It is considered that the simplest, and most scientific form for an ice-house, is a double cone, that is to say, two cones joined base to base, the one sunk into the earth with its point downwards, into which the ice is rammed, the other being a conical roof, generally of wood-work, covered with thatch and pointed at top. The entrance should be placed always on the north side, and provided with two doors some distance apart, and the spot screened from the sun by trees, shrubbery, a hill, cliff, or other barrier. The lower part may be dug about 16 feet in diameter, terminating below like the point of a sugar-loaf. Its ordinary depth, for a moderate family, may be about 24 feet. The larger the dimensions, the longer will it preserve the ice, provided it be filled. In digging, the workmen should slope the ground progressively towards the axis of the cone, to prevent the earth falling in. This conical slope should be faced with brick or stone work about one foot thick, and jointed with Roman cement, so as to be air and water tight. A well is to be excavated at the bottom two feet wide and four deep, covered at top with an iron grating for supporting the ice, and letting the water drain away.

The upper cone may likewise be built of brick-work, and covered with thatch; such a roof would prove the most durable. Whatever kind of roof be preferred, there must be left in it an oblong passage into the interior. This porch should face the north, and be at least 8

feet long by $2\frac{1}{2}$ feet wide; and perfectly closed by a well-fitted door at each end. All round the bottom of this conical cover, a gutter should be placed to carry off the rain to a distance from the ice-house, and prevent the circumjacent ground from getting soaked with moisture.

The ice-house should have no window to admit light; but be, so to speak, hermetically sealed in every point, except at its cess-pool, which may terminate in a water-trap to prevent circulation of air.

A clear day should be selected for charging the ice-house; but before beginning to fill, a quantity of long dry straw should be laid on the bottom crosswise; and as the ice is progressively introduced, straw is to be spread against the conical sides, to prevent the ice from coming into contact with the brick or stone work. The more firmly compacted the ice is, the better does it keep. No layers of straw should be stratified among the ice, for they would make its body porous. Some persons recommend to pour in a little water with the successive layers of ice, in order to fill up its small crevices, and convert the whole into one mass. This may answer well when the ice is put up very cold, as the water may then be directly frozen into a solid mass.

Over the top-layer a thick bed of straw should be spread, which is to be covered with boards surmounted with heavy stones, to close up the interstices in the straw. The inner and outer doors should never be opened at once; but the one should always be shut before the other is opened.

Dry snow well rammed keeps equally well with hard ice, if care be taken to leave no cavities in the mass, and to secure its compactness by sprinkling a little water upon the successive charges.

To facilitate the extraction of the ice, a ladder is set up against its sloping wall at one side of the door, and left there during the season. (*Ure's Dict.*)

The time preferred for filling an ice-house, should, when practicable, be during the prevalence of extreme cold, or as soon after as possible, since the colder the ice when packed away, and the thicker the blocks, the longer it will last. Ice and snow can often be laid by, even in the Middle States, many degrees below 32° or the common freezing point of water. The larger the quantity of ice accumulated in one place, the slower will be the rate at which it will melt.

One of the principal objects to be kept in view in the construction of an ice-house, is to have it so that the water will pass off directly, as fast as the ice thaws. If the situation is sandy, or if you come to a layer of sand or gravel about the proper depth, no further care will be necessary; but if you find a stiff clay, rock, or earth of any kind impervious to water, you must contrive an outlet or abandon the place. This outlet may be constructed in several ways. If on the side of a hill, dig a drain and make it air-tight by means of a water-trap or inverted syphon; or the water may be drained into a well and pumped out; or you may sink a well in the bottom until you come to sand or gravel, and fill it up with stone. The cellar

walls may be laid with stone, brick, or even lined with wood, as is most convenient or economical. A space of 8 or 10 inches is generally left between the wall and surrounding earth, which is filled in with tan, charcoal, straw, corn-stalks, or any other non-conductor of heat, the first-named article being generally preferred. A house 9 feet square in the clear, and 9 feet deep, will hold about 25 cart-loads of ice, which will be enough for a large family.

A cheap ice-house may be made thus:—Dig a cellar, say 10 feet square, and 10 feet deep. Then cut small timber from the woods the proper length, and build up in the cellar after the plan of building log-cabins, leaving a space between the logs and earth to be filled in with straw, tan, or other suitable material. Raise the wooden walls 2 or 3 feet above the surrounding ground, and heap up a bank so as to turn off the rain-water. A thatched roof is generally recommended, as the best to keep out heat, but some object to such covering as affording harbour to rats and other vermin.

The importance of keeping ice well surrounded with a non-conductor, and having the water absorbed as fast as melting takes place, is shown in the following extract from the *Kentucky Farmer*:—

“We take at sunrise from the ice-house, as much as will be probably wanted through the day, and cover it up in some saw-dust placed in a barrel in the dairy-house. At night, the size of any given piece is scarcely perceptibly diminished. It is a perfect charn.”

In some parts of the United States where thick ice is rare, some persons pack away large quantities of snow, which, if the mass be large, and the snow dry or previously well drained, will often keep through the summer. In most seasons ice may be collected in sufficient quantities to fill ice-houses in every latitude of the Middle States. If no pond or stream of water of sufficient size be at hand, advantage may be taken of any little rill, which, by the erection of a small dam, may be made to overflow a considerable space. If the water be not more than 6 or 8 inches deep it will answer every purpose.

In stowing away ice the pieces should be as square as possible, and as large as they can be got or handled. They should be placed closely together like stone in a wall, and the crevices well filled with smaller fragments. The plan sometimes recommended of pounding or crushing the large pieces is reprehensible.

ICHNEUMON FLIES. Insects belonging to the natural order *Hymenoptera*, which includes bees, wasps, ants, saw-flies, &c. The injury caused by this whole order is so small, and the benefits derived from many of them so great, that instead of being enumerated among destructive insects, they may be pronounced the benefactors of the human race.

With regard to the ichneumon flies, they perform an important and very singular part in the economy of nature, by working the destruction of caterpillars, plant-lice, and other destructive insects. This they effect by piercing their bodies with a kind of sting or piercer called ovi-positor, and thus laying their eggs in a living nest. Each ichneumon fly seems

to single out the larva or pupa of some particular kind of caterpillar or other insect, to which it therefore stands in the relation of parasite. The eggs hatch in due time, and the larva of the ichneumon commences feeding upon its victim, the vitals of which are soon destroyed, after which the parasite or ichneumon comes forth in due time to another state of existence.

Some of the ichneumon flies are extremely small, and confine their attacks to the eggs of other insects, which they puncture, and the little creatures produced from the latter find a sufficient quantity of food to supply all their wants within the larger eggs they occupy. The ruby-tails and cuckoo-bees lay their eggs in the provisional nests of other insects, whose young are robbed of their food by the earlier hatched intruders, and are consequently starved to death. The obligations which the farmer and society at large owe to certain parasite insects is forcibly illustrated in the case of the Hessian fly, the devastations of which are often prevented through the destruction, during a single season, of nearly a whole race by its parasite.

Professor Peck has described a minute ichneumon fly, stated by Mr. Westwood to be a species of *Encyrtus*, that stings the eggs of the slug-fly, and deposits in each one a single egg of her own. From this in due time a little maggot is hatched, which lives in the shell of the slug-fly's egg, devours the contents, and afterwards is changed to a chrysalis, and then to a fly like its parent. Professor Peck found that great numbers of the eggs of the slug-fly, especially of the second hatch, were rendered abortive by this atom of existence.

In treating of the *pigeon tremex* (*Tremex columba*), which in its larva state is a destructive tree-borer, Dr. Harris observes that it is often destroyed by two kinds of ichneumon-flies, (*Pimpla atrata* and *lunator* of Fabricius), which may be frequently seen thrusting their slender borers, measuring from three to four inches in length, into the trunks of trees inhabited by the grubs of the tremex and by other wood-eating insects; and, like the female tremex, they sometimes become fastened to the trees, and die without being able to draw their borers out again.

The ichneumon flies are little busy-bodies, ever on the alert, and with untiring scrutiny continually prying into every place to find the lurking caterpillar, grub, or maggot, wherein to thrust their eggs. (Harris.)

A specimen of this extensive family is represented in Pl. 15, fig. 12, in the *Trogus fulvus*, which commits great havoc among caterpillars and grubs. See APHIDIANS, &c.

IGNIS FATUUS (Lat. vain or foolish fire; a translation of the French *feu follet*.) A kind of luminous meteor, which flits about in the air a little above the surface of the earth, and appears chiefly in marshy places, or near stagnant waters, or in churchyards, during the nights of summer. There are, we are told, many instances of travellers having been decoyed by these lights into marshy places, where they have perished; and hence the names *Jack-with-a-lantern*, *Will-with-a-wisp*; the common people ascribing the appearance to the agency of evil spirits, who take this mode of alluring men

to their destruction. The cause of the phenomenon does not seem to be perfectly understood; it is, however, generally supposed to be produced by the combustion of some highly inflammable gas, such as phosphorated hydrogen, which takes fire spontaneously on rising and mingling with atmospheric air.

Milton, in his *Paradise Lost*, b. ix. l. 634, thus alludes to it:—

A wandering fire,
Compact of unctuous vapour, which the night
Condenses, and the cold environs round,
Kindled through agitation to a flame,
Which oft, they say, some evil spirit attends,
Hovering and blazing with delusive light,
Misleads the amazed night wanderer from his way
To bogs and mires, and oft through pond or pool,
There swallowed up and lost, from succour far.

IGNITION (Lat. *ignis*, fire). The act of setting fire to, or of taking fire, as opposed to combustion, or burning, which is a consequence of ignition. The term "spontaneous ignition" is applied to cases in which substances take fire without previous application of heat. This is illustrated in the burning of hay-stacks, when the hay has been put up too green; the scorching of corn-stacks from the same cause, and the taking fire of ships laden with fermentable products.

