in position, one of the edges being for the most part turned to the sky.

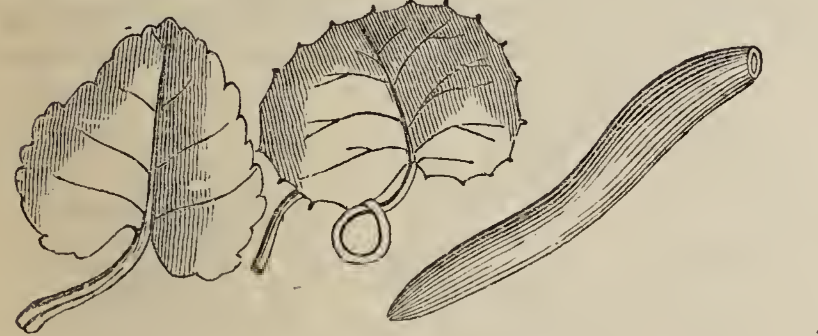
The form, size, texture, &c. of leaves, furnish many specific distinctions. Some are named from their resemblance to parts of animal bodies. Others from their resembling instruments of war, of music, or of well known machines. Others again are named from geometrical figures, or from the heavenly bodies. They have also names to signify to what part of the plant they are attached; as whether *radical*, springing directly from the root; *caulinar*, growing on the stem; *rameum*, borne on the branches; *axillary* proceeding from the angle between the stem and a branch: the same term is used in describing flowers, peduncles, or stipules arising from the same place. Leaves are also said to be *floral* when placed near the flower, and *seminal* if they are the first which spring from the seed.

The terms which most commonly occur in descriptive botany are as follow:—

Cordate, a heart-shaped leaf or leaflet, fig. *a*, as exemplified in the birthwort and many other plants.

Reniform or kidney-shaped, as in ground ivy, fig. *b*. This term is also frequently applied to seeds.

Linguiform, that is tongue-shaped. This description of leaf is frequently seen among what are called succulent plants, as in the families of aloes and mesembryanthemums. It is "linear and fleshy, blunt at the end, convex beneath, and having usually a cartilaginous border," fig. *c*.



a *b* *c*

Auriculate, ear-shaped, or rather having appendages like ears, or lobes at the base, fig. *d*.

Palmated, a hand-shaped leaf; example, the common passion-flower, fig. *f*.

Digitate, a fingered leaf. This is distinguished from the palmated leaf, in the leaflets representing fingers, being all attached to the point of the petiole or footstalk; whereas the other has a broad space like a palm of a hand, whence the divisions proceed; the digitate leaf is exemplified in those of the horse-chestnut, fig. *g*.

g *f* *d*

Pedate, that is like a foot of a bird; a leaf divided into several slender divisions, fig. *h*.

Ovate, an egg-shaped leaf, in which the base is somewhat broader than the point, fig. *i*.

Oval, an oval-shaped leaf; in which both ends are equal, fig. *j*.

Elliptical, a leaf like an oval, only more elongated,

j *i* *h*

fig. *k*. It often happens in leaves of some of the preceding forms, that the broadest part is most distant from the petiole; in which case they are said to be *obovate, obcordate*, &c., that is, inversely heart, or egg-shaped.

Sagittate, arrow-head shaped leaf. This occurs frequently in the arum family, and many other kinds of plants, fig. *l*.

Hastate, are such leaves as are shaped like the head of a halbert or battle-axe. This differs but little from the auriculate leaf, fig. *d*.

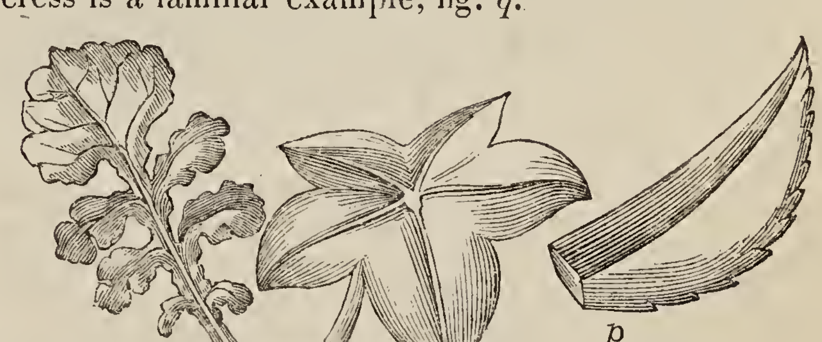
Lanceolate, an oblong leaf which tapers to each end, this is exemplified in the common ribwort, or ribbed leaved plantain, fig. *n*.

Ensiform, or sword-shaped leaves, are such as those of the iris, fig. *o*.

o *n* *l* *k*

Acinaciform, are leaves resembling the Persian cimiter: one edge being convex and sharp, the other nearly straight and thick. Example, *mesembryanthemum acinaciforme*, fig. *p*.

Peltate, a target-shaped leaf; in such the footstalk instead of being inserted into the margin of the leaf, is fixed at or near the centre of the under surface. The ivy-leaved geranium and nasturtium, or Indian cress is a familiar example, fig. *q*.



p

r *q*

Lyrate, leaves shaped like the musical instrument, the lyre. It is somewhat like a *pinnatifid* leaf, only the terminal segment is very large and rounded, fig. *r*.

Dolabriform, a hatchet-shaped leaf. This very peculiarly formed leaf only occurs among the mesembryanthemums. It is thick and succulent; narrow where it is fixed to the stem, but spread out and rounded at the point like the edge of an axe, fig. *s*.

Deltoid, a trowel-shaped or three-sided leaf, resembling the Greek letter delta, fig. *u*.

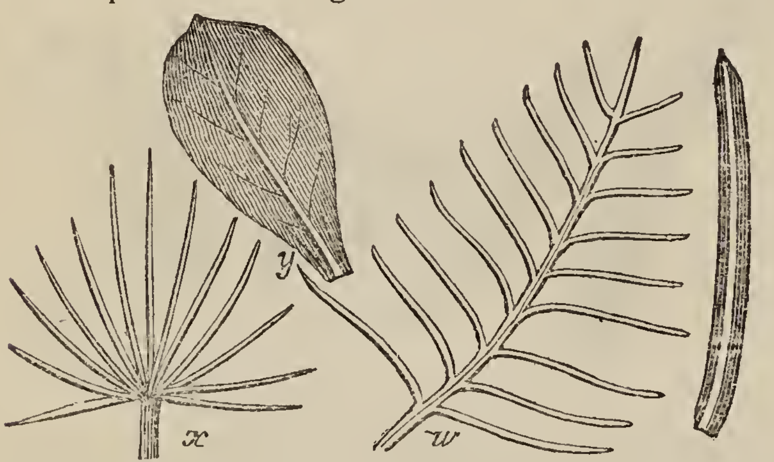
Subulate, awl-shaped leaf; it tapers from the base to the point, and is so called whether it be flattened, or hollow; if the latter, it is said to be *tubular*, fig. *v*.

v *u*

Acerose, all leaves which bear a resemblance to those of the yew or fir-tree, are said to be acerose. They are linear, awl-shaped, rigid, and evergreen, and either sitting singly and regularly along the branches, or placed in bundles of several together, fig. *t*.

Pectinate, is a sort of pinnate leaf, only the pinnæ are so narrow that they resemble the teeth of a comb, fig. *w*.

Flabelliform, is a fan-shaped leaf, that is the disk is split into spokes or radii. The term is mostly used in describing the fronds or leaves of palms. One is represented at fig. *x*.



t

Spatulate, a form of leaf resembling the instrument used by apothecaries for spreading salve; that is a flat knife, very broad and rounded at the point, fig. *y*.

Cuneiform, or, wedge-shaped; this is very much like what is called deltoid.

Carinate, keel-shaped; said of leaves whose centre of the back is prominent like the keel of a ship.

Lunated, are such leaves as resemble a crescent or new moon. In some plants the horns point toward the stem, in others from it. In either case, they are said to be lunated.

Stellated, is a star-like leaf, or rather leaves placed in star-like order. This term is however seldom used; *verticillate* is the term applied to such leaves as stand round the stem like rays pointing every way, as those of the cleavers and woodroffe, fig. 1.

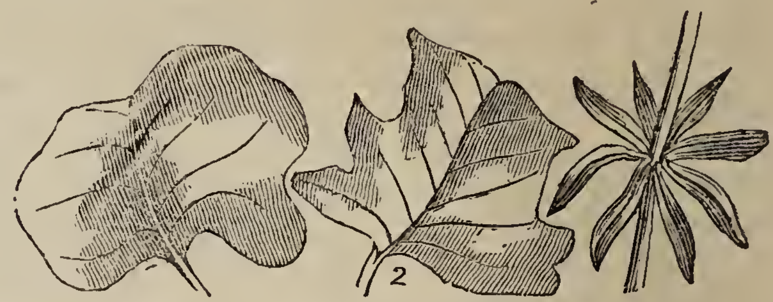
Cucullate, leaves are called cucullate, if they take the shape of a cowl or hood reversed; that is, wide at top and narrowing to a point at bottom.

Truncated, is spoken of a leaf which appears as if its apex were cut off, as those of the common saddle-leaved tulip tree, fig. 2.

Retuse, leaves are said to be retuse when they terminate bluntly, or have a slight sinuosity instead of an acute point, as fig. 3.

Unequal, is when the two sides of a leaf do not correspond in size, as may be observed in those of the elm.

Besides the foregoing, there are several other forms of simple leaves introduced into specific descriptions of plants, such as *bifid, trifid, quadrifid*, that is two, three, four-cleft, and so on. There are also *orbicular, round*, and *cylindrical* leaves, with modifications of these into *subrotund*, roundish; *rhomboid*, diamond-shaped; *linear*, all of the same breadth; *integrum*, entire, or undivided; *lobed, parted, laciniated* or torn, &c.

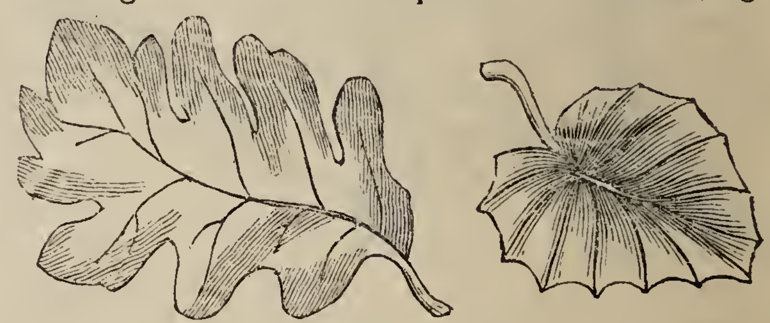


3 1

Hitherto the general outline or form only of the leaves have been noticed; we have next to advert to the terms used by botanists in describing the margins of leaves, and which are applicable to all leaves whether simple or compound.

Integerrimum, most entire; this term is only used in allusion to the margin, not to the leaf itself. A leaf may have many sinuosities, as the passion-flower for instance, and yet have an entire margin like a hem all round; and it is in this sense that the term only integerrimum is used.

Repand, bowed or bent back, in consequence of the margin being confined by internal segments of circles preventing the horizontal expansion of the leaf, fig. 1.



2 1

Sinuated. Leaves having deep rounded indentations like those of the oak, fig. 2.

Undulated. A leaf receives that character when its margin is waved up and down vertically like those of the holly, but without prickles, fig. 3.

Crispum. That is having the margin curled or contorted like some varieties of cabbage, fig. 4.

4 3

Plaited, "folded like a fan, the plaits being acute." This beautiful conformation is exemplified in the common meadow plant, called ladies' mantle, fig. 5.

Eroed. That is when the margin is so irregular that it appears as if gnawed by an insect.

Cartilaginous. This is spoken of some leaves whose margin is composed of a harder substance than the rest of the leaf.

Glandular. That is when the edge of the leaf is studded with little glands or processes.

Dentated. When the margin is cut into teeth, or projections shaped like the canine teeth of animals, fig. 6.

Doubly-dentate is when the teeth are each indented and all pointing upwards, fig. 7.

7 5

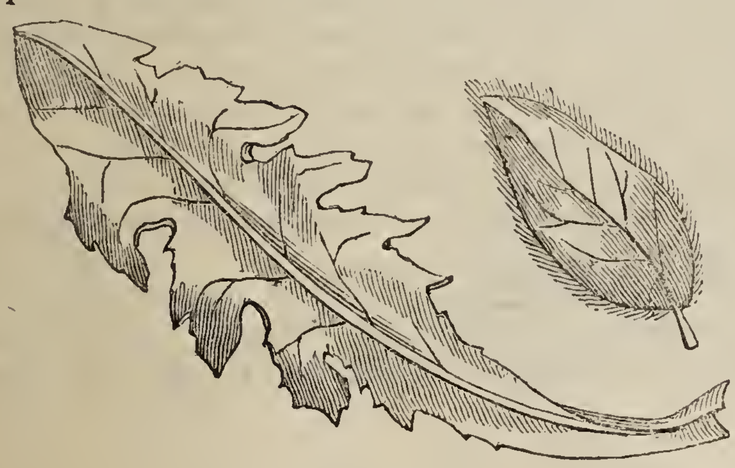
Serrated. That is when the margin is cut like a saw, fig. 8. When the projections are small and fine, the margin is said to be serrulate.

Crenate is when the projections are blunt and point neither upwards or downwards, fig. 9. The margin so described may be either obtusely crenate, acutely crenate, or doubly crenate.

Armed. This is said of leaves whose margins are defended with prickles as the common holly, the pine apple, and many other plants, fig. 12.

Ciliated, from cilium, an eye-lash. This term applies to the margin of the leaf, and means that it is fringed with hairs, fig. 10, example *Protea ciliatum.*

Runcinate. Leaves are called runcinate when the margin is cut into deep gashes like the teeth of a pit saw, the points of the teeth pointing backwards, exemplified in the common dandelion, fig. 11.



11 10

TERMS DESCRIPTIVE OF THE SURFACE.

Wrinkled. The leaves of sage, and all others similar, are said to be *rugose* or wrinkled, caused by the web of the leaf between the veins being more dilated than the veins themselves.

Blistered. Having a surface like the preceding only extremely so.

Lacunosum. That is, pitted on the upper surface, caused by the depression of the web of the leaf between the more rigid veins.

Punctated. The surface covered with dots, usually "arising from glands imbedded in the surface of the leaf."

Coloured. Leaves are said to be coloured when they are of any other colour but green.

Ribbed. A leaf is said to be ribbed when the divisions of the mid-rib or costa run in direct and parallel lines from the centre to the margin.

Nerved. When the nerves run in lines from the base to the point.

Veined. When the divisions of the costa are numerous, and form a net-work over the web of the leaf.

Armed. When the disk is partially covered with prickles, as the thistle, rose, and some varieties of holly.

OF THE SITUATION OF LEAVES.

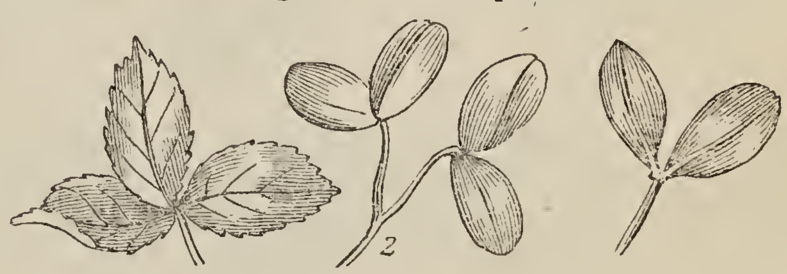
If a leaf be seated upon, and clings closely to the stem, it is said to be *adpressed.* If leaves rise from the stem one above another on opposite or on nearly opposite sides, they are described as *alternate.* If their bases surround the stem, they are said to be *amplexicaule.* If so thickly placed as to hide the stem they are said to be *conferted.* If two opposite leaves are united by their bases, so that the stem appears to run through them, they are said to be *connate,* that is growing together. If the leaves of water plants grow under the surface, they are described as *submersed;* if above the surface, they are *emersed;* and if they float they are said to be *natant.*

COMPOUND LEAVES.

Some of these have been already described, and two of them (the palmate and digitate) have been already figured; we now proceed to name and give figures of those of most common occurrence.

A compound leaf differs from a simple one in this, that whereas the latter stands singly on the petal or footstalk, the former stand in pairs, threes, &c.

If two leaflets are borne on the footstalk, they are said to be *binate,* fig. 1. If the petiole divide at the



3 1

summit, and each division end in two leaflets, it is called *bigeminate,* or a twice-twinned leaf, fig. 2. If one petiole bears three leaflets attached to the end, it is called a *ternate* leaf, example the wood-sorrel, or shamrock, fig. 3. If the petiole be divided, and on the end of each division three leaflets be attached, this disposition is called *biternate,* fig. 4. Suppose

5 4

again that the petiole has three branches, each bearing three times three leaflets, then we have a *triternate* compound leaf, fig. 5.

When a petiole is undivided, but bears on each side any number of leaflets, either placed alternately or in opposite pairs, it is said to be a *pinnated* or winged leaf, fig. 6. In describing such a style of foliage, it is usual to particularise the number of *pinnæ* by the terms *trijugous*, *quadrijugous*, and so on.

Sometimes the pairs of leaflets are equal, in which case the leaf ends abruptly, hence called *abruptè pinnatum*, fig. 7. But if the petiole bears, besides the side ones, a single leaflet at the end, then it is called *pinnated with an odd one*, fig. 8. If instead of this odd leaflet at the end, the extreme point of the petiole be resolved into a tendril, as is the case with the pea, then it is called *pinnatum cirrhosum*, fig. 6.

7

8 6

Another form of winged leavés is called *interruptè pinnatum.* This is when between every larger pair of leaflets a smaller pair is placed, fig. 11. A compound leaf which has the leaflets connected by a leafy expansion running along the edges of the petiole, is called *decursively pinnate.* If the petiole be articu-

11 10

lated at the points where the pinnæ are fixed, the whole is called *jointedly pinnate*, fig. 10. When a petiole is divided and bears pinnæ on each division, it is called a conjugately pinnate leaf, fig. 12.

13 12

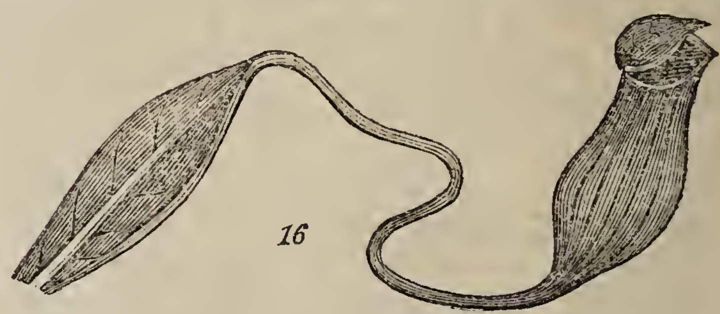
In the digitate leaf each leaflet is entire; and there are digitate leaves where the leaflets are pinnated, hence called *digitatum pinnatum*, being both fingered and winged, fig. 13.

Bipinnate and tripinnate leaves may be easily understood by a glance at the cuts on which they are represented, figs. 14 and 15.

There are some plants whose leaves are of so remarkable a shape, that they do not belong to any of the foregoing characters. Of these we may notice the pitcher plant (*Nepenthes distillatoria*). The proper leaves are lanceolate, and beyond the apex of each the mid-rib protrudes like a tendril to the length of several inches. The extremity of this tendril becomes inflated into a bladder-like vessel, two or three inches in length, and nearly one in diameter; the outer extremity of the bladder is open, but supplied

15 14

with a hinged lid which shuts close upon it, like the lid of a flagon, fig. 16. The vessel is always more



16

or less filled with water, which appears to be distilled from the plant itself, as the lid prevents rain falling directly into it. No rational account has yet been given of the use of this appended cistern, to the plant itself, or to any other creature near it.

There is another plant (*Cephalotus*), which is furnished with similar, but far more elegant appendages of the like kind. Both are marsh plants, and therefore it is the more remarkable that they should have reservoirs for the retention of the very element in which they stand.

The *Dionæa muscipula*, or vegetable fly-trap, may be mentioned as having leaves of very odd conformation. At the point of each leaf two smaller leaflets are placed opposite each other, on hinges at bottom. These open and shut against each other, and their upper edges are furnished with bristles, which fit in between each other crosswise when shut. In fine weather they are generally wide open; and should a food-seeking fly creep into the furrow between the leaflets, these suddenly collapse and crush the intruder to death.

Of Bracte. This is a foliar appendage which accompanies the flower, but different from both the proper leaves and the members of the flower in shape

Bracte of the lime and helleborus.

and texture, and frequently in colour. Though most commonly seated below the florets, as in *Justitia*, it is above them in *Eucomis.* In some instances it resembles the proper leaves, as in *Mespilus;* but is often of a membranous texture as in *Helleborus.* In some of the *Orchideæ* the leaves are gradually resolved into bracte, so that it is difficult to decide where the leaves terminate, and the bracte commence. The chaff of grasses are bracte.

Of Involucre. This is allied to bracte, but as it occurs conspicuously on umbelliferous plants, it is deemed proper on this account to distinguish it by this name. The involucre consists of one or more leafy expansions, differing in shape from the proper leaves of the plant, situate at the base of an umbel.

Involucre of a phlox and Chinese primrose.

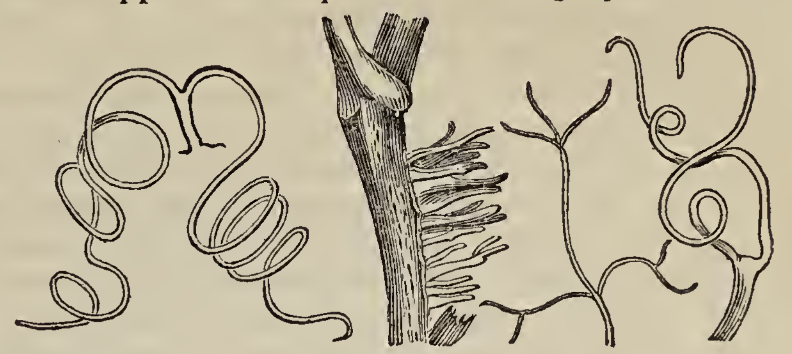
When at the base of a compound umbel it is called the general involucre, and when at the base of the partial umbel the involucellum. The bracte of the anemone has been supposed to be involucre, but this is not generally allowed.