IMBRICATED. In botany, a term used in speaking of the arrangement of bodies, to denote that their parts lie partly over each other in regular order, like the tiles upon the roof of a house, as the scales upon the cup of some acorns; also applied in speaking of the æstivation of petals or leaves, to denote that they overlap each other at the margin without any involution. (*Brand's Dict. of Science*.)

IMPLEMENTS, AGRICULTURAL. Almost all the operations of agriculture may be performed by the plough, the harrow, the scythe, and the flail; and these, or similar tools for performing the same work, are the sole implements in the primitive agriculture of all countries. With the progress of improvement, however, many other implements have been introduced, the more remarkable of which are the drill-plough, the horse-hoe, the winnowing machine, the thrashing machine, and the reaping machine. The object of all these implements and machines is to abridge human labour, and to perform the different operations to which they are applied with a greater degree of rapidity, and in a more perfect manner than before. In the present work the different implements are treated of in their alphabetical order. Of the progress made in the construction of agricultural instruments in England, the judges of implements at the Liverpool meeting of the English Agricultural Society, in their report very justly remark, when speaking of "the good effects which have already resulted from the public exhibition of implements at the Society's meetings, in stimulating the talent of the mechanic and the zeal of the husbandman. At Oxford the show-yard may be said to have presented an epitome of the state of agricultural mechanism existing in 1839, the era of the formation of the Royal Agricultural Society of England. No spectator of that show can have failed to be struck with surprise and admiration at the Liverpool exhibition. At Oxford there were some examples of good machinery

and workmanship, but many more of rude, cumbrous, and ill-executed implements. At Liverpool many machines were exhibited, not only of surpassing skill in contrivance and execution, but also having for their object the effecting of processes in tillage-husbandry of the most refined nature and acknowledged importance, but hitherto considered of very difficult practical attainment. Some of these may already be considered as forming part of the necessary apparatus of every well-managed farm, and to be essential to its economy and profit. This vast stride in the mechanics of agriculture, made within so short a period, has doubtless arisen from the congregating together of agriculturists and mechanicians from all parts of the empire: and a still higher perfection in machinery may be confidently anticipated from the opportunity offered, under the auspices of the Society, of periodically contrasting and estimating the merits of varied implements used for similar purposes in different localities and soils. It is apparent that the manufacture of even the commoner instruments has already, to a great extent, passed out of the hands of the village ploughwright and hedge-carpenter, and been transferred to makers possessed of greater intelligence, skill, and capital. The improved style of finish, the greater lightness and elegance of construction, and the generally superior adaptation of the means to the end, in every class of implements, were sufficient manifestations of the beneficial results arising from the encouragement given by the Society to these objects. Neither were examples wanting in the higher classes of machines to show that the fourth important object for which the Society was incorporated is, to some extent, fulfilled—viz. ‘to encourage men of science in their attention to the improvement of agricultural implements.’”

The great variety of soils and fluctuations of climate in the extensive territory of the United States, call for multiplied expedients to till the various plants, and provide shelter from heat as well as cold. The wants and exigencies known in various parts of the country must therefore contribute to make the United States a fruitful field of inventions. Accordingly, by consulting the records of the Patent Office at Washington, we find that since the year 1793, when the first patent law was instituted, and up to the year 1836 inclusive, the number of patents taken out for inventions is 6000, of which 124 are for improvements in the plough,—119 for threshing-machines,—80 for churns,—125 for washing-machines, &c.

The remarks of the Messrs. Ransome, of Ipswich, upon the preservation of agricultural implements in general, are such as every farmer should be guided by. They suggest to farmers generally, that a little instruction given to the workmen in the use of the machines, and care in preserving them, would add to their efficiency and durability. Attention to washing implements and machines before laying them by, a little oil on such as have revolving wearing parts, and a coat of paint occasionally to each, will cost but little, and make the difference between having a machine ready for use, or covered with rust and want-

ing repair just as the season for its use commences. These suggestions are so obvious, that one would think no apology needful for making them, as experience proves that a large proportion of the repairs required arises from want of attention to these apparently trifling matters. And to this end the advice of Mr. Crosskill, of Beverley, may be acted upon with considerable advantage: he says, “Select the most likely labourer on the farm, put the implements under his care, make it a strict rule with all the men that each implement done with for the season shall be brought to one particular place, say near the pond or pump; the man having charge of the implements must then wash and clean them well before putting them into the shed.”

IMPOSTHUME. In farriery a sort of swelling, or collection of matter or pus in any part of the body of an animal. See **ABSCESS**.

IN-AND-IN-BREEDING. The practice of breeding from close relations. See **BREEDING, CATTLE, SHEEP, &c.**

INCH. A measure of length, the twelfth part of a foot.

INCISORS or **INCISORES** (Lat. *incido*, I cut). The teeth implanted in the inter-maxillary bones of the upper jaw, and in the corresponding place in the lower jaw, and which are generally shaped for the purpose of cutting or coarsely dividing the food. The ruminating animals, including the bull and cow, sheep, goats, the deer tribe, and the camel have no incisors in the upper jaw; but some of them have canine teeth, which project from the mouth. See **AGE OF ANIMALS**.

INCLOSURE (Lat. *inccludo*, I shut up). See **ENCLOSURE**.

INCUBATION (Lat. *incumbo*, I brood over). Hatching or the laying down of an animal upon her own or another's eggs, communicating to them heat, and maintaining them at her own temperature, a condition essential to their developement. In many animals the developement of the fœtus takes place after the exclusion of the egg, and whilst it is maintained in contact with the external surface of the parent's body, as in the crab and lobster tribes beneath the caudal plates; or agglutinated to the surface of the abdomen, as in certain species of pipe-fish (*syngnathus*), or concealed in cutaneous marsupial cavities, as in other species of *syngnathus*, and the *hippocampus*; but in these and other instances from the cold-blooded animals, the eggs are retained by special contrivances in contact with the parent, without occasioning any restraint upon her postures or movements.

That a due degree of warmth is the essential object of incubation in birds is proved by the ancient and well-known practice of substituting artificial heat, by which fertile eggs are hatched in the same period, and the excluded chick is as fully and strongly developed as when produced by natural incubation.

Artificial incubation has been practised from a remote period by the Egyptians and Chinese: the former, indeed, have carried this process to such a high degree of perfection, as in many instances to have entirely superseded the use of the hen in hatching.

It is effected either by means of an oven, stove, or steam, and it has been calculated that the ovens of Egypt every year communicate life to about 93,000,000 chickens. This process has received considerable attention from the French philosophers; but perhaps the best exemplification of its results, that has been witnessed in Europe, was given by the proprietor of the *Eccalcobion*, which was lately exhibited in Pall Mall, London.

The mean temperature of incubation is 100° Fahr.; it may vary from 95° to 105°, and towards the close of the process may be suspended for one or two hours, or for a longer period, according to the degree of extraneous heat which the eggs may derive from their situation, without fatal consequences to the embryo. The power of communicating the requisite degree of warmth to their eggs arises out of the unusual development of, and determination of blood to, a peculiar plexus of vessels, distributed over the skin of the abdomen, and which, in most birds, is connected with a derivation of blood from the internal organs of generation after the subsidence of the functional activity of the ovarium and oviduct to the external integuments. The vascular, hot, and sensitive condition of the skin of the abdomen is the exciting cause of that uncontrollable propensity to incubate, which the Greeks denominated "storage," and which, with its associated phenomena of patience, abstinence, and self-denial, forms so remarkable a feature in the economy of birds. The eggs of the bird present several peculiarities in relation to the circumstances under which the fœtus is to be developed; their oval form permits a greater proportion of their surface to be in contact with the heat-communicating skin of the parent, than if they had been a spherical body; while the shell, by virtue of its hard, calcareous texture, and its arched disposition about the soft contents, sufficiently defends them from the superincumbent pressure. As warmth is the only essential influence which the egg derives from the parent, the shell is porous and permeable to air, and the germ is surrounded by an adequate store of nutritious matter. See *EGG*.

The period of incubation is generally directly as the size of the bird, but the degree of development which the chick attains prior to exclusion varies. As a general rule, it is inferior in birds of flight, as the Accipitrine and Passerine orders, than in the terrestrial, wading, and swimming birds; and the warmth and complexity of the nest bears relation to this difference of development. If the thrush had been forewarned that her young would be excluded from the egg naked and helpless, she could not have prepared beforehand a warmer and more comfortable abode than her instinct had led her to construct for their accommodation; and if with such a nest we contrast the rude mass of straw in which the hen deposits and incubates her eggs, it might be imagined that she knew beforehand that her chickens would come into the world well clothed and strong enough at once to run about and pick up their own food. In this case, therefore, the nest relates only to incubation; in the other, to incubation and subsequent rearing of the

young; and according to the degrees of development attained during incubation, and the associated condition of the nest and habits of the parent, birds have been divided into two great groups, the *Aves altrices* and *Aves pracoces*. See *GESTATION*.