Of the Spathe. This member is the membranous covering which involves the flowers of the snowdrop, onion, arum, and palms before their expansion. By some botanists it is called bracte, by others involucre, but as it is not decided which it really is, it is as well to call it by the conventional term most generally known.

Spathe.

Arum. Narcissus.

Of the Tendril (*Cirrhus*). The tendrils are those convolving strings or claspers by which plants are occasionally supported. They are produced on different parts of flexible stems, and attach themselves to other bodies for the support of the plant; on the grape-vine they



are inserted from the young shoots opposite the leaves, fig. 1; in the pea the points of the footstalk of the leaves are resolved into compound tendrils, fig. 2; the superb lily bears them on the points of the leaves, fig. 14; and on the ivy they are short processes issuing from the bark, fig. 4.

Of the Armature. Plants are furnished with defensive appendages called spines, prickles and stings.

Spines (*Spinæ*) are woody processes issuing from the stem, and appearing to be abortive shoots, as those of the white thorn and wild crab apple; from the points of the leaves, as butchers'-broom; from the calyx, as the thistle; from the seed-vessel, as the thorn apple; and from the seed, as spinach.

Prickles (*Aculeus*) are situate on the bark, and appear to be articulated therewith, as in the rose and gooseberry. Sometimes they take the place of other members of the plant, as instead of stipulæ in the berberry, and bastard acacia. In the genus *Mammalaria* and other succulent plants, prickles appear to do the office of leaves.

Stings (*Stimuli*) are a smaller kind of prickles, but with this difference, they emit a poisonous juice into the punctures made by them, causing painful irritation and inflammation. Example, the common nettle.

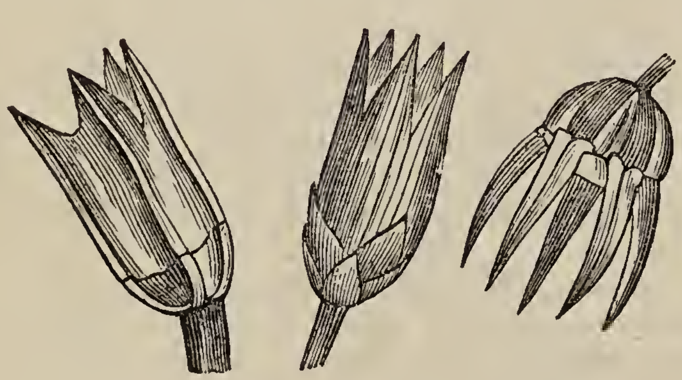
Glands are small protuberances seated on various parts of plants. They are either secretory or excretory organs. Fibrous roots are observed to issue from those situate on the bark of the common laurel, if the branch be layered in the ground. Professor de Candolle remarks that these bear the same relation to the roots that buds bear to young branches. They are very conspicuous on the petioles of the peach, and passion flower. Glands are described by botanists under various names, as miliary, bladder, scaly, lenticular, cup-shaped, and utricular, the latter being very visible on the young shoots of the vine, and on several species of fig-marigold, appearing like globes of crystal.

Pubescence. The exterior cuticle of plants is either perfectly smooth and naked, or covered with hairs; in some cases, soft and fine as silk, as the silver tree (*Protea argentea*); or rough and harsh (*asper*) when the whole plant is covered with short rigid bristles, as borage. Botanists employ many different terms in describing this clothing of plants, viz., *hirsutus*, hairiness; *villosus*, villous; *tomentosus*, downy; *glochidatus*, barbed or bearded; *sericeus*, silky; *arachnoid*, cobweb-like; *rostella*, hooked, &c.

Scales. The cuticle of some plants is profusely covered with scale-like processes, giving a greyish hue to the surface. They are microscopic objects, and may be met with on the leaves of the pine-apple; plants bearing them are said to be leprous (*lepidotus*). Another cuticular excrescence of a scale-like character is borne on the young shoots and backs of the leaves of ferns, these are called *ramenta*.

Of the Flower and Fructification. The members of the flower are the calyx, corolla, stamens, disk, nectarium, pistillum, and receptacle.

The Calyx. This is the external investment of the flower, and in which it sits as in a cup. By the early botanists it was said to be the termination of the outer bark; but this is no longer a proper distinction; because in composite flowers, the parts called *pappus* are deemed calyces, although they occupy the centre of the disk. The common calyx is sometimes entire, in which state in some instances it is thrown off by the growth of the corolla and stamens. More frequently, however, it is divided into segments (*sepals*), which separate from each other more or less from its outer edge downwards. It is most commonly green, but in some flowers it is highly coloured, as in the marvel of Peru, mezereon, and fuchsia. In many cases it is quickly deciduous, in others it remains till after the fruit or seeds are ripe. In size the calyx varies from a mere ring to a considerable tubular expansion. It is said to be inferior if situate below the ovarium, and superior if attached to its side, or seated on its apex, as exemplified in the apple and pear. In some cases it is double, or formed of many scales, as in the camellia; and in syngenesious flowers, as the artichoke, that part which used to be called a scaly calyx is now called *Anthodium.* In some flowers, as the tulip, it is said to be wanting; but this is not admitted by the first authorities. In the flower just named, the three outer petals are to be considered calyx, and the three inner ones corolla. And it is laid down as a rule that, where there is a plurality of floral investments, the outer one must always be considered as the calyx. This organ is usually deemed the external defence of the more delicate members of the flower; but besides this its most ostensible office, it is destined to perform others, and to be transformed into the most valuable products of the plants. In the order *Gymnospermia*, of the class *Didynamia*, the calyx becomes the seed-vessel; and in the genus *Pyrus*, the incrassated bottom of the calyx becomes the fruit. The following figures represent several of the most common forms of the calyx.



The Corolla is the delicate and usually high-coloured row of leaves (petals) which stand immediately within the calyx. If the petals are distinct from each other they are said to be *polypetalous*, if united into a tube the corolla is said to be of one petal (*monopetalous*). When thus united, the tube is of more or less length and the lip more or less open; if regularly divided, and the divisions diverge regularly, it is said to be wheel-shaped (*rotate*); if so flatly as to resemble a plate, they are called salver-shaped (*hypocratiform*); or funnel-shaped (*infundibuliform*); or bell-shaped (*campanulate*); or lipped (*labiate*). If the exterior lips or edges of the corolla be unequally divided, and if the upper division be arched, that is bending over, it is called the helmet (*galea*); if the lips be very wide apart, the corolla is said to be gaping (*ringent*); if the upper and lower divisions meet and are pressed together, it is said to be like a mask (*personate*). The central opening of such a corolla is called the throat (*faux*), and the petals which form it when separately considered are said to consist of two parts, viz., the claw (*unguis*), by which it is fixed to the receptacle, and the lip or border (*limbus*) which is expanded in the air.

According to the order in which a many-petalled corolla is disposed, botanists have designated them by different appellations, viz., like a rose (*rosaceous*); like a lily (*liliaceous*); like a pink (*caryophillaceous*). Some are disposed like a cross, hence called *cruciform;* others resemble a butterfly (*papilionaceous*); and the different members of these last named flowers receive characteristic names, viz., of five petals, the upper one is called the standard (*vexillum*); the two side ones are the wings (*alæ*); and the two lower ones being united form the keel (*carinæ*), fig. 22.

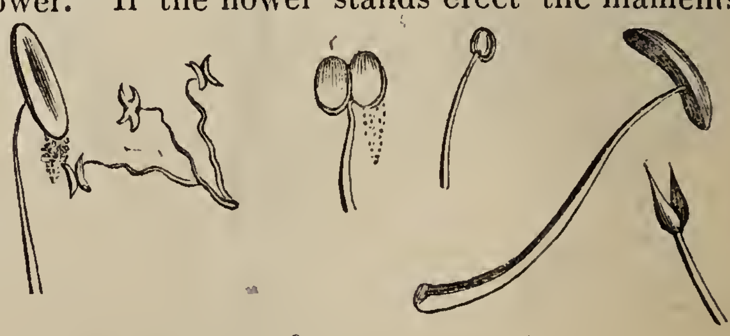
The corolla of a floret is called *corollula;* if the corolla be wanting, the flower is said to be *apetalous;* and if a part of the corolla be lengthened behind into a hollow tube, it is called a spur (*calcar*). Example the larkspur.

From the great variety of forms in which the corolla is exhibited, the terms equal and unequal, regular and irregular, are properly applied; and though in the generality of plants it forms but one rank of petals within the calyx, yet in some there are several, as in the flowers of the water-lily.

The corolla is sometimes furnished with certain appendages attached to the throat, or to the interior base of the petals. These are commonly called *nectarium*, because they hold, and are supposed to secrete honey. They are sometimes in the shape of a rim or cup encircling the throat, as in the auricula; like erect scales at the bottom of the claw, as in the ranunculus; or extended like a trumpet, so conspicuously beautiful, as in some species of narcissus. In the passion-flower it is divided into numerous parti-coloured filiform rays like a rich fringe. When the corolla is prolonged into a spur behind, it is also called the nectary.

The annexed figures represent the most common forms of flowers. See plate.

The Stamens. These are situate within the corolla and are the male parts of the flower, consisting of three distinct members, viz. the filament, *a*, the anther on its summit, and the pollen or dust discharged from the anther *c*. In some plants the filament is wanting: but the anther and pollen are essential. The filaments when present serve to place the anthers above or on a level with the female organ, or stigma of the flower, and are of different lengths, and assume different positions, according to the position of the flower. If the flower stands erect the filaments are



as long, or longer than the style, but if the flower nods, or hangs, they are usually shorter. The filaments either stand distinctly separate from each other or are united by a membrane at their bases, in which case they are called a brotherhood (*adelphia*); if in one united rank they are said to be one brotherhood *monadelphous*; if in two, three, or many ranks one within another, the flower is called *diadelphous*, *triadelphous*, or *polyadelphous*. If two out of four stamens be shorter than the other two, the flower is said to be *didynamous;* if two out of six are longer, the flower is *tetradynamous*.

In some flowers, as swallow-wort, the filaments converge towards the centre, and there unite and form a solid body called *columna*; in which are locaments for the anthers.

The anther is composed, in most instances, of two cells, containing pollen, and generally fixed to the apex of the filament. If attached by their base, they are said to be *innate;* if by the bark, they are *adnate;* and if by a single point near the middle, so as to swing, they are called *versatile*. When fully ripe, the cells burst longitudinally, or at the ends, to allow the escape of the pollen. Sometimes the latter is discharged by an elastic force.

The pollen is the matter which contains the fecundifying influence or principle, without the contact of which the seeds already formed in the ovarium would be abortive. The granules of the pollen are of various forms; under the microscope, they appear to be globular, oval, square, &c.; that of the sunflower is like a prickly ball, of mallow toothed, like a watch-wheel. Some have little tails (*caudicula*), and others are discharged in masses, several adhering together. The dispersion of the pollen is not only caused by the spontaneous action of the anthers, but is much facilitated by the visits of bees and other insects. The stamens are very fugitive, disappearing very shortly after the pollen is discharged.

The Disk. Between the base of the stamens and that of the seed-vessel there is a vacant space, or raised rim, of regular or irregular projections, called by modern botanists the disk, and which, by Linnæus and his followers, is called nectarium. This member of the flower is not always met with in the place

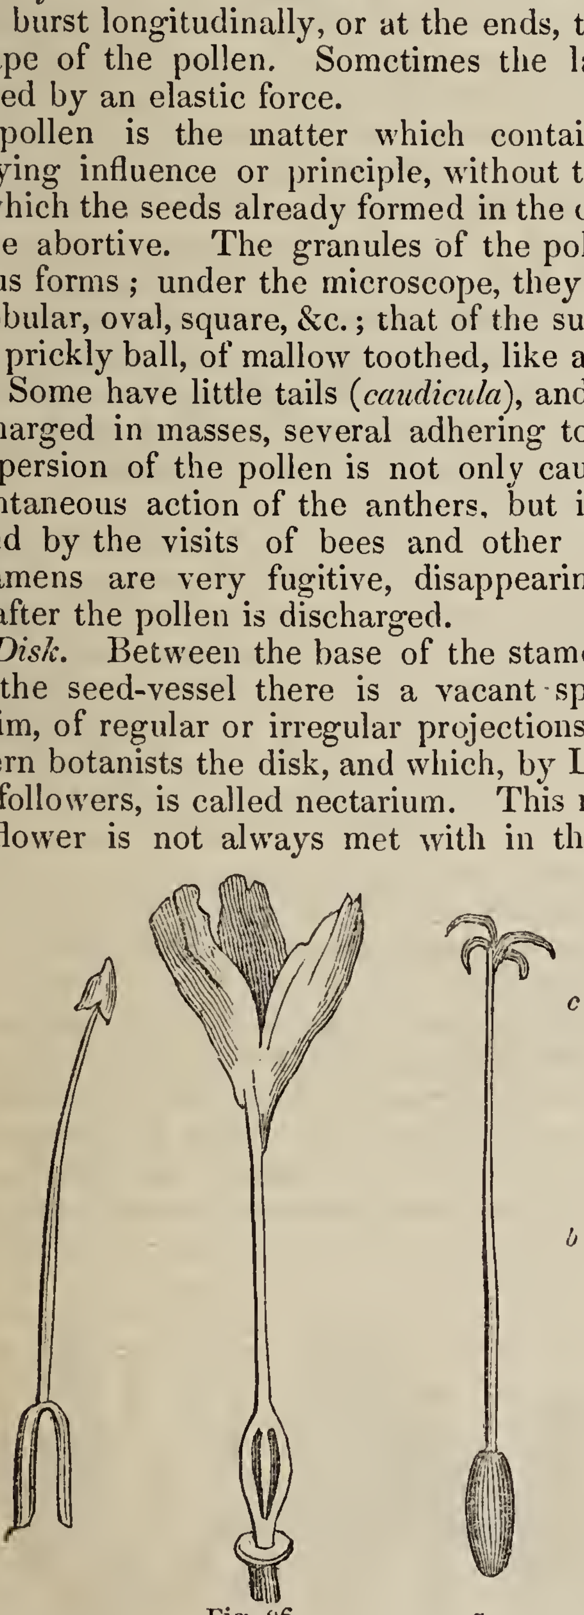


Fig. 26.

assigned to it, for it is sometimes above the germen. It also assumes so many different forms, that the most acute botanists are puzzled to find a proper name for it. Sometimes it is only a little shining cavity, or slight groove, in each of the petals; sometimes, as before observed, it is an erect scale at the bottom, or a fringe on the throat of the petals. In some cases it forms the principal member of the flower, as in the narcissus and ladies' slipper, in which two instances the forms do not at all accord with the title. But, whatever may be the station, shape, or size of the disk, it is considered in the modern schools of botany to be only imperfect, or metamorphosed portions of some of the other members of the flower.

The Pistillum. This is the principal organ of the fructification, and occupies the principal station, namely, the centre. It is the female, or reproductive part of the plant, and consists of three divisions, viz., the seed-vessel or germen *a*, the style *b*, and the stigma *c*. Fig. 26.

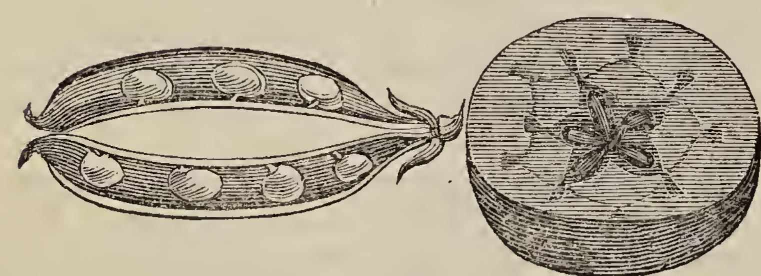
The first and third of these divisions are constant; the second is sometimes wanting.

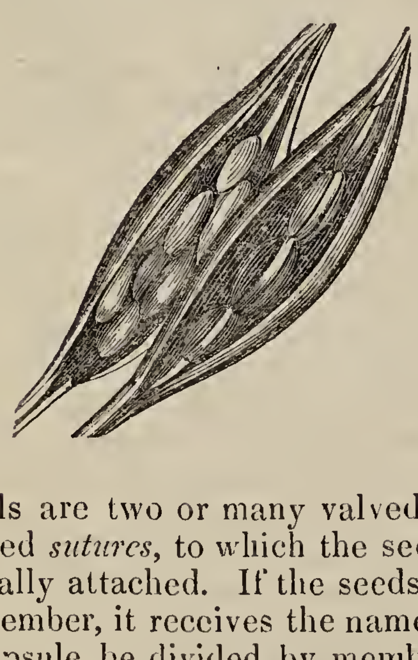
The seed-vessel has all the other members of the flower placed around or upon it. If below all the other parts, as in the pear and gooseberry, it is said to be inferior; if above the calyx, corolla, and stamens, it is said to be superior, as in the peach, orange, &c. It is one or many celled, and contains one or many seeds. In one class of plants it is formed of the calyx, the seeds lying naked in the bottom; hence such flowers are said to be gymnospermous. The seed-vessel is usually seated on the receptacle, hereafter to be described, but is sometimes elevated on a peculiar kind of stem, called *thecaphore*, either singly or several, in a kind of bunch.

As the ovarium is very differently constructed, and assumes many different shapes, it has many characters applied to it. In Linnæan botany it is called *capsula*, a little chest; *siliqua*, a pod; *silicula*, a short pod; *legumen*, also a pod; *folliculus*, a little bag; *drupa*, a pulpy valveless integument; *pomum*, an apple; *bacca*, a berry; and *strobilus*, a woody cone. Some of these names have fallen into disuse, and new ones, of more apposite meaning, substituted. Dr. Lindley, in his "Introduction to Botany," 1832, has arranged seed-vessels into four classes, viz.: First, APOCARPI, containing four divisions, namely, *Utriculus*, one-celled; example, Amaranthus. *Achenium*, one-seeded; example, Borago. *Drupa*, one-celled, one or two-seeded; example, Plum. *Folliculus*, one-celled, many seeded; example, Pæonia. *Legumen*, a pod; example, Pea. *Lomentum*, differs from the legumen in having contractions between each seed; example, Ornithopus. Second, AGGREGATA, fruit aggregate, viz., *Etæris*, ovaries distinct; examples, Ranunculus and Fragaria. *Syncarpium*, ovaries cohering into a solid mass; example, Magnolia. *Cynarrhodum*, ovaries distinct, pericarpia hard; example, Rose. Third, *Syncarpi*, fruit compound, viz., *Caryopsis*, one-celled, one-seeded; example, Wheat. *Regma*, three or more celled; example, Euphorbia. *Carcerulus*, many celled, superior; example, Mallow. *Samara*, a key, two or more celled, superior; example, the Ash. *Pyxidium*, one-celled, many seeded; example, Anagallis. *Conceptaculum*, two-celled, many seeded; example, Asclepias. *Siliqua*, one or two-celled. *Silicula*, similar in structure to the preceding, only more rotund; example, Shepherd's Purse. *Ceratium*, one-celled, many seeded; example, Corydalis. *Capsula*, one or many seeded; example, Primrose. *Amphisarca*, many celled, many seeded, pericarpium fleshy; example, Adansonia. *Tryma*, by abortion one-celled; example, Juglans. *Nuculanum*, two or more seeded; example, the Grape.

Hesperidium, many celled, few seeded; example, Orange. *Glans*, one-celled, one or few seeded; example, the Oak. *Cypsella*, one-seeded, one-celled; example, all compound flowers. *Cremocarpium*, two to five-celled, inferior; example, umbelliferous plants. *Deplotegia*, one or many celled; differs from the capsule only in being adherent to the calyx; example, Campanula. *Pomum*, two or more celled; example, the Apple. *Pepo*, one-celled, many seeded; example, the Melon. *Bacca*, a berry, many celled, many seeded; example, the Gooseberry. *Balausta*, many celled; example, Pomegranate. Fourth, ANTHOCARPI, collective fruits, viz., *Diclesium*, one-seeded, indehiscent; example, Spinach. *Sphalerocarpum*, one-seeded, enclosed within a fleshy perianthium; example, the Yew. *Syconus*, a fleshy rachis, having the form of a hollow receptacle; example, the Fig. *Strobilus*, cone, an amentum, the eupella of which are scale-like; example, Pinus. *Sorosis*, a spike, converted into a fleshy fruit by the cohesion of the ovaria with its envelopes; example, Mulberry.

These are the names or titles by which the different forms and structure of seed-vessels are known among botanists, and which, when committed to memory, are of the greatest use in abridging descriptions of plants, seeing that a single term, properly applied, serves the purpose of very many words. The annexed are figures of fruit.





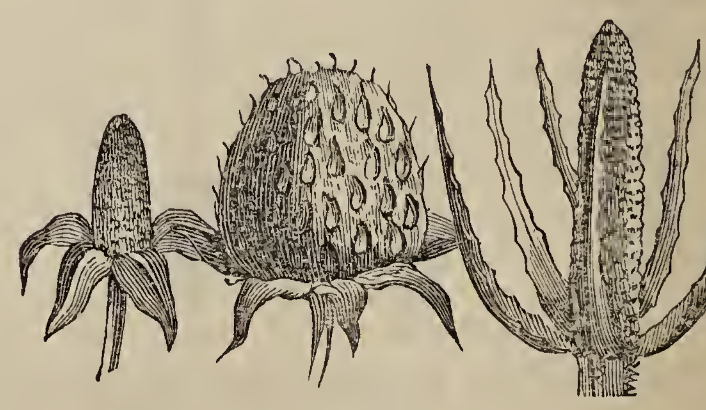
Seed-vessels are two or many valved. The junctures are called *sutures*, to which the seeds are sometimes umbilically attached. If the seeds are borne on an internal member, it receives the name of *placenta*; and if the capsule be divided by membranous partitions, these are called *dissepiments*.