INDIA, THE AGRICULTURE OF. The British farmer will, I am afraid, not derive many useful hints from the most careful study of the agriculture of the eastern portions of Asia. In Hindostan, for instance, too many causes have contributed to retard the march of agricultural improvement. The innate dislike of the natives to innovations of all kinds, the nature of their region, their indolence, and the political oppressions under which they have long been labouring, are amongst the many causes of the degraded state of Indian agriculture. I am indebted to my brother, Mr. George Johnson, of the Supreme Court of Calcutta, for most of the following sketches of Indian modes of cultivation. He says, in describing the residences of the Indian ryots or farmers, "When I speak of an Indian farm, the image must not rise to the mind of the European reader of a substantial dwelling-house, surrounded by commodious outbuildings, and conveniently placed amongst its compactly enclosed fields; such an agricultural establishment bespeaks a far advance in the art of cultivation, the employment of large capitals, and remunerating prices to the cultivator. Now, none of these contingencies occur in Hindostan; but, on the contrary, the operations of agriculture are rudely executed; the cultivators are poor, the profits are small, the results correspondent. The dwellings of the ryots throughout India are in no degree superior to the other mean huts with which they are associated in the village. No barn is attached to the residence of the poorer cultivators, for the pittance of grain annually raised is immediately beaten out—the major part sold at once to the merchant, and the small residue for seed and sustenance is stored in baskets or jars, and these are usually placed in the room where the family dwells. The outbuildings rarely extend beyond an enclosure in which to secure the cattle at night. By far the greatest number of farms do not exceed a size requiring a single yoke of oxen, for the occupier is the only ploughman."

The various imposts to which these little farmers are exposed, sound strange to English agriculturists; they are enumerated by Dr. Buchanan. (*Ind. Rech.* vol. ii. p. 200.) The ryot's heap of grain is usually about 3000 seers: of this is first set apart—

	Seers.
For the gods, or rather for the priests - - -	5
For charity to the brahmins and other mendicants -	5
For the astrologer - - - - -	1
For the hereditary brahmin of the village - - -	1
For the barber - - - - -	2
For the potter - - - - -	2
For the carpenter and blacksmith - - - - -	2
For the measurer - - - - -	4
For the washerwoman - - - - -	2
For the beadle - - - - -	7
For the chief of the village - - - - -	53
For the accountant - - - - -	200
For the watchman - - - - -	10
For the conductor of the water - - - - -	20

This leaves a residue of 2686 seers; of this government takes 10 per cent., and, after all the drains have been satisfied, the grower is left in possession of a residue of two thousand seers of rice. (*Buchanan's Mysore*, vol. i. p. 265.)

Irrigation is practised in India, and in almost all the hot countries of Asia, to an extent of which the English farmer has little conception; for, as Mr. George Johnson remarks, "In every district of Hindostan, as in all other tropical climates, irrigation is the most effectual mode of promoting fertility. In places favoured by nature, whole plains are occasionally flooded merely by the construction of a dam across the outlet of some mountain stream, or it is confined nearer to its source, so as to form a reservoir, from which the water may be obtained at the most desirable seasons. In less favourable situations, the water frequently has to be raised to a considerable height, in order to attain an elevation level with, or slightly above the cultivated land. This is very generally effected by a scoop of matting suspended between two ropes, the ends of which are held by two men who bale it from the reservoir into a hole some feet above it, and from thence it is similarly baled by others, from hole to hole, until the desired height is attained. Sometimes the scoop is suspended between poles erected in the form of a gallows; at others, as in the Jaut wells, from which the water is raised by cattle or by hand in some districts. The extensive canals formed in the neighbourhood of Delhi and in the Punjab are no longer employed. The machinery, so general in China, is nowhere used in India for raising water. In 1798, Dr. Tennant relates, that the practice of the natives then was, and is still followed, after ploughing the fields in the usual manner, but before sowing, to divide them into regular small squares, like a chess-board; each square is surrounded with a shelving border about four inches high, capable of preventing the escape of water. Between these square enclosures, small dykes are formed for conveying a rivulet over the whole field; when the water has stood a sufficient time in one square, it is let off into the surrounding dyke, and conveyed to another, and so on in succession through the whole field. The fertility induced amply recompenses the labour, and the neatness imparted to the country by this husbandry is very striking." (*Ind. Rech.* ii. 167.) In some places the water has to be raised from deep wells, several of which are in the most elevated parts of each field. The work of drawing the water is performed by two bullocks, not travelling round in a mill, but pacing in a line direct from the well's mouth. The various little trenches already mentioned, all radiate from these wells. About Patna the irrigation water is raised from the wells by means of a bamboo lever, with its fulcrum on a frame about 10 feet high, a weight at the opposite end being employed to assist the workmen in counterpoising the leather bag of water; this plan is only resorted to when the wells are shallow, and the water near the surface of the earth, and then not bags but buckets are used, sometimes of leather, but

more frequently of iron. Four bullocks and three labourers are engaged nine days in irrigating one acre of land thoroughly. The importance of this branch of agriculture is evidenced by the great number of wells, which even these most indolent people sink in districts deficient in streams. Near Madras, at Saymbrumbacum, a reservoir more than 7 miles long and 3 broad, for the purposes of irrigation, has been formed by merely raising a bank across a natural ravine. In the Tamul language a reservoir of this kind is called an Eray. This supplies 32 villages containing 5000 persons employed in agriculture (should the rains fail) for 18 months. Sluices lined with bricks pass under the banks to supply the fields; the inner opening of the sluice is covered by a flat stone, in which is cut a circular hole, through which the water is allowed to pass as required, by means of a plug fixed to a bamboo, and secured from escape by means of stone pillars and cross-bars. When bullocks are employed to raise water from wells, a leathern bucket is used which holds 45 gallons; this two bullocks will raise every minute and a half from a well 44 feet deep, and they work eight hours per day.

To the insoluble matter of the water employed in irrigation, must be attributed a considerable portion of its value. These vary at different seasons. That of the Ganges, which is extensively employed in irrigation, was examined by Mr. Everett. He found in it of insoluble matters—

		Grains.
July 3.	In a wine quart	- - - 1
7.	- - -	- - - 8
23.	- - -	- - - 10
Aug. 1—8.	- - -	- - - 58.10
22.	- - -	- - - 26
Sept. 6.	- - -	- - - 17
24.	- - -	- - - 8
Oct. 8.	- - -	- - - 6

This insoluble or mechanically-suspended matter was analysed by Mr. Piddington: he found in 200 parts from the banks of the Ganges, at Mohulpore—

	Parts.
Vegetable matter	- - - 5½
Saline matters, chiefly muriate of potass	- - - 1
Carbonate of lime	- - - 16½
Phosphate of lime	- - - 1
Oxide of iron	- - - 12
Silicx	- - - 139
Alumina	- - - 14½
Water	- - - 2
Loss	- - - 6½
	200

As these rich, purely divided matters, are depositing on the lower grounds within reach of the flood waters, it follows as a natural consequence that "the higher soils are generally and rapidly impoverishing, and this to a degree of which few, who have not made the subject one of attention, are aware."

The rapid effects produced by a copious artificial watering of grass lands under the burning sun of India, may be judged by the following report made in 1841, by Sir Edward Burnes to Lord Auckland, upon the artificial grasses of Cabool.

"There are three kinds of grasses cultivated in Cabool—'rishku,' or lucern, 'shutul,' a kind of trefoil, and 'si barga,' or clover. The first

and the last continue to yield crops for some years, but the 'trefoil' (shuftul) is an annual. The lucern (rishku) is sown in spring, generally about the vernal equinox; for each jureeb, or about half an English acre, 2 seers of Cabool, or about 28 lbs. English, are required as seed. In 40 days it comes to perfection, and is cut down, and will yield 4 full-grown crops ere winter sets in, but by early cutting 6 or 8 crops may be drawn; the last may sometimes be inferior from premature cold. One jureeb or half an English acre yields on an average ten camel loads of grass at each cutting, as a camel carries about 500 lbs.; this is a produce of 5000 lbs. the jureeb, or 10,000 lbs. the English acre, and for four fine crops 40,000 lbs. English. The third crop is considered the best, and from it the seed is preserved: of this the half acre sown with the two seers of Cabool will yield 40 sears, or about 560 lbs. This plant requires the best black soil, much manure, and is watered 5 times each crop—in fact whenever it droops. It is sometimes sown along with barley, but in that case the grain, by exhausting the soil, injures the crop. The seed is never exported, but the grass is so plentiful, though all the cattle are fed on it, as much to exceed the consumption; it is, therefore, dried, and that produced at any distance from a market is generally stored in this manner, and sold during winter. A camel load of it, or about 500 lbs. English, whether green or dry, sells for one Cabool rupee, a coinage of which 115½ are equal to 100 Company's rupees. Lucern generally lasts for 6 years, but it will yield for 10 years if manure be abundantly scattered over it. The seed is at present sold for a rupee, a stone of 14 lbs.; but as it is not cultivated for exportation, this is much dearer than it might otherwise be had, and its price has been almost doubled by the arrival of the British troops. The trefoil or 'shuftul' in cultivation, in the time of sowing, reaping, and soil, resembles lucern, and the calculations of produce for the one will suffice for the other, only it is an annual plant. The seed, too, is dearer by one half than that of lucern.

"The clover or 'si barga' (i. e. three leaves), assimilates likewise to the lucern, and it lasts as long. I may, however, observe, that the climate of Cabool is much later than that of England, and, excepting the seed sown in autumn, nothing is put in the ground here with advantage before the 1st of April."

Of a rotation of crops, or of fallows, the ryots of Bengal have but little idea: their richest low-lying grounds are devoted to the growth of rice, and on the uplands they generally crop the soil till it is exhausted, and then abandon it to the weeds, which soon occupy it in profusion: they have, besides, a wretched method of sowing various seeds together, in a manner that cannot be sufficiently reprehended. It is only in some parts of India that any thing like rotation of crops is observed. In the highlands of Behar, the following rotation is usually adopted:—1. Year-fallow and wheat; 2. Maize (muckai), followed by big or bear, a kind of barley; 3. Murwa, sama, and cowaree, being species of millet, followed by cotton.