The *Style* is that portion of the pistillum which, when present, serves to elevate the stigma. It is usually seated on the topmost part of the germen, and is of various lengths, sometimes protruding beyond all the other members of the flower. In form it is commonly cylindrical, and in structure tubular, to permit the descent of the influence of the pollen, which is disintegrated upon the stigma. Sometimes the style is entirely absent; in which case the stigma is seated close upon the capsule, as it appears on the poppy. As soon as the ovarium is impregnated, the style shrinks and withers away, leaving on some fruits a very small portion of its base. In many plants there is but one style, but in several of the Linnæan classes there is a plurality, so that the term polygynia (many females) is frequently used. The style and stigma are the most delicate members of the flower, being more easily injured by frost, or withered by the sun, than the other less essential organs.

The *Stigma*. This organ is always borne on the summit of the style, if the latter be present; or, in default of this, on the apex or crown of the germen or ovarium. It is the only part of a plant which has no cuticle, and when perfect, is usually covered with a thin lymph or fluid, the more readily to catch and retain the pollen discharged from the anthers upon it. In this fluid it is said the granules of pollen undergo some kind of change or solution preparatory to the descent of their influence into the ovarium. This change of the pollen has been repeatedly observed; and from the effects of foreign pollen artificially applied, there can be no doubt but that this is the course in which the sexual powers of plants are united and consummated.

The pistillum, consisting of the three divisions just described, is pretty uniform in appearance in most of the Linnæan classes, except *Syngenesia* and *Gynandria*, the *Compositæ* and *Orchideæ* of Jussieu. In the latter named order the filaments of the anthers and the style of the pistillum are united, forming a column on which both anthers and stigma are seated, but in such positions as to make the means of contact not very apparent. But diligent observers have discovered that there is not only a channel of communication, but a peculiar mechanism and elastic power in the filaments, by which a conjunction takes place with the greatest facility.

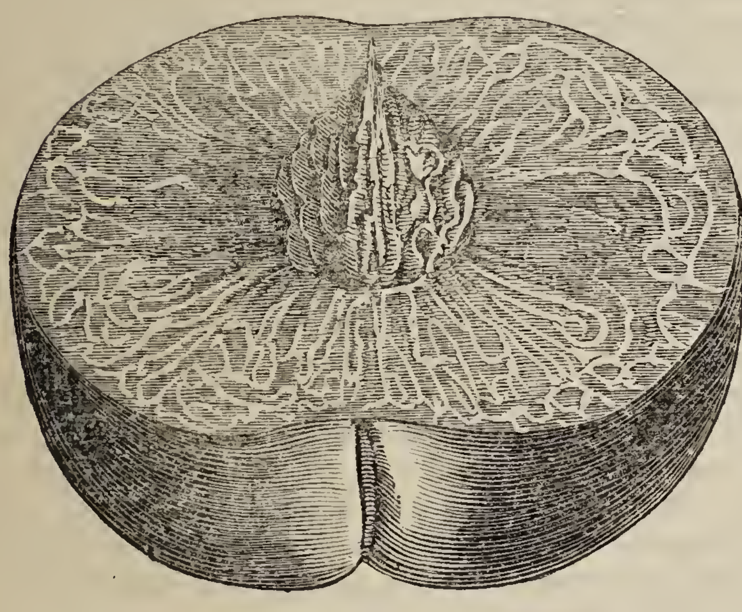
The *Receptacle*. This is the last member of the flower which remains to be noticed. It is that part on which all the other members are seated, either directly or indirectly. The calyx is usually borne on its edge; the corolla, stamens, and pistillum, on its disk. It is the termination of a fruit-bearing branch, or that of a peduncle, and is either nearly flat,



Receptacles.

elongated out in the shape of a slender cone, or enlarged into a thick fleshy cup.

The foregoing are the names of the different parts or members composing a perfect flower, but they are not all present in every flower. In some instances the calyx is wanting, or merged in the corolla, as in the tulip ; in the mezereon the corolla is absent, or it is absorbed into the calyx, which is coloured. Filaments are sometimes produced without anthers, and in some plants this defect appears to be constitutional, as the filaments are alternately barren and fertile. Some anthers have very short, or no visible filaments, they being non-essentials. The disk is often wanting, or inconspicuous, and so is the style ; but the stigma, seed-vessel, and anthers, must all be present to constitute a perfect flower in its normal or natural state. Some of these members, as has already been stated, are quickly perishable, others persisting to complete their functions. For instance, the calyx of the apple is united to the undistinguishable bases of the corolla and envelope of the ovarium, becoming a thick pulpy mass, bearing the sepals, which form the crown or eye, as it is called, of the fruit. The like is the case in the gooseberry. The strawberry is a fleshy receptacle; so is the fig. The peach, and other stone fruit, are pulpy pericarpiums composed of an outer skin (*epicarpium*), an intermediate pulp (*sarcocarpium*), and the stone (*endocarpium*), containing the ovula.



Section of a peach.

Plants which have been long in cultivation are very liable to have deformed or monstrous flowers, and for which peculiarity many receive the utmost care of the gardener and florist. This transformation happens in consequence of so many of the species and varieties of the same kinds being planted near together, and thereby allowing intermixture of the pollen of each other. High cultivation is also productive of unnatural luxuriance, particularly of the floral appendages. Not only are the sepals of the calyx, the petals of the corolla, the filaments of the stamens, all engrossed and deformed, but multiplied in some cases beyond measure. Even the pistillum itself becomes misshapen, its cuticle being dilated and produced upwards into leaf-like expansions, and coloured like the common foliage.

Naturalists have, until these few years, attributed all such transformations to excessive cultivation, and the interference of art, by which the natural condition of the vegetable organs suffer derangement. Such appearances are never seen on plants in their natural state, unless produced by the depredations of insects or other animals. Vegetable membrane is often seen unnaturally distended in consequence of wounds received on the stem, or fractured branches of the head. These distensions, however, never take the form of any other perfect organ; being mostly shapeless masses of bark and wood.

The illustration of these anomalies in vegetation, have in the modern schools of botany been advanced to a distinct branch of the science called " *Morphology*, or the metamorphosis of organs." A digest of the very curious doctrines involved in this new branch of the science, need not be entered into here ; suffice it to observe that they are founded upon what appears to be a dereliction from the general laws of nature. In all organised things, whether animal or vegetable, we find a compages of distinct members, each of which has its own place and functions. These are the vital, nutritive, conducting, preservative, and reproductive. The last is very manifest in animals; and to common understanding, the reproductive organs are as obvious and palpable as are any other of the appendages of vegetables. But it seems this idea is a mistake ; because, according to the new doctrine, the fructiferous organs of a plant have no rudimental identity, they being only accidental associations of the leaves ; that is, the calyx, corolla, stamens, and pistillum are only transformed and contorted leaves, in consequence of the shoot on which they are placed, becoming, by another accident " stunted."

It is needless to go farther by way of comment on this new view of the constitutional structure, malformations, and transformations of plants; it is a subject open to the consideration of every phytologist, who may come to such conclusion as he thinks most rational and agreeable to the laws of nature. It may just be added, however, that the morphologist succeeds pretty plausibly when employed in describing the changes of the leaves of a tulip into corolla, &c. or in doing the same with the garden poppy, till the capsule is opened displaying thousands of seeds, each of which he is bound to consider a convolved leaf, or a series of convolved atoms of leaves.

This opinion of the metamorphosis of plants having been first suggested by Linnæus,—sung of by the celebrated Goëthe—and embraced by De Candolle and other eminent botanists on the continent and in England,—has received very great attention ; but except in Dr. Lindley's " Introduction to Botany," it has not as yet received so full an investigation as the subject demands.

The foregoing descriptions of the different parts of plants, with the names given them by botanical writers, together with the accompanying figures, will serve to convey a general idea of the physiology of plants. On them the various systems of botany have been founded, as will appear in the subsequent sections of this article. But before entering on an exposition of the three most celebrated systems which have from time to time been given to the world, it may be requisite, perhaps, to advance a few observations on the growth of plants, or what is commonly called

Vegetable Life. That vegetables are organised bodies and endowed with a kind of life, is perfectly evident. Under favourable circumstances they are increased from a very small, to a considerable, and in some cases to a vast bulk. This phenomenon is commonly called growth ; and it is one of their properties which should be well understood, as well by the botanical student as by the practical cultivator of plants. It is impossible, however, to have a right conception of the accretion of vegetable bodies, without a clear understanding of the nature and properties of the membrane of which they are composed, the changes to which this is subject, and the essential qualities with which it is charged.

Vegetable membrane is not a homogeneous solid, but an aërolated mass, composed of innumerable vesicles or cells slightly attached to each other, and arranged in different forms, as the specific organisation of the plant requires. It is either extended into fibres and filaments, fig. 36, dilated into tissues, depressed into horizontal layers, fig. 37, compressed into perpendicular partitions, or disposed in regular columns. Each cell of these depositions is an insulated vesicle, having a thin, pellucid, elastic integument: originally inconceivably minute, but being capable of being distended to a limited size, but in a definite order, incident to the plant to which it belongs, and in any direction; the cells leaning, and clinging to each other, are consequently pressed into the various figures of spheres, ovals, hexagons, tetragons, cubes, or parallelopipedons. There are also intercellular spaces, which serve for conducting of fluids, or depositories of the secretions of the plant.

When the vegetable membrane is uniform in character, it is called *cellular;* when varied by being disposed into tubes and other organs, it is said to be *vascular.* The pellicles of the cells are of various consistence and properties as to durability. In the lower orders of vegetation they are mucilaginous and fugitive; in the higher orders they become ligneous; and along with the secreted juices of the plant, constitute what is called timber.

This organic structure of cells, &c., receives the nutriment necessary to the plant, consisting of aqueous and gaseous qualities extracted from the earth and atmosphere; and when combined in the aërolated fabric of the system, become elaborated and assimilated to the essential qualities thereof. By this reception of the elemental food, viz., oxygen, hydrogen, and carbon, the vessels of the system are supplied with these elastic principles; which when acted on by the heat, light, and humidity of air, intestine motion and consequent distension of the membranes take place, and thus the phenomenon of growth is exhibited.

It is only by constant attention, and the assistance of the microscope during the development of vegetable membrane, that the above stated facts can be illustrated. When first visible, it resembles a homogeneous jelly; no signs of organisation can be detected even under the best glasses: but as it acquires consistence, fibres, and ranks of cells gradually come into view; and soon afterwards the perfect structure is apparent. Hence it is reasonable to conclude that the cellular structure has form before any of the parts are visible; and that it is gradually developed as the season advances, until it arrives at its perfect volume.

This description is referable to every annual production, whether it be a single leaf, or shoot, or new layer of wood on the trunk of a tree; or whether it be a new bulb, tuber, root, or runner under ground.

The growth of an annual herb is perfected in a few weeks or months; its life is a gradual expansion, from the time it bursts from the seed till it ripens new seed, which is the last effort of the plant, and after which the whole dies. Some require a period of twenty months to arrive at full bulk and produce seed; such are called biennials. A few continue to grow for several years before they attain their perfect form to produce flowers and fruit. But in respect of the majority of shrubs and trees, there really appears no assignable limit to their growth; as their life only becomes extinct in consequence of being shattered to pieces by storms of wind.

The life of annual and biennial plants may be perpetuated by art. Sometimes by merely preventing their flowering, or by renewing them by the means of layering, or by rooting cuttings of their branches; and which layers or cuttings continue to grow for another season, and may, again and again, be preserved for several years by similar means. This expedient, however, is of little use in a practical point of view, as it is only necessary in the case of annuals which do not ripen seed in this country, nor are easily procurable from another.

Herbaceous plants called perennials, (living from year to year), produce stems and flowers, which die down after the seeds are ripe; but their roots increase and continue to live, barring accidents, for ever. In the same way the foliage, flowers, and fruit of deciduous trees are annually produced and shed; but the shoots and principal parts of the roots by which these were produced remain. The leaves of evergreen trees are shed in the second or some following year; and even the outer bark of some trees is triennially thrown off; while their interior axis of wood is permanent and remains sound for many years, according as it is more or less saturated with resinous sap, or more or less durable in quality. Thus, it is observable that all vegetables are increased by periodical expansions, some of the accretions being perishable, while others endure; some truly ephemeral, while others exist for ages. The largest tree is increased by annual additions, each perfectly distinct from all that preceded, and all that may follow. The permanent productions of this year, like all those of former years, remain, as to place and amplitude, ever after unchanged, till they fall to decay. This particularly applies to the new additions of wood, which, when once formed, undergo no further change in bulk or structure.

The longevity of trees depends upon the durability of the woody deposits. In most, if not all deciduous trees, the first formed layer or zone of wood, namely, that surrounding the pith, is the first to fall to decay. When this begins to take place, the layers, exterior to the first, decay rapidly; and though the trunk be receiving annually new layers of wood and bark on the outside they, together, do not keep pace with the destruction going on within; so that at last the trunk becomes a hollow cylinder; all the first formed layers of both wood and bark being dead, the life is compressed into a very narrow space between the alburnum and liber, and where it would ever continue, were the enfeebled trunk not laid prostrate by the tempest. This is the manner of what may be called the natural decay and death of a deciduous tree. It happens sooner or later, according to the solidity or texture of the wood, and to the conservative quality of the concreted sap with which it is saturated; and also according to the suitableness of the soil on which it is grown. The durability of fir and pine timber (except larch perhaps) depends entirely on the preservative qualities of the resinous sap, and this being usually in greater quantity at the centre than towards the exterior, the heart-wood, as it is called, is most lasting whether while the tree is standing, or after it is put to use.

The foregoing remarks include a brief description of the phenomena of vegetable growth, and involve the intricate question—what is vegetable life? From the facts adduced relative to vegetable organisation and expansion, we can only venture to assume, that, notwithstanding much may be traced to combined chemical and physical action, we must admit the existence of a vital principle which seems independent thereof; more especially in its power of existing for ages unimpaired in the bowels of the earth; and, while thus dormant, may be deemed an excitable or fermentable fluid, contained in an organised expansible body.

It is thus assumed, that all and every vegetable membrane, organ, or member, has rudimental existence before expansion. This is perfectly evident on dissection of any gross-growing plant. The flower of a bulb may be seen in the bosom of its investments long before it comes into view; so may the flowers of fruit trees be detected with the assistance of a microscope, twelve months previous to the bursting of the diminutive bud which contains them. Not only is it quite obvious that no plant whatever can come into existence unless from a seed, a sporule, or from a pre-existing part of itself, so neither can any one membrane of a vegetable body gain identity, unless from a pre-existing rudimental source.

It may be asked, what then, are all vegetable accretions only distensions or expansions? From what has been already stated, we must be of opinion that growth is nothing more or less than simple developement. Whatever vegetable, or part of a vegetable we attend to during growth, the only perceivable change is from small to greater bulk,—only from indistinct to evident and appreciable formation. The small shoot, leaf, or flower, is as perfect in its first visible state, as it is after full amplification. While the influences of air, and heat, and light, are acting on the elastic fluids of the system, the cellular and vascular membranes are elongated, and enlarged in definite order; the enlargement and inflation of the membranes being filled up by the induction of the elemental food imbibed from the earth and atmosphere.

This appears all very feasible in regard to the exterior accretion of plants; but what can be said of the interior growth—that of the new zone of wood for instance. It must be confessed that there is some difficulty here; principally because it is an invisible process. The fact that a new layer of white wood or alburnum is formed every summer, is known to every body; but whence it is derived, or how it is formed, is still involved in obscurity. By some physiologists it is supposed to be generated by the sap; which after perfect elaboration becomes coagulated into woody substance. Others suppose that the new zone of alburnum is formed by woody fibres, which descend from every bud above, in the same manner as seeds or cuttings send down fibrous roots into the earth. One contends, that it is a dilatation of the last year's alburnum; while another insists that it proceeds from the liber.

Without attempting a long drawn out refutation of the above suppositions, let it suffice to mention only a few facts bearing on some of the ideas, and a few doubts relative to others. The liber which comes into view at the end of the preceding summer, remains distinct and unchanged for many years after its first appearance; (instance the numerous layers of liber or inner bark of the common lime, or linden-tree, of which Russia mats are made) so that it is an error to imagine that the new alburnum is formed from liber. Neither is it a dilatation of the alburnum. This has been proved a hundred times by experiments of marking the last formed alburnum, which marks ever after remain undisturbed, though covered by the succeeding layers of new wood. That the new layer is formed by fibrous processes descending from the buds is plausible, if we only consider a stem or trunk of a few feet in length; but when we see the new layer of alburnum forming at the bottom of a lofty tree, almost as soon as it appears in the immediate neighbourhood of the buds, we have reason to doubt whether actual fibres can possibly reach so far down in so short a time, as intervenes between the bursting of the buds and the appearance of the new alburnum so far below. Another thing rather in favour of this notion, is, if the attachment of a bursting bud be examined, there are seen prominent bundles of fibres, apparently descending from the base of the bud, and disappearing downwards on the surface of the last year's alburnum. Whether these processes actually descend, or whether they are sap ducts, enlarged as they approach the craving outlet, is, perhaps, questionable. At any rate the supporters of this opinion must know that the buds, which burst into shoots in this year, are the production of, and attached to, the alburnum of the last year; and therefore cannot directly serve to increase the alburnum formed in this. The next idea relative to the accretion of alburnum yet to be noticed, is that which attributes the formation of wood, and indeed every other member of the plant, to the organisable property of the perfect sap. This fluid, it is said, after being elaborated in the leaves, returns down into the space between the last year's alburnum and liber; and there losing its fluidity, becomes pulpy or granulated, and by some other consolidating process is changed into a ligneous consistence, and into all the varied structure, viz. cells, tubes, air-vessels, and fibre of perfect timber.

Whether a fluid purely homogeneous, like the sap of plants, be capable of transformation into regularly organised matter, is a circumstance of which, perhaps, we have no parallel instance in nature. Even with the assistance of all the great natural agents, it is not probable that the simplest plant, or the simplest organised part of one, can come into existence fortuitously. We would therefore infer, that as all plants, and parts of plants, arise from a rudimental organised source, the new layer of alburnum has a similar origin; and that vegetable physiologists will in time be able to detect the source, and be able to show it in winter as well as in summer: for throughout the latter season, while in the state of what is called *cambium*, it is not only visible, but tangible, though wholly imperceptible to the naked eye in winter.

Having taken a brief view of the phenomenon called growth, we may next advert to that principal component of plants commonly called the sap. This is so intimately connected with vegetable structure, and evolution, that it is impossible to understand the developement of the one without appreciating the nature and uses of the other. As plants are composed of a vast assemblage of cells and vessels, fluids either gaseous or aqueous are necessary for their distension and completion. Water is the principal medium in which the elementary food of plants is conveyed to them, and for the reception of which their organs are so admirably fitted. The head of the plant waving in the air is, from the previous structure of its exterior surface liable to much waste by evaporation; this induces absorption of water at every inlet; and as these inlets are chiefly in the soil, where there is always some degree of moisture, the latter is readily received or absorbed: and hence a current upwards is generated, to supply every waste, and to fill and distend every vessel.

If the sap be drawn from the stem by boring near the root, it is found but little better than pure water; but if withdrawn from the top of the stem, or from the branches, it is found much richer in essential qualities. This is proof that the aqueous food of the plant undergoes a material change in the vascular frame of the vegetable; not only by simple admixture with the essential juices, but by assimilation thereto, by the agency of the peculiar elaborating apparatus incident to the plant. Hence we have resins, gums, acids, &c. Moreover, the elaborating powers of plants are so great, that chemists have detected chemical bodies in their juices, of which no trace could be found either in the earth or water in which they had been nourished.

The motion of the sap is visibly and principally upwards, also laterally, and downward. It is diffusible in all directions; passing into, and through every membrane where there is depletion. In this respect it is exactly like the absorption of water by a piece of sponge, or a knob of salt or sugar. In a high temperature, the sap is thin and its motion is accelerated. As heat declines, it becomes clammy, and in the cold of winter it is quite stagnant. At all times when in motion, and in sufficient quantity, it flows from wounds made through the bark; and when exposed to air either assumes the consistence of resin, gum, thick serum, or acidulous water. The recently formed layers of bark and wood, are the principal channel for the conduction of the fluids. When the first-formed parts of wood cease to act as channels, the sap becomes in them concreted in the cells and intercellular passages, giving solidity, a darker colour, and weight to the timber. This is very visible in pine timber, and easily proved by maceration in a proper acid. By such trials on oak and lignum vitæ, both colour and ponderosity are lost, and the fibrous frame only remains, as light and as fragile as that of willow. The outer layers of bark of many trees, also become, after a certain time, useless as sap ducts; and being no longer living members of the tree, retain those concreted qualities, which were deposited in their vascular substance when the sap used to traverse them:—instance oak bark.

The annual subsidence of the sap from the branched head, down in a body to the roots in the autumn, is a very old and generally received opinion; but it has never been clearly proved. There are several circumstances which appear to militate against such doctrine, and which, when stated, will enable the reader to judge how far such an idea is worthy acceptation.

The roots are never so destitute of sap, nor so capacious as to admit such an additional surcharge. The sap in the branches is not visibly diminished by such subsidence. The spring motion of the sap begins at the top of the tree; before it is at all liquefied at the bottom, which could not happen did the returning tide flow from the root. If we consider the motion of fluids in general, and in all ordinary circumstances, we invariably observe that their motions are caused by fluidity, ponderosity, or temperature; if they flow from a place which is full, it is because there is a vacant space to receive them: a rarer fluid will give place to one that is heavier; and consequently the warmest parts of a fluid will rise above those which are colder. But in all these cases an outlet or vacuum must exist, or the removal of some pre-occupying fluid must take place before any motion can be generated.