There is nothing remarkable in the domestic

animals of Bengal: the oxen are inferior, and their sheep are described as "small, lank, and thin;" the colour of three-fourths of each flock is black or dark-gray. The quality of the fleece is worse, if possible, than its colour; it is harsh, thin, and hairy, in a very remarkable degree: no part of clothing or domestic furniture, so far as Dr. Tennant had observed, is manufactured of wool, except a coarse kind of blanketing which some of the boatmen (dandies) and people in the upper districts use during the cold season, as a wrapper at night.

The same system of irrigation which prevails in Arabia, in Persia, and in Hindostan, is carried on to a very considerable extent in the empire of China, where the soil is cultivated perhaps more carefully, and with a greater minuteness of detail, or garden system of husbandry, than in any other country. I do not allude in this work to their cultivation of crops such as the tea plant, or those from which the English cultivator is as little likely to derive useful hints. They are remarkable for the care with which they deepen, even by the spade, their cultivated lands, and their husbanding of manures of all kinds is admirable; every thing that is produced in their cities endued with fertilizing properties, is collected and preserved with the utmost care. The night-soil, for instance, is made into a kind of bricks with calcareous matter, and carried into the most distant provinces, for the use of the farmers. "There is, perhaps," says the author of *British Husbandry* (vol. i. p. 273), "no part of the world in which the preparation and the practical application of vegetable and animal manure is so well understood as in China; but, owing to its overflowing population, almost the whole of the labour is performed by man, by which the number of working animals is so much reduced, that night-soil forms the principal dependence of the farmer. It is extensively employed in a dried state, and is sold as an article of commerce throughout the empire, in the form of cakes, mixed up with one-third of their weight of marl." To the same end the poor are employed in collecting in the public roads and streets all the horse and other dung, which is also made into cakes with marl, and these are afterwards dried in the sun.

The system of tillage formed by the Chinese, however antiquated, is not of a general description, calculated to instruct the English cultivator; and the Chinese husbandmen are entirely uninformed as to any scientific principles, by the observance of which the cultivation of the earth is improved. The same remark, in fact, extends to most oriental farmers: they merely follow a regular routine of operations, because it is that which their forefathers adopted: followed without consideration, it is transmitted unimproved. See IRRIGATION, and NIGHT-SOIL. (*Memoir on the Agriculture of India*, by G. W. Johnson.)

INDIAN CORN. See MAIZE.

INDIAN CRESS. See CRESS, INDIAN.

INDIAN MILLET (*Sorghum vulgare*). *Sorghum* is the Indian name, according to Bauhin. The French call it *grand millet*, the Italians *saggena* or *sorgo*, and the Spaniards *alcandia*. It is much cultivated in Arabia and most

parts of Asia Minor, and has been introduced into Italy, Spain, Switzerland, and some parts of Germany; also into China, Cochin-China, and the West Indies, where it grows commonly five or six feet high or more, and, being esteemed a hearty food for labourers, is called Negro Guinea corn. Its long awns or bristles defend it from the birds. In England, the autumnals are seldom dry and warm enough to ripen the seeds well in the field. In Arabia it is called *dora* or *durra*. The flour is very white, and they make good bread of it, or rather cakes, about two inches in thickness. The bread which they make of it in some parts of Italy is dark and coarse. In Tuscany it is used chiefly for feeding poultry and pigeons; sometimes for kine, swine, and horses. Brooms are made of the spikes, which are also sent to England for the same purpose. The Indian millet, as well as the common sort (*panicum*) is cultivated in some parts of North America, and has been tried in England, but it is only in the warmest autumns that it ripens its seeds. (*Loudon's Encyclopaedia of Plants.*) See GUINEA CORN.

INDIAN RUBBER, *Gum Elastic*, or *Caoutchouc*, is a well-known tough and yielding substance, obtained in South America and Java from the sap of a tree called the *Siphonia caluca*. To procure the sap, incisions are made through the bark in many places, and the milky juice which exudes is spread over clay moulds, and dried in the sun, or by a fire, the smoke from which last blackens it.

The juice itself has been of late years imported. It is of a pale-yellow colour, and has the consistence of cream. It becomes covered, in the bottles containing it, with a pellicle of concrete caoutchouc. Its specific gravity is 1.012. When it is dried, it loses 55 per cent. of its weight: the residuary 45 is elastic gum. When the juice is heated, it immediately coagulates, in virtue of its albumen, and the elastic gum rises to the surface. It mixes with water in any proportion; and, when thus diluted, it coagulates with heat and alcohol as before.

The specific gravity of caoutchouc is 0.925, and it is not permanently increased by any degree of pressure. By cold or long quiescence, it becomes hard and stiff. By long boiling in water it softens, swells, and becomes more readily soluble in its peculiar menstrua; but when exposed to the air, it speedily resumes its pristine consistence and volume. It is quite insoluble in alcohol; but in ether, deprived of alcohol by washing with water, it readily dissolves, and affords a colourless solution. When the ether is evaporated, the caoutchouc becomes again solid, but is somewhat clammy for a while. When treated with hot naphtha, distilled from native petroleum, or from coal-tar, it swells to 30 times its former bulk; and if then triturated with a pestle, and pressed through a sieve, it affords a homogeneous varnish, which being applied by a flat edge of metal or wood to cloth, prepares it for forming the patent water-proof cloth of Mackintosh. Two surfaces of cloth, to which several coats of the above varnish have been applied, are, when partially dried, brought evenly in contact, and then passed between rollers, in order to

condense and smooth them together. This double cloth is afterwards suspended in a stove-room to dry, and to discharge the disagreeable odour of the naphtha.

Caoutchouc dissolves in the fixed oils, such as linseed oil, but the varnish has not the property of becoming concrete upon exposure to air. It is more or less soluble in the oils of lavender and sassafras.

It melts at 248° Fahrenheit, and stands afterwards a much higher heat without undergoing any further change. When the melted caoutchouc is exposed to the air, it becomes hard on the surface in the course of a year. When kindled, it burns with a bright flame and a great deal of smoke.

Neither chlorine, sulphurous acid gas, muriatic acid gas, ammonia, nor fluosilicic acid gas affects it, whence it forms very valuable flexible tubes for pneumatic chemistry. Cold sulphuric acid does not readily decompose it, nor does nitric acid, unless it be somewhat strong. The strongest caustic potash ley does not dissolve it, even at a boiling heat.

Mr. William Henry Barnard, in the course of some experiments upon the impregnation of ropes with caoutchouc, at the factory of Messrs. Enderby, at Greenwich, discovered that when this substance was exposed to a heat of about 600° Fahrenheit, it resolved itself into a vapour, which, by proper refrigeratory methods, was condensable into a liquid possessing very remarkable properties, to which the name *caoutchoucine* has been given. For this invention "of a solvent not hitherto used in the arts," Mr. Barnard obtained a patent, in August, 1833. His process for preparing it is described in his specification as follows:

"I take a mass of the said caoutchouc, or Indian rubber, as imported, and having cut it into small lumps, containing about two cubic inches each (which I prefer), I throw these lumps into a cast-iron still. I then apply heat to the still in the usual manner, which heat is increased until the thermometer ranges at 600 degrees of Fahrenheit, or thereabouts. And as the thermometer ranges progressively upwards to 600 degrees of Fahrenheit, a dark-coloured oil or liquid is distilled over, which I claim as my said invention, such liquid being a solvent of caoutchouc, and other resinous and oleaginous substances. When the thermometer reaches 600 degrees, or thereabouts, nothing is left in the still but dirt and charcoal.

"I afterwards subject the dark-coloured liquid thus distilled to the ordinary process of rectification, and thereby obtain fluids varying in specific gravity, of which the lightest hitherto has not been under 670, taking distilled water at 1000, which fluids I also claim as my said invention.

"At each rectification the colour of the liquid becomes more bright and transparent, until, at the specific gravity of 680, or thereabouts, it is colourless and highly volatile.

"In the process of rectification (for the purpose of obtaining a larger product of the oil colourless) I put about one-third of water into the still. In each and every state the liquid is a solvent of caoutchouc, and several resinous and oleaginous substances, and also of other

substances (such as copal), in combination with very strong alcohol."

The discovery of the chemical solvent which forms the subject of the patent above described, has excited considerable interest in the philosophic world, not only from its probable usefulness as a new article of commerce, but also from two very extraordinary characteristics which it is found to possess, viz., that, in a liquid state, it has less specific gravity than any other liquid known to chemists, being considerably lighter than sulphuric ether, and, in a state of vapour, is heavier than the most ponderous of the gases.

Its elementary constituents are,

Carbon	-	-	6.812	-	-	8 proportions.
Hydrogen	-	-	1.000	-	-	7 ditto.

This new material (when mixed with alcohol) is a solvent of all the resins, and particularly of copal, which it dissolves, without artificial heat, at the ordinary temperature of the atmosphere; a property possessed by no other solvent known; and hence it is peculiarly useful for making varnishes in general. It also mixes readily with oils, and will be found to be a valuable and cheap menstruum for liquefying oil-paints; and, without in the slightest degree affecting the most delicate colours, will, from its ready evaporation, cause the paint to dry almost instantly.

Cocoa-nut oil, at the common temperature of the atmosphere, always assumes a concrete form; but a portion of this caoutchoucine mixed with it will cause the oil to become fluid, and to retain sufficient fluidity to burn in a common lamp with extraordinary brilliancy.

Caoutchoucine is extremely volatile; and yet its vapour is so exceedingly heavy that it may be poured, without the liquor, from one vessel into another, like water. (*Ure's Dict.*)

INDIAN TOBACCO. See EYE-BRIGHT.