These are a few facts bearing on the question, and which must be explained away before we can fully understand how a general subsidence of the sap in autumn can possibly take place. It has been already observed, that vegetable membrane is permeable to fluids in all directions, and that the whole body of fluid sap in the autumn is of congenial quality, and equally diffusible into the roots as well as into every other part of the system; still direct proof is wanting to establish the truth of the opinion, that a *principal portion* of the sap of the head *descends* to the roots in winter.

SYSTEMATIC BOTANY.

Systematic botany has no very alluring aspect to a beginner. The great number of titles of the classes and orders, to say nothing of the generic and specific names, is a bar to commencing the study of the science. But when set about in earnest, the first difficulties quickly vanish; still much attention and time is required before such a knowledge of it can be acquired as to yield real pleasure to the student.

Initiation into this, like that of all other sciences, is laborious; stepping over the threshold is a kind of mental drudgery, and which is in fact the most irksome part of the undertaking; but when the student is fairly within the pale, the different avenues into the interior and more occult regions of the science are opened up; those thick clouds of difficulty which timidity or indolence had formed, are soon dispersed, and the student soon finds himself in an open expanse —in a new world, where he finds a thousand new objects which he can name at first sight. When this much is attained, the study becomes every day more and more interesting; every new plant is sought and examined with avidity: research is no longer toil; on the contrary, such investigation becomes delightful exercise, yielding positive pleasure; while every accession to the previous stock of knowledge is attended by fresh gratification.

The amateur botanist proceeding in this way soon acquires a competent knowledge of this pleasing science; he gradually becomes cognisant of the greater features, and gains such an insight into the details as dispels every obscurity which he thought he saw before him on his first entrance on the study. And when this much is accomplished, he enjoys every satisfaction that can arise from the knowledge of one of the most interesting branches of natural history, and which, moreover, is a necessary accomplishment of every well-educated mind.

To ladies particularly, and to the young of both sexes, the study of botany is a most agreeable exercise and amusement. Flowering plants always claim the regard of the young, of refined minds; and none are more enthusiastic lovers of fine plants than the aged botanist. For the pencil of the female artist, where can such elegance of form and delicacy of colour be found for imitation as in the parterre? or what can embellish the dwellings of the rich, or cottages of the poor, more than the floral products of vegetation?

Many are lovers of flowers who are not at the same time botanists. This feeling is as innocent as it is rational; it is a source of pleasure, but only in a subordinate degree to that enjoyed by those who to their love of flowers add scientific knowledge; who not only know the name, but can tell to what class or tribe the plant belongs—whether native or foreign—whether sanatory or noxious. No portion of human lore in natural phenomena yields more gratification to the well constituted mind than a scientific knowledge of plants.

To be a practical or professional botanist requires a long lifetime of close application and study. To store in memory nearly one hundred thousand names requires a power of retention enjoyed by few; and to nomenclature must be added acknowledge of the history of plants — their natural habitat as well as their culture: without an intimate acquaintance with these things no one can be a practical botanist.

Such a portion of knowledge is not merely a mental embellishment, nor is it merely an elegant amusement; though it may be employed as such by the affluent, yet it is in many respects eminently useful. To the medical man a knowledge of botany is indispensable; the virtues of plants are almost as various as are the genera; and their essential qualities furnish a very large proportion of materia medica. In the arts the products of vegetables are universally employed; and their value, as supplying articles of human diet, &c., hardly need be mentioned.

That both the culinary and medical uses of plants were discovered without the assistance of scientific botany, is perfectly true; but as the latter has been so much improved, discoveries for either purpose are made with much more certainty and success. There was a time when herbalism, or the study of the medical virtues of plants, was carried to an extravagant length, but since the excellent science of chemistry has been so closely united to that of medicine, the dreams and fooleries of astrological herbalism have been deservedly driven from the schools. That different plants possess different qualities is well known; and it is observable that the same qualities prevail, in a greater or lesser degree, in every species of the same genus. In this point of view, the Jussieuan system is superior to every other. This, indeed, is one of its most useful traits; because, if the predominating qualities of any one plant of a family, or, in many cases of an order, are known, it may be safely assumed that all the others partake of the same. Thus in the *Cruciformes* of Tournefort, the *Tetradynamia* of Linnæus, and the *Crucifera* of Jussieu (all different titles for the same family of plants), an acrid yet wholesome quality is found more or less in every species. Although this be pretty generally the case among the families of plants which Jussieu has placed together in the same order, yet there are some exceptions. Wholesome and poisonous plants are sometimes found in the same order; and this circumstance has been laid hold of to bring the whole *natural* system into disrepute by those who are averse to the study of it. Those opponents affirm that it contains incongruous associations, and refer to the order *Urticeæ* as a proof. It is true that in this order we find the bread-fruit, nettle, mulberry, fig, hop, &c., plants certainly very different in external form and manner of growth; but they have, besides their similar mode of flowering, some strong characteristics of affinity; for instance, the tough fibrous substances found in the nettle, hemp, hop, and others.

That the Jussieuan system is not yet perfect is true, but it is not incapable of improvement. Were it, as has been already observed, a little more abridged in its orders and in its vast number of genera by disregarding minor differences of form or position, it would be much more inviting as a study. In some of the natural families there may be groups which, compared with each other, are obviously distinct, so much so indeed as to have induced some very able practical botanists to separate them entirely from their congeners. Such intermeddling may be scientifically justifiable, but such diffusion of the system is always to be regretted, and should never be had recourse to if it can be possibly avoided. Errors or misconceptions of former authors certainly require correction, but old established genera should be cautiously dealt with.

In fine, in this improving age we have every reason to believe that no obstruction to the acquirement of pure botanical science will long remain in the way to impede the progress of the careful student. Every approach will be rendered open and every path made easy and inviting by those masters who are now so deservedly at the head of the science. It may be added that those who have no intention of aspiring to be scientific botanists may yet devote their leisure hours to a kind of botanising with great advantage and pleasure to themselves, if they have ever so small a piece of ground; or if wanting that, they may for amusement form a herbarium requiring only a few sheets of brown paper. By filling this receptacle with the commonest flowers they may gain a very clear insight into systematic botany by merely putting together every flower they meet with (whether they know the names or not,) according to its general character. For instance, collect all the bell-shaped flower (*campanula*) and place them together; do the same with the funnel-shaped (bindweed), the masked (snapdragon), the lipped (dead nettle), the cross-shaped (charlock), the rose-shaped (poppy), the lily-like (daffodil), the butterfly-shaped (broom), the compound (daisy), and so forth. Even such an attempt as this would be a pleasing and rational employment; a valuable first step to a better and more refined knowledge of plants; and which might be exercised in every walk into the garden, or in every ramble in the fields.

In entering on this part of the subject it occurs to us as unnecessary to notice any scheme previous to that of Tournefort, because, although his was not the very first, it was the first in respect of its acceptation with cotemporary botanists and kept its hold of public estimation till it was superseded by the new system of Linnæus. Tournefort founded his system on the absence or presence, the figure, situation, and proportion of the corolla. This part of the flower is always, when present, the most conspicuous and imposing; and attracted the notice of the earlier botanists (as it does that of children now) more than it really deserved; because in fact no part of the flower is more subject to incidental change than the corolla. He divided the vegetable kingdom into two principal parts, viz. herbs and trees; the primary divisions he subdivided into twenty-two classes; the first seventeen of which comprise the herbs, and the other five the ligneous vegetables; these are again separated into one hundred and nineteen sections, but without names or titles being applied to them, as in those of other botanists. The characters of these sections were not always sufficiently defined; and consequently the young botanist often met difficulties in arranging plants in their proper places.

In presenting a view of the system it will only be necessary to enumerate and name the divisions and classes, with their leading characters, which are as follow:—

DIVISION I. HERBS.

Class I. *Campaniformes.* Herbs having a simple, regular bell-shaped monopetalous corolla.—This class contains nine sections, distinguished from each other by the character of the fruit, as whether berry, capsule, folliculus, naked seeds, &c.

Class II. *Infundibuliformes.* Herbs having a simple, regular, funnel, salver or cup-shaped monopetalous corolla.—This class contains eight sections distinguished from each other by the character of the fruit.

Class III. *Personatæ.* Herbs having masked flowers, simple, monopetalous and irregular; the seeds contained in a pericarpium. This class contains five sections, differing from each other in the attachment and character of the fruit.

Class IV. *Labiati.* Herbs having lipped flowers, simple, monopetalous, and irregular, the seeds four, attached to the bottom of the persisting calyx. The sections of this class are four, differing from each other in the form and position of the upper lip.

Class V. *Cruciformes.* Herbs with cross-shaped flowers, simple, tetrapetalous, and mostly regular; the fruit a siliqua or a silicula.—This class has nine sections, founded on the shape, and number of locaments of the pods or fruit.

Class VI. *Rosacei.* Herbs having flowers resembling the rose, simple and regular, with from five to an indeterminate number of petals.—This class comprises ten sections, distinguished from each other by the character of the fruit.

Class VII. *Umbellatæ.* Herbs having their flowers disposed in an umbel, simple, pentapetalous, regular, and having two naked seeds attached to each other.—The sections of this class are nine, differing from each other by the size, shape, and markings on the seeds.

Class VIII. *Caryophyllei.* Herbs with flowers resembling the pink, simple, pentapetalous, regular, the claws of the corolla long, and attached to the bottom of a monophyllous calyx. The sections of this class are two, differing in one having a compound, and the other a single capsule.

Class IX. *Liliacei.* Herbs having flowers resembling the lily, simple, regular, monopetalous, with the limb deeply divided into six segments, tripetalous, or hexapetalous; the seeds contained in a capsule of three locaments. This class contains five sections, distinguished from each other by the pistil or calyx becoming a capsule.

Class X. *Papilionacei.* Herbs with butterfly-shaped flowers, simple, polypetalous, the fruit a legumen. This class contains five sections, differing from each other in the form, locaments, and numbers of the pods.

Class XI. *Anomalæ.* Herbs having simple polypetalous, irregular flowers, which do not conveniently fall in with any of the other of the above classes. This term, therefore, expresses only the extraordinary or irregular habit of the flowers of those plants which it contains. The sections of this class are three, distinguished by having capsules of one or several cells, formed out of the calyx or pistil.

Class XII. *Flosculosi.* Herbs with compound flowers, consisting of many tubulose, monopetalous florets, placed on a common receptacle; the stamens united by the anthers, in the second, third, and fourth sections. This class contains five sections, distinguished from each other from having no seeds(!) single seeds with a pappus, single seeds without a pappus, florets having a calyx, and the same with a calyx, but with distinct anthers.

Class XIII. *Semiflosculosi.* Herbs having compound flowers, consisting of many monopetalous, ligulate corollets, placed on a common receptacle, the stamina united by the anthers. The sections of this class are two, distinguished by having ligulate flowers, the seeds crowned with a pappus; and ligulate flowers, the seeds without a pappus.