INDIAN TURNIP (*Arum triphyllum*), Wake-robin, &c. An American plant, distinguished by its head of beautiful red berries growing upon a single stem, and its perennial bulbous root, resembling a small rough turnip, possessing such an extremely acrid juice as, when bitten or chewed, causes violent inflammation in the mouth and salivary glands, inducing copious salivation. This acrid quality of the root is, however, dissipated by boiling or drying. The dried root, grated and boiled in milk, is a popular remedy for coughs and pulmonary consumption.

The English wake-robin, or cuckoo-pint, is the *Arum maculatum*, which in many of its sensible qualities resembles the American Indian turnip.

INDIGENOUS PLANTS. Such plants as are natives of or are common to a country.

INDIGO (*Indigofera*, from *indigo*, a blue dye-stuff, a corruption of *Indicum*, India, and *fero*, to bear; most of the species produce the well-known dye called indigo, the finest of all vegetable blues). This is an extensive genus of rather elegant plants, the shrubby kinds of which are well worthy of cultivation. The stove and green-house shrubby kinds thrive best in a mixture of sandy loam and peat, and may be increased without difficulty by cuttings of the young wood, planted in sand, under a glass, in heat. The annual and biennial kinds

must be raised from seeds sown in a hotbed in spring; and when the plants have grown a sufficient height, they may be planted singly into pots, and treated as other tender annuals and biennials. The genus belongs to the natural order *Leguminosæ*: hence the flowers resemble the pea tribe. The vexillum is round, emarginate; the keel furnished with a subulate spur on both sides; stamens diadelphous; style filiform; legume continuous, one or more seeded, two-valved. The *Indigofera cœrulea* yields the finest indigo; the *I. argentia*, an inferior kind, which comes from Egypt; the *I. tinctoria*, besides yielding indigo, is also medicinally employed; and the powdered leaf of *I. anil* is used in some diseases of the liver. (*Paxton.*)

Indigo, when cultivated, thrives best in a free, rich soil, and a warm situation, frequently refreshed with moisture. The usual course pursued for its culture is as follows:—

Having first chosen a proper piece of ground, and cleared it, hoe it into little trenches, not above two inches or two inches and a half in depth, nor more than fourteen or fifteen inches asunder. In the bottom of these, at any season of the year, strew the seeds pretty thick, and immediately cover them. As the plants shoot, they should be frequently weeded, and kept constantly clean, until they spread sufficiently to cover the ground. Those who cultivate great quantities, only strew the seeds pretty thick in little shallow pits, hoed up irregularly, but generally within four, five, or six inches of one another, and covered as before. Plants raised in this manner are observed to answer as well as the others, or rather better; but they require more care in the weeding. They grow to full perfection in two or three months, and are observed to answer best when cut in full blossom. The plants are cut with reaping-hooks, a few inches above the root, tied in loads, carried to the works, and laid by strata in the steeper. Seventeen negroes are sufficient to manage twenty acres of indigo; and one acre of rich land, well planted, will, with good seasons and proper management, yield five hundred pounds of indigo in twelve months; for the plant ratoons (stools, stoles, or tillers, *i. e.* it sends out stolones, or new growths), and gives four or five crops a year, but must be replanted afterwards. (*Browne.*)

The process by which the blue colouring matter is extracted from the plant in Mexico, the East Indies, &c., is as follows:—

The leaves are gathered at maturity, and immersed in vessels filled with water till fermentation takes place. The water then becomes opaque and green, exhaling an odour like that of volatile alkali, and evolving bubbles of carbonic acid gas. When the fermentation has been continued long enough, the liquid is decanted and put into other vessels, where it is agitated till blue flakes begin to appear. Water is now poured in, and flakes are precipitated in the form of a blue powdery sediment, which is obtained by decantation, and which, after being made up into small lumps and dried in the shade, is the indigo of the shops. It is insoluble in water, though slightly soluble in alcohol; but its true solvent is sulphuric acid, with which it forms a fine blue dye, known by

the name of liquid blue. It affords by distillation carbonic acid gas, water, ammonia, some oily and acid matter, and much charcoal; whence its constituent principles are most probably carbon, hydrogen, oxygen, and nitrogen. Indigo may be procured also from several other plants besides *Indigofera tinctoria*, and particularly from *Isatis tinctoria*, or woad, a plant indigenous to Britain, and thought to be the plant with the juice of which the ancient Britons stained their naked bodies, to make them look terrible to their enemies. If this plant is digested in alcohol, and the solution evaporated, white crystalline grains, somewhat resembling starch, will be left behind; which grains are indigo, becoming gradually blue by the action of the atmosphere. The blue colour of indigo, therefore, is owing to its combination with oxygen.

Indigo is not cultivated to so great an extent in the United States as formerly, the imported article being obtained so readily. The following process of manufacturing indigo in small quantities for family use is extracted from the *Southern Agriculturist*:—Cut the indigo when the under leaves begin to dry, and while the dew is on them in the morning; put them in a barrel, and fill this with rain water, and place weights on to keep it under water; when bubbles begin to form on the top, and the water begins to look of a reddish colour, it is soaked enough, and must be taken out, taking care to wring and squeeze the leaves well, so as to obtain all the strength of the plant; it must then be churned (which may be done by means of a tolerably open basket, with a handle to raise it up and down) until the liquor is quite in a foam. To ascertain whether it is done enough, take out a spoonful in a plate, and put a small quantity of *very strong lye* to it. If it curdles, the indigo is churned enough, and you must proceed to break the liquor in the barrel in the same way, by putting in lye, (which must be as strong as possible,) by small quantities, and continuing to churn until it is all sufficiently curdled; care must be taken not to put in too much lye, as that will spoil it. When it curdles freely with the lye, it must be sprinkled well over the top with oil, which immediately causes the foam to subside, after which it must stand till the indigo settles to the bottom of the barrel. This may be discovered by the appearance of the water, which must be let off gradually by boring holes first near the top and afterwards lower, as it continues to settle; when the water is all let off and nothing remains but the mud, take that and put it in a bag, (flannel is the best) and hang it up to drip, afterwards spreading it to dry on large dishes. Take care that none of the foam, which is the strength of the weed, escapes; but if it rises too high sprinkle oil on it.

Seven or eight species of indigo are found in the United States, most of which are in the south. The wild indigo (*Dyer's Baptisia*), common in Pennsylvania and other Middle States, yields a considerable proportion of blue colouring matter of an inferior kind. (*Flora Cestrica.*)

INDURATED (Lat. *induro*). A term implying that a substance naturally soft is hardened.

It is a term frequently used in botanical works to signify the above-mentioned change.

INERT VEGETABLE MATTER. The inert vegetable matters of the soil are those which decompose very slowly, and consequently afford very little nourishment to the growing plant. Of this kind are woody fibre, tanner's bark, peat, &c., all of which, if not previously rendered more easily soluble by being mixed with farm-yard dung, or other easily fermentable substances, afford food to vegetation by very slow degrees.

INFIRMARY (Lat. *infirmitas*, weak). An hospital for the reception of the sick. The Veterinary College in London have an infirmary for sick and diseased horses, to which the horses of their subscribers have access and medical treatment, free from charge.

INFLAMMATION. In farriery, is a disease or affection consisting in an increased heat and action in any part of an animal, arising from various causes, external or internal, local or universal. In animals, the chief causes are wounds, bruises, and sudden or excessive cold, and the application of heat afterwards.

The horse is subject to inflammation of the lungs, stomach, bowels, kidney, and of the eye and foot. Of inflammation of the bowels I have already spoken (see **BOWELS**). Of inflammation of the stomach in the horse, except from poisonous herbs or drugs, we know little. It very rarely occurs, and then can with difficulty be distinguished from inflammation of the bowels; and in both diseases the assistance of a skilful veterinary surgeon is required.

Among the causes of inflammation of the kidney are, improper food, such as mow-burnt hay, musty oats, &c. Bleeding, in this case, must be promptly resorted to, and carried to its full extent. An active purge should next be administered; and a counter-inflammation excited as near as possible to the seat of disease.

Inflammation of the lungs is one of the causes of roaring: it is generally brought on by the respiration of heated and poisoned air, in neglected and filthy stables; by sudden changes from heat to cold, or cold to heat, from grass to the stable, or stable to grass, and so on. Bleeding, blistering, and relaxing medicines should be resorted to under the advice of a professional man; for the cure of this malady can scarcely be safely undertaken without proper advice.

Cooling applications, such as Goulard's extract, one drachm or half an ounce of the tincture of opium to a pint of water, with mash diet and gentle physic, will usually get rid of common inflammation of the eye, or the inflammation will subside itself; but should three or four days pass and the inflammation not be abated, we may begin to suspect that it is specific and fatal inflammation, or true ophthalmia, for which there is no cure. See **EYE**.

Inflammation of the foot is brought on by over-exertion. If a horse that has been ridden, or driven hard be suffered to stand in the cold, or if his feet be washed and not speedily dried, he is very likely to have "fever in the feet." Bleeding at the foot, and poultices of linseed meal to cover the whole of the foot and pastern, with sedative and cooling medicines, should be

resorted to. And to promote evaporation it is advisable to remove the shoe, pare the sole as thin as possible, and have the crust, and particularly the quarters, well rasped. See GREASE.

For inflammation in sheep, see SHEEP.

In inflammatory fever in cattle, *profuse* bleeding, followed by immediate purging (1½ lbs. of Epsom salts dissolved in water or gruel), must be had recourse to. (*Youatt on Cattle*, p. 359.)

INFLORESCENCE (Lat. *inflorescere*, to flourish). The general arrangement of the flowers upon a stem or branch. It consists of the following principal kinds: viz., the spike, the raceme, the panicle, the capitulum, the cyme, and the umbel.