Class XIV. *Radiati.* Herbs having compound flowers, consisting of many monopetalous corollets, placed on a common receptacle; the florets of the disk tubulose, and those of the margin ligulate. The sections of this class are five, and differ from each other by the seeds being crowned by a pappus, or palea (chaff), or naked, or contained in capsules, or having the rays composed of broad folioles.

Class XV. *Apetalæ.* Herbs having stamens and pistils, but no corolla, the calyx being the only part that envelopes these organs. This class contains six sections, having the following characters:—apetalous flowers, in which the calyx became the fruit; the same in which the pistil became a single seed; the same, but in which the seeds contained farinaceous matter, (viz. all kinds of corn and grasses); apetalous flowers in scaly heads; the same, with stamens and pistils separate on the same root, and the like on separate roots.

Class XVI. *Apetalæ et Aflores.* Herbs having neither stamens nor pistils, but only seeds on the back of the leaves. The sections of this class are two, viz. with seeds symmetrically disposed in clusters or lines on the backs of the leaves; or with seeds growing in ears, or in capsules.

Class XVII. *Apetalæ, et Aflores, et Acarpii.* Herbs having neither flowers nor apparent seeds. This class contains only two sections, viz. such as grow on the earth, or on other vegetables; and such as grow under water. This class contained the mosses, funguses, and all the algæ, except the lichens.

DIVISION II. TREES AND SHRUBS.

All plants of these characters are arranged by Tournefort in five classes, founded on their modes of flowering, and forms of the fruit.

Class XVIII. *Apetalæ.* Trees or shrubs having stamens and pistils, but no corolla. This class contains three sections; the first having stamens and pistils in the same flower; the second having stamens and pistils separate on the same plant; and the third having stamens and pistils on different roots.

Class XIX. *Amentaceæ.* Trees and shrubs having their male flowers, and some of their female flowers also, disposed in an amentum. This class contains six sections, and are distinguished by their unisexual flowers being separate and dissimilar on the same root, producing a nut; or the like on the same root, the fruit being contained in a leathery capsule; or a simple or compound berry; or in a strobilus; or in a globular scaly receptacle; or lastly, trees and shrubs with male and female amentaceous flowers on separate roots.

Class XX. *Monopetalæ.* Trees and shrubs having monopetalous, campanulate, or infundibuliform flowers. This class contains seven sections, distinguished from each other by the character of the fruit; that is, whether drupe, berry, capsule, follicle, &c.

Class XXI. *Rosacei.* Trees and shrubs having rosaceous polypetalous flowers. There are nine sections in this class, founded on the character of the fruit.

Class XXII. *Papilionacei.* Trees and shrubs having papilionaceous flowers and leguminous fruits. This class contains three sections, distinguished from each other by the character of their leaves, viz. whether simple, or pinnate, or ternate.

The above is an abridged sketch of the system of Tournefort; and is given with the view that the reader may see by what gradual steps the science of botany has risen from a chaotic mass of indistinction to its present improved state; and to show also how much is really due to the great industry of its author as a practical botanist. His labours, considering the state of the science when he lived, were indeed great, and far surpassing those of either Linnæus or Jussieu. In fact, Tournefort was pioneer to both; and amassed, and in many cases assorted to their hands, the materials of which both their systems are formed.

THE LINNÆAN, OR SEXUAL SYSTEM.

The sexuality of plants had been discovered long before the time of Linnæus. But as far as is now known, he was the first who suggested the idea of classifying plants according to the numbers, connection, and stations of the male and female organs. From the moment the idea occurred to him, he was indefatigable in the completion of a system which he, no doubt, fondly flattered himself was founded in nature. His great acquirements as a scholar, his love of natural history, his station among learned men, and his connection with many learned societies, eminently fitted him for achieving this great and laborious work.

The plan of the Linnæan system of botany was intended to comprehend the whole vegetable kingdom, and which was arranged in two grand divisions, namely, plants having visible flowers (*Phænogamia*), and plants having no visible flowers (*Agamia* or *Cryptogamia*).

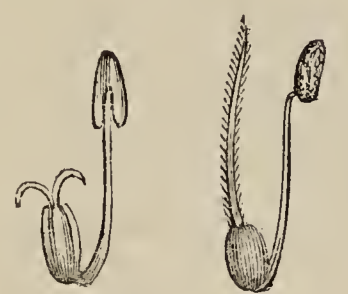
The first grand division comprises twenty-three classes, founded on the number, the position, and stations of the stamens and pistils. The first eleven classes proceed in an uninterrupted series, from one to twelve stamens, and are named respectively from their number. The titles or terms used to express the classes, are compounded of the Greek numerals and the word *andria*, signifying man. These classes are subdivided into orders, which are designated from their number of pistils by Greek numerals also, with the addition of the word *gynia*, which signifies woman. There being no plants which have invariably eleven stamens, this class in the order is called *Dodecandria*, and contains all plants having from eleven to nineteen stamens. The twelfth class is known from having twenty or more stamens, seated upon the corolla or calyx, and which sufficiently distinguishes it from the thirteenth class, which has also twenty or more stamens, but these are seated on the receptacle or base of the flower.

The fourteenth and fifteenth classes are distinguished, not by the number of their stamens, but by their unequal length: the first has four stamens, two of which are longer than the others. This class is further distinguished from having invariably ringent, that is, gaping flowers. The fifteenth class has six stamens, four long and two short, with one pistil and cross-shaped flowers.

The sixteenth class is known by having the filaments united in one body at the bottom, and without regard of their number. The seventeenth class has stamens united in two sets, and is otherwise easily known from having also papilionaceous flowers. The eighteenth class has its stamens in three or more sets. The nineteenth class contains all the compound flowers, and a few other genera having single flowers. The leading character of this class is in the anthers being united in a cylinder round the style. The twentieth class is known by having its anthers growing on the pistil, and not on the receptacle. The twenty-first class has male and female flowers separate, but on the same plant. The twenty-second has male flowers on one plant, and females on another. The twenty-third class contains those genera which have not only unisexual flowers on different plants, but also bisexual flowers intermixed. The twenty-fourth class contains all plants whose flowers are inconspicuous. To these Linnæus added another class, which he called *Palmæ*, the flowers of which were not sufficiently known in his time to admit of their being properly placed in the system.

The foregoing is a general sketch of the classes of the Linnæan system; we have next to present a view of the subdivisions or orders of each class, which, with figures of the parts on which the distinctions are formed, will give as clear a view of the system as is consistent with the plan of this article.

The first class, Monandria, having one stamen, contains only thirty-three genera, and two hundred and fifty species. Some of the genera, as the *Cannas* and *Hedychiums*, are highly ornamental exotics; and the *Zingiber officinale*, the common ginger, is an important article of commerce; both seeds and roots of many plants in this class are used in medicine, as well as by the dyer, as galangale, turmeric, arrowroot, and zedoary. Their predominating qualities are aromatic. They are chiefly reed-looking, herbaceous plants, with large leaves and showy flowers. Several of the genera are British, as centranthus, glass-wort, mares-tail, and wrack-grass. The mares-tail, *Hippuris*, is a curious plant, not uncommon in ponds and ditches. It has a single jointed stalk, and at each joint are twelve or more linear leaves, placed verticillate or in a whorl. To each of these leaves, and close to the stalk, sits a little flower consisting of a single stamen and pistil, one seed and nothing more; both calyx and corolla being wanting. All the plants alluded to above are in the first order, Monogynia, they having only one pistil. In the second order, Digynia, having two pistils, there are seven genera, one of which is the *Callitriche*, or water starwort, which is also an aquatic, being frequently met with in ditches. There is another plant, sometimes sown in flower borders as an ornamental annual, which belongs to this order. Its chief ornament is its fruit, which are thickly set on its branches, resembling strawberries: hence it is called strawberry blite,—*Blitum capitatum*. The sexual distinctions of this first class, with the two orders, are represented thus:—



Class Monandria.

The second class is Diandria, that is, flowers having only two stamens. There are sixty-one genera in this class, and which are divided into three orders.

The first order, Monogynia, having one pistil, contains by far the greater number of the genera. Here we find the useful olive, the beautiful and fragrant jasmine, and many fine evergreen shrubs. The lilac, the fringe tree, and catalpa, also belong to this order. Nor are the herbaceous plants found here less prized. The wild and cultivated speedwells, the delicate schizanthus, the showy justitias, and the elegant slipperworts, are some of the choicest gifts of Flora. The rosemary, and numerous species of sage, those fine medicinal plants, are ranked in this order. Some botanists have suggested the removal of this last named genus to the class *Didynamia*, because, although there be but two perfect stamens, there are the rudiments of two others in the flower. "The structure of the stamens in the sage is singular: the two filaments are very short, but two others are fastened to these transversely by the middle; and at one end of these is a gland, at the other an anther. This circumstance distinguishes the genus from all others, and is called its essential character."

Class Diandria.

In the second order, Digynia, plants with two pistils, there are only three genera, and they are properly grasses. Here we find the sweet vernal grass, *anthoxanthum odoratum*, which so greatly assists to give to hay its agreeable scent. It is also one of our best pasture grasses, and much cultivated.

In the third order, Trigynia, that is, plants with two stamens and three pistils, there are only two nearly allied genera, namely, the pepper and *peperomia*. The first is universally used as a spice; is extensively cultivated in India, and is a most important article of commerce. Even the leaves of *Piper Betel* are a necessary of luxury, if not of life, in India, being used to chew along with the betel-nut of that country.

The distinctions of this class and order are graphically annexed.

The third class of the system is Triandria, and which contains three orders. It comprises two hundred and seven genera and one thousand five hundred and forty-nine species. The plants arranged here are of the most interesting character. They form the general verdant covering of the earth, affording pasturage for our flocks and herds at almost all seasons, and fodder when the fields are buried in snow. Almost all the useful plants, significantly called *cereals*, are found in this class; the "staff of life," and all the different sorts of grain which serve to feed and to fatten the animals which serve for our "sport or gust," are derived from one or other of the triandrious class. In bulk the grasses are so diminutive as aggregately to form the compactest carpet-like turf; and on the other hand, on the banks of lakes and rivers they grow up into impenetrable reedy thickets. Nor are the other genera ranked here less remarkable for the beauty of their flowers than are the cereals for their usefulness. The well-known crocus, the corn-flag and iris, and many allied foreign genera, are among the chiefest ornaments of our gardens, and which compensates in some measure for their want of usefulness when compared with their associates the cereals. No class shows more decidedly the artificial character of the Linnæan system than this; for assuredly the iris and wheat can claim no congeniality with each other, either in external structure or constitutional properties; but these having each three stamens compelled the author to place them together.

Class Triandria.

The class is divided into three orders, Monogynia, Digynia, and Trigynia, the first having one pistil, the second two, and the third three. The second order, Digynia, contains most of our common grasses, as millet, panic grass, bent grass, fox and cats' tail, oat and cocks'-foot grasses, besides wheat, barley, &c., together with the far-famed sugar cane, that source of wealth to the tropical planter, and indispensable condiment in the diet of all nations.

The third order, Trigynia, contains only twelve genera, most of them and and water annual weeds:

some are curious or pretty, but none are cultivated out of botanical collections.