The spike is a long rachis of flowers sessile, or without foot-stalks. The term raceme is commonly applied to flowers when they are arranged round a filiform or thread-like simple axis, each particular flower being stalked. The panicle is a loose disposition of inflorescence, in which the primary axis develops secondary axes, which themselves produce tertiary, as in oats; or, in other words, it is a raceme bearing branches of flowers in place of simple ones. Capitulum implies the arrangement in small heads. The cyme is a mode of inflorescence resembling a flattened panicle, as that of the elder.

Of the particular arrangement of the umbel, the carrot is a familiar example; the peduncles and pedicles spring from a common centre, and rise till they form a nearly flat tuft. The difference between an *umbel* and a *corymb* is, that whilst in the latter the flowers form a flat head, the pedicles do not, as in the former, spring from a common centre. (*Paxton's Bot. Dict.*; *Brande's Dict. of Science*.)

INFLUENZA. An epidemic catarrh, attended by febrile and other symptoms, which often run very high, and assume a variety of aspects, dependant upon the seasons and other causes. The possibility of the existence of a peculiar state of the atmosphere, although we have no means of detecting it, is undoubtedly the true cause of influenzas. Miasms, or vapours of a noxious kind, may exist, though in very minute quantity, also as exciting causes of influenza, an idea suggested by Dr. Prout. It may possibly be of volcanic origin; and such a substance as seleniuretted hydrogen, which, even in extremely minute quantity, is highly deleterious, might perhaps account for some of the phenomena of influenza; but we must acknowledge that nothing certain is known respecting the cause of this disease. See DISTEMPER, EPIDEMIC, and MURRAIN.

INOCULATION. An operation in the management of fruit trees, which is sometimes called budding. It is a kind of grafting practised in the summer months on various trees and plants, and often succeeds better than the common method of grafting. (See BUDDING and GRAFTING.) It is also a term used to signify the process of transplanting grasses. See GRASSES.

INSECTS (Lat. *insecta*). A very extensive and to the cultivators of the earth, important class of animals. *Insects* are distinguished from *Worms* by always having feet in their perfect or winged state, as the beetle, butterfly,

moth, &c. *Worms* crawl on their bellies, and have no feet, as the earth-worm, snail, slug, &c. *Insects*, above all other animals, are by far the most destructive to vegetation.

On the subject of the science of entomology in this work, we propose only to touch upon those which are the most injurious or important to the farmer; and many of these, such as the *bee*, *ant*, *fly* in turnips, *wireworm*, &c., will be found under their respective heads; indeed the mere list of known insects is so numerous, that the catalogue alone would be too extensive for a work of this description. "The great characteristic of this vast assemblage of animals," says Mr. Swainson "is the total absence of internal bones; hence, their hardest parts are always external, and the muscles are usually attached to the under side of the substance which forms the covering of the animal. The body is always divided into rings or transverse joints, from which circumstance naturalists have agreed to call them *annulose*, or ringed animals." This name is peculiarly applicable, since it expresses a marked distinction from such as have an internal skeleton, analogous to that of man, and which are called *Vertebrata*, from possessing a spine. The *Annulosa* contain *Insecta* (insects proper); *Arachnida* (spiders); *Crustacea* (crabs); and *Annelida* (worms); excluding the soft *Vermes* of Linnæus, which include the shell-fishes, or *Mollusca*. So diversified, indeed, are the different groups of this immense assemblage, or sub-kingdom of the animal world, that it is impossible to assign to them any other character, as a whole, than that just mentioned.

From the works of Mr. Swainson, of Kirby and Spence, the papers of Mr. Duncan, in the *Quart. Journ. of Agr.*, the work of V. Köllar, *On Insects injurious to Gardeners, Foresters, and Farmers*, and especially from that of Dr. Harris, the chief facts are obtained. In the words of M. Köllar, "To enable the readers, for whom this work is intended, to find more easily the insect particularly interesting to each, it has been considered proper not to treat of families and species in any systematic arrangement, but according to the branch of culture to which they are particularly injurious." And, in pursuance of this object, I shall only briefly allude to some of the chief of the insect depredators, for "to enumerate," says Davy, "all the destroying animals and tyrants of the vegetable kingdom, would be to give a catalogue of the greater number of the classes in zoology; almost every species of plant is the peculiar resting-place or dominion of some insect tribe; and from the locust, and caterpillar, to the minute aphid, a wonderful variety of inferior insects are nourished, and live by their ravages upon the vegetable world."

Of the considerable extent to which the various insect tribes commit their depredations, no farmer will for a moment doubt, and yet he forms his judgment only upon the ravages of the larger insects. Of the smaller tribes—the minute trespassers—the animalculæ—those only discernable through the microscope, he forms no estimate. Yet of those that he does see, the catalogue is fearfully alarming.—"There is," says Mr. Duncan, "scarcely one

of our most useful plants which is not assailed in some way or other; and the forms of insects, and their modes of living, are so infinitely diversified as to enable them to continue their depredations in all the different states of these plants. The various kinds of grain, for example, have a host of enemies in the subterraneous larvæ of beetles which consume the roots; various kinds of caterpillars feed on the blade; some particular species attack the ear; and even when laid up in apparent security, a small beetle is often found to scoop out the interior of each grain, and convert it into an abode for itself. (See CORN WEEVIL.) In England, if the seed of the turnip escape the attack of a minute weevil, another enemy awaits the unfolding of the cotyledon leaves, and a third buries itself in the bulb and rootlets, which become diseased and covered with unseemly excrescences (see ANEURY), while the mature foliage is often consumed by caterpillars.

“But even when there is no remarkable augmentation of their numbers, there is reason to believe that the injury occasioned to vegetation by insects is at all times greater than is generally supposed. Their operations are often carried on under cover, either beneath the surface of the soil, within the substance of the plant, or in other situations where they escape observation. Many kinds again feed only during the night, and conceal themselves during the day in holes and crevices. In consequence of this latent and insidious mode of attack, there is no doubt that we are often led to ascribe the unhealthiness and decay of plants to badness of soil, unfavourable weather, and other causes, when in reality they are produced entirely by insects.” (*Quart. Journ. Agr.* vol. viii. p. 97.) “The only course,” adds Mr. Duncan, “which is likely to lead to the discovery of proper remedies, is to investigate carefully the habits and natural history of insects in connection with the structure and general physiology of the plants which they attack. In prosecuting this object, the attention should be directed to ascertain the time when, and the manner in which, the eggs are deposited, as well as their composition, and that of the enclosing membrane, with a view to determine in what way the vital principle might be most easily destroyed. The habits of the larvæ call for particular attention, as it is generally in this state that the mischief is committed; the period of their appearance, their times of feeding, plants on which they feed, and (if attached to more than one) the kind they seem to prefer, the part of the plant attacked, duration of the larvæ state, should be carefully noted; an acquaintance with the places to which the larvæ usually retreat when about to change to pupæ, and with the structure, duration, &c. of the latter, might probably suggest some easy means of destroying many in that dormant state. A knowledge of the economy of the perfect insect is of course of the utmost importance; if we could become acquainted with the retreats in which they pass the winter, or find means to destroy the few that generally survive, when they first appear in the spring, and before they have de-

posited their eggs, the injuries which are sustained by their means might be altogether prevented.” (*Ibid.* p. 99.)

Let not, however, the farmer, when he is thus warmly engaging in the destruction of the annoying insects of the field, omit to consider whether many of these are not, in some shape or other, productive of benefit—whether they do not serve to keep within reasonable limits other insects, or perhaps perform some other wise purpose in the works of the creation. This has been proved to be the fact in the case of the common earth-worm, whose casts so often annoy the gardener and the farmer. (See EARTH-WORM.) For these not only assist in the continual admixture of different strata of earths, but, by boring the soil, they promote in it the circulation of the atmospheric gases, and even the drainage from it of its superfluous moisture. And as White, of Selborne, remarks in his *Natural History*, “The most insignificant insects and reptiles are of much more consequence, and have much more influence in the economy of nature, than the incurious are aware of. From their minuteness, which renders them less an object of attention, from their numbers and fecundity, earth-worms, though in appearance a small and despicable link in the chain of nature, yet, if lost, would make a lamentable chasm.”

Insects have been divided by entomologists into two great divisions—the *winged* and the *wingless*.

Winged insects are divided into the following orders:—

1. *Coleoptera*. Of this order are the weevils, the rose-bug, ground and dung beetles, &c.

2. *Orthoptera*. Of this order are the cockroach, field cricket, grasshopper, &c.

3. *Hemiptera*. Of which are the field, tree, and bed-bugs, fetid bugs, &c.

4. *Neuroptera*. In which are comprehended the dragon fly, lace fly, ephemera, &c.

5. *Hymenoptera*. In this order are bees, wasps, ants, saw-flies, gall-flies, &c.

6. *Lepidoptera*. Of which order are the butterflies, moths, &c.

7. *Rhipiptera*. Of which are certain minute insect parasites living on bees, wasps, &c.

8. *Diptera*. Of this order are gnats, house flies, musketoos, ox and horse flies, &c.

The insects without wings (*Aptera*) are divided into the following orders:

9. *Myriapoda*. Of this are the centipede, Iulus, &c.

10. *Thysanura*. Including small, soft, leaping insects, generally covered with a silvery down, and found in damp places, under logs, &c.

11. *Parasita*. The lice tribe, &c.

12. *Suctoria*. The flea.

I. *The Transformation of Insects*.—Insects commonly change their form several times in the most apparently magic manner. A few, the Aphis, for instance, are viviparous, but they are generally produced from eggs, that is, the eggs are produced in the body of the mother. “The female,” says Köllar, “lays her eggs (which are often stuck on and covered with a kind of glue to protect them from the weather) shortly after pairing, instinctively in the place best adapted for their development;”

and which offers the proper food to the forthcoming brood.

Most insects issue from their eggs as larvæ; those of the butterflies are provided with feet, and are called caterpillars; those of beetles, grubs; and when they have no feet, they are called maggots. In this state, as their bodies increase, the insects often cast their skin, and sometimes change their colour. Many winged insects, such as the grasshoppers, dragon flies, &c., very much resemble in their larva state the perfect insect; they only want the wings, which are not developed till after the last change of the skin. The larva state is the period of feeding; and insects are then usually the destructive enemies of other productions of nature, and objects of persecution to farmers, gardeners, and foresters.

The nymph or pupa state succeeds that of the larva. Insects do not now require nourishment (with the exception of grasshoppers and a few others), and repose in a death-like slumber. To be safe from their enemies and the weather, the larvæ of many insects, particularly butterflies, prepare for themselves a covering of a silky or a cottony texture. Many form themselves a house of earth, moss, leaves, grass, or foliage. Many even go into the earth, or decayed wood, or conceal themselves under the bark of trees, and other places of security.

After a certain fixed period the perfect insect appears from the pupa. It is usually furnished, in this state, with other organs for the performance of its appointed functions, as for the propagation of its species, &c. The male insect seeks the female, and the female the place best suited for laying her eggs; hence most insects are furnished with wings. Food is now a secondary consideration; consequently, in many, the feeding organs are less perfectly developed than in the larva state, or very much modified, and suited for finer food, as, for example, in butterflies, which, instead of the leaves of plants, only consume the honey out of their flowers.

II. *The food of insects* is indeed procured from an extensive pasture. "From the majestic oak," observes M. V. Köllar, "to the invisible fungus or the insignificant wall-moss, the whole race of plants is a stupendous meal to which the insects sit down as guests. Even those plants which are highly poisonous and nauseating to other animals are not refused by them. But this is not yet all. The larger plant-consuming animals usually limit their attacks to leaves, seed, and stalks: not so insects, to the various families of which every part of a plant yields suitable provender. Some which live under the earth, attack roots; others choose the stem and branches; a third division live on the leaves; a fourth prefers the flowers; while a fifth selects the fruit or seed. Even here a still further selection takes place. Of those which feed on the roots, stems, and branches, some species only eat the rind like the bee-hawk moth; others the inner bark and the alburnum, like the bark beetle; a third division penetrates into the heart of the solid wood, like the family of the long-horned beetles. (See BORERS.) Of those which prefer the foliage, some take nothing but the juice out of

the sap vessels, as the aphides: others devour the substance of the leaves without touching the epidermis, as the mining caterpillars; others only the upper or under surface of the leaves (leaf rollers), while a fourth division (as the larvæ of the *Lepidoptera*) devour the entire leaf.

Of those feeding on flowers, some eat the petals (the rose-bug, &c.), others the farina (bees, &c.); a still greater number consume the honey from the nectaries (wasps, flies, &c.); other insects injure the plant by puncturing it, and laying their egg in the wound, and with it an acrid matter, which causes a peculiar excrescence in which their young are hatched and live, until they are able to eat their way out, to perform the functions of the parents, such as the gall-fly, &c. The death-watch or ticking beetle (*Anobium*) feeds on dry wood, long used, as portions of our dwelling houses.

Those insects which tenant and feed upon animal matters, have an equally varied taste: of these are the different kinds of bird and sheep lice, &c., gnats, midges, breeze flies, bugs, fleas, &c. Some of the carnivorous beetles devour their prey entire; others only suck out their juices; others live upon the food they obtain in water, and devour swarms of the infusoria. Many live on carrion and the excrements of the larger animals, such as the dung-beetle, and carcass-beetle; others live in the stomachs of animals; many moths live entirely upon hair, leather, wool, and feathers.

The food of insects varies strangely with their transformations: the caterpillar requires very different food from the butterfly; the maggot from the beetle and fly. The larva of the *Sirex gigas* feeds on wood, the perfect insect on flies. Those of some melolonthians live on roots and tubers, the beetle on leaves. The quantity of food consumed by different insects varies very much: many consume more than their own weight in a day. The maggot of the flesh-fly, according to Redi, becomes 200 times heavier in the course of 24 hours. Caterpillars digest every day about one-third to one-fourth of their weight; hence the ravages they commit in a few days. Of others, however, such as the day-flies (*Ephemeridæ*) and the breeze-flies, and even amongst the *Lepidoptera* which spin cocoons, many appear to abstain from nourishment. Some eat only during the day, others in the evening; and others, such as the caterpillars of the night moths, during the night. Most of them provide their own food; but a few which live in communities, such as the wasps, bees, ants, &c., are fed by the perfect insect. Many provide a store of food, but the greater number die unprovided with a store: others feed their larvæ." See BEETLE, and BORERS.

III. *Destruction of Insects, &c. by Artificial Means.*—Various have been the recipes suggested for the destruction of the insects which destroy the cultivator's crops. *Ants*, it is said, may be easily destroyed by toasting the fleshy side of the skin of a piece of bacon till it is crisp, and laying it at the root or stem of any fruit tree that is infested by these insects, placing something over the bacon to

keep it dry—the ants will go under it; after a time lift it up *quickly*, and *dip* it into a pail of water. While treating of insects, I may incidentally allude to worms and slugs, or naked snails. For the destruction of *slugs*, warm in an oven, or before the fire, a quantity of cabbage leaves, until they are soft, then rub them with unsalted butter, or any kind of fresh dripping, and lay them in the places infested by slugs. In a few hours the leaves will be found covered with snails and slugs. Woodlice are destroyed in the same way. For field operations, perhaps, the best means of destroying slugs and worms is common salt, an agent too little known for this purpose, yet its powers are undoubted.

No person has employed common salt for the purpose of destroying worms to a greater extent than Jacob Busk, Esq., of Ponsbourn Park, in Hertfordshire. His valuable experiments have extended over some hundreds of acres of wheat. To use his own words,—“In every situation, and at every time, the effect appeared equally beneficial.” The quantity per acre,—“about four or five bushels sown out of a common seed-shuttle.” The period,—“In the evening.” The effect,—“In the morning each throw may be distinguished by the quantity of slime and the number of dead slugs lying on the ground. In some fields it has certainly been the means of preventing the destruction of the whole crop.” Six bushels of salt per acre was applied by hand, in April, 1828, to a field of oats attacked by the slugs and worms, and the crop was completely saved by this application, although an adjoining field, *not salted*, was entirely destroyed by this sort of vermin.

Salt, too, is a complete preventive of the ravages of the *weevil* in grain. It has been successfully employed in the proportion of a pint of salt to a barrel of wheat. I learn from an American merchant, that wheat placed in old salt barrels is never attacked by these destructive insects. Six or eight pounds of salt sprinkled over 100 sheaves in stacking, produces exactly the same effect.

The *Eriosoma lanigera* upon apple trees, and several other insects (See AMERICAN BLIGHT), may be killed by clay and water, made as thin as whitewash, and mixing with every 6 gallons of it 2 lbs. of cream of tartar, 1 lb. of soft soap, and half a peck of quicklime. “When you think,” says Mr. Loudon, “that the weather is likely to continue dry for some time, take a bucketful of this mixture, and with a large brush wash over the bark of the trees, wherever you think it has been infested with the bug. A man will dress a number of trees over in a few days with a whitewash brush and this liquid; it is only necessary to be careful to do it in dry weather, so that the rain may not wash over the mixture for some time. The clay and water alone are sometimes effectual. *Flies and wasps*.—A mixture of pepper, sugar, and water will speedily attract and destroy them. (*Gard. Mag.* No. 37; *Quart. Journ. Agr.* vol. iii. p. 1071.)

Moss and Insects.—Mr. Thomas recommends that the trees infested should be sprinkled with a fine powder in March, and again in Oc-

tober, on a foggy day when the trees are damp but not dripping, and I have no doubt of its efficacy. It is composed as follows: slack five bushels of lime, hot from the kiln, with common salt and water (say one lb. of salt to each gallon of water). When the lime has fallen to a fine powder, add by small quantities at a time a bushel of soot, stirring it until completely incorporated. Mr. Thomas has found that one man can dust over with the powder fifty trees in a day, and that the moss in the turf under fruit trees thus treated is also completely destroyed by the application. (*Trans. Soc. Arts.*) *Worms* in grass plats may be readily destroyed by copiously watering the turf with lime-water (half a pound of the hottest quick-lime well stirred in each gallon of water), or by sprinkling common salt (20 bushels per acre) over it, or by strewing it on gravel walks in rather large proportions. Lime is recommended for the destruction of the worm which sometimes injures young larch plantations; coal-tar and tar water to preserve hop poles and other wood from the ravages of insects. The caterpillars on cabbages may be readily destroyed by sprinkling them with finely powdered lime; and when some years since a black caterpillar attacked very generally and extensively the turnips, in some instances they were very successfully destroyed by turning into the fields considerable numbers of common ducks. Heavy rolling, especially during the night, is in many cases destructive of slugs; and it is certain that, by occasional material variations in the rotation of crops (see ROTATION OF CROPS), the number of predatory insects may be very considerably reduced in cultivated soils by depriving the larvæ of their particular and essential food.

Mr. Knight recommends the use of carbonate of ammonia for the destruction of the insects upon the pine and other plants. Mr. Baldwin, in effect, does the same, when he commends the use of the steam from hot fermenting horse dung. Mr. Robertson found soot (which contains ammonia), when diffused in water, to be an excellent application. When speaking of the use of fermenting horse dung in the destruction of insects, Mr. Knight remarked, “I conclude the destructive agent in this case is ammoniacal gas, which Sir Humphry Davy informed me he had found to be instantly fatal to every species of insect; and, if so this might be obtained at a small expense by pouring a solution of crude muriate of ammonia upon quicklime; the stable or cow-house would afford an equally efficient, though less delicate fluid. The ammoniacal gas might, I conceive, be impelled by means of a pair of bellows amongst the leaves of the infested plants, in sufficient quantity to destroy animal without injuring vegetable life.” Ammonia seems peculiarly distasteful to insects. Carbonate of ammonia is often successfully placed in meat-safes to prevent the attacks of flies.

IV. *The natural Enemies of Insects*.—Amongst the enemies by which insects are kept in check, may be numbered long-continued rains, late frosts, inundations, storms; and, among the animals, bats, mice, moles, squirrels, foxes, &c. Birds devour them by myriads; the green

finch tears open (says Reaumur) the strong nest of the yellow-tailed moth, and eats the infant caterpillars. The woodpeckers and tree-creepers commit great ravages amongst the beetles and caterpillars. Crows, which in some sections destroy the corn, commit great ravages upon cutworms and destructive insects. In one of the English counties where the rook (a bird allied to the crow) had increased so as to do some damage to the crops, a destructive war was waged against them, so that they were nearly exterminated. But under these circumstances various species of the insect tribe increased so rapidly, that it became necessary to import the rooks again from the adjoining counties. In fact, it remains to be proved whether *any* omnivorous bird is more prejudicial than useful. Insects in their various states exist throughout the warm season, whilst the crops are exposed to the birds for a comparatively short period. Every protection should be given to birds, and boxes should be fitted up for martins, wrens, and bluebirds. To these may be added the frog, the toad, &c. Many insects, such as the ground beetles, devour the pupæ of others. Then, again, there is the numerous order of the *Ichneumonidæ*, which lay their eggs in the bodies of other insects and destroy them. The eggs are hatched within the body of the living insect, and the young parasites, in the most literal sense, fatten on the entrails of their prey. At last the wounded caterpillar sinks, the enemies escape through the skin and become pupæ; or the caterpillar, notwithstanding its internal parasites, enters the pupa state; but, instead of a butterfly, one or more *Ichneumonidæ* appear. The beautiful little red insect familiarly known as the lady-bird or lady-bug, is of vast service by the havoc which it makes among the plant and bark-lice. Many a friendly ichneumon fly or lady-bird has been killed by those whose want of knowledge led them to consider these insects destructive to vegetation. To these wonderful animals we often owe the preservation of our orchards, woods, and grains. Many other modes, besides those I have enumerated, have been suggested, by which the number of the cultivator's predatory insects may be reduced, most of which I shall notice under their respective heads. I am quite of the opinion, however, of the authors of the work I have so extensively quoted, "that the most essential and necessary means to be opposed to the serious injuries caused by insects, consists in the universal dissemination of the knowledge of the natural history of hurtful insects amongst farmers, gardeners, foresters, and all those, in fact, who are in any manner connected with agriculture."

V. *Of the Insects which live and propagate on domestic animals.*—The chief are lice, which commonly originate from want of cleanliness, poor, unwholesome food, or from the weakening effects of other diseases. Old horses are more subject to them than young ones; they are common in sheep, and in swine; for which the best remedies will be found under their respective heads. (For the bots in horses, see **BOT**; for those in sheep, see **SHEEP BOT**; for the ox-warble, see **WARBLE**.) The forest fly,

or horse fly, lives chiefly on horses. It flies in short flights quickly, and moves about with considerable agility. The female lays but one egg at a time, from which the fly is hatched. They abound in the New Forest. See **HORSE FLY**.

The well-known sheep tick has no wings; the fore part of its body is very small, but the abdomen is large. Its colour reddish, with white lines on the side of the abdomen. The farmer will find the following an excellent receipt for a sheep-dipping wash, by which they are readily destroyed:— $\frac{1}{2}$ a lb. of powdered white arsenic, $4\frac{1}{2}$ lbs. of soft soap. Boil these for a quarter of an hour, or until the arsenic is dissolved, in five gallons of water. Add this to the water sufficient to dip fifty sheep. The quantity of arsenic usually recommended is too large. See **TICKS**.

VI. *Insects which injure Bees.*—There are several insects which injure bees, such as a parasite bee-louse, which is about the size of a flea, has no eyes, but the rudiments of four feelers. They tenant chiefly populous hives: sometimes two or three are found on a bee. These parasites disturb and annoy even the queen bee. "A bee," says M. Köllar, "infested with a bee-louse, endeavours, but to no purpose, to get rid of such an unwished-for guest, till at last she creeps under a number of other bees, and rubs off the louse from her back, when it immediately betakes itself to the back of another bee. That the presence of this parasite causes pain to the bee, is apparent from the restlessness with which she runs out at the hole and back again. The queen is also disturbed in her employment of egg-laying, when she is infested by them, so that the hive suffers in another way by impoverishment. It may even happen that when many of these parasites infest a queen, she must eventually perish. In winter the infested bees usually fall to the floor, and perish with cold and hunger." Spiders also destroy bees, but only in their nets. Then there is the caterpillar of the honeycomb-moth, whose ravages are very considerable, when once they find their way into a hive. They devour only the wax. Three hundred have been found in a hive, and there are two generations of these caterpillars in a year. Ants also are very fond of honey, and find their way into hives. Wasps very frequently do the same. Bees even rob each other's hives.

VII. *The Insects which injure Grain.*—These are numerous: the chief of them are the larvæ which feed on the green leaves and roots of grain. On these the blackbirds, crows, and other useful birds feed very copiously. The barley-midge (*Tipula cerealis*) attacks the barley and spelt plants.

VIII. *Insects which injure Meadows.*—This is also a very numerous class. "Most of the insects that choose the various sorts of corn for their food," says M. Köllar, "do not reject the other sorts of grasses, in the meadows. The herbage of the meadows has also often peculiar enemies, which are very difficult to find out and destroy. In most cases the meadows suffer from the roots of the grass plants being injured, which is chiefly occasioned by the larvæ of various species of cockchafers, living

in the earth. When bare spots are seen on meadows, we may be pretty sure that the larvæ of some species of melolontha are there carrying on their work of destruction. The sub-turf plough disturbs the operations of these vermin; the crows devour them.

IX. *Insects injurious to cultivated Vegetables*.—Are also numerous, and highly injurious to the gardener's crops. The flea-beetles (*Haltica*) are great pests to the gardener: they attack and devour, during the summer months, various members of the cabbage tribe, such as the cabbage, cauliflower, and colewort, the turnip, the radish, common and water cress: they also prey upon flax, hops, sainfoin, &c. (See *FLY IN TURNIPS*.) The mole cricket (*Gryllotalpa*) is often peculiarly injurious to the German cultivators. It does not confine its ravages to the garden crops, but injures very materially those of the meadow and corn-fields. It measures, when full-grown, about two inches in length. The plant-lice (*Aphis*) chiefly haunt the cabbage, peas, and beans. They are devoured in great numbers by several of the ladybirds (*Coccinella*) and fly tribes.

X. *Insects which injure Green-house Plants*.—Of these I need only mention the orange scale insect (*Coccus hesperidum*); the pine-apple scale insect (*Coccus bromeliæ*); the mealy bug (*Coccus Adonidum*); the oleander scale insect (*Aspidiotus Nerii*), abounding on oleanders, acacias, aloes, palms, &c.; the rose scale (*A. rosæ*), found in old rose stems and twigs; the cactus scale (*A. echinocacti*), on the cacti; the sweet-bay scale (*A. lauri*), on the sweet bay; the rose-moth (*Tinea (Ornix) rhodophagella*); and the plant-mite or red spider (*Acarius telarius*).

XI. *Insects which attack Fruit Trees*.—The number of insects which live either partially or entirely upon fruit trees, is very considerable. I can hardly do more in this work than give the names of the most formidable of these little depredators.

XII. *Insects injurious to Forest Trees*.—These are divided by M. Köllar into two classes:—1. Those which attack deciduous trees; and, 2. Those which are injurious to the evergreens.

XIII. *Insects which attack the Fir and Pine Tribe*.—These often injure very seriously the leaves, bark, and young shoots of some of the Pinus tribe.

Such, then, is a very brief glance at that immense and important class of animals which are included in the science of entomology. It must be considered, to use the words of Mr. Swainson, only as suggestions and stimulants to further inquiry. The review, however, cannot but fill us with astonishment; for, although we see only a very limited portion of the insect world, yet that view, limited as it is, is fraught with instruction to the cultivator. It will lead him, perhaps, to a clearer understanding of the often-repeated truth, that nothing is created in vain. It may suggest to him also the means, in some cases, of arresting their ravages, when, by their excessive numbers, they become a nuisance; and it may perhaps be instrumental in saving from destruction many a useful bird, when the sportsman is made aware of the number of predatory insects which they so unceasingly destroy. The astonishing number, habits,

and instincts of the insect tribe, too, are equally instructive, and can only be explained in one way. These phenomena did not escape the notice of the great Paley. Thus he observes, "Moths and butterflies deposit their eggs in the precise substance (that of a cabbage, for instance) from which not the butterfly herself, but the caterpillar which is to issue from her eggs, draws its appropriate food. The butterfly cannot taste the cabbage; cabbage is no food for her; yet in the cabbage, not by chance, but studiously and electively, she lays her eggs." And when referring to this immense mass of animal life, he says, in another place, "To this great variety in organized life the Deity has given, or perhaps there arises out of it, a corresponding variety of animal appetites. For the final cause of this we have not far to seek. Did all animals covet the same element, retreat, or food, it is evident how much fewer could be supplied and accommodated than what at present live conveniently together, and find a plentiful subsistence. What one nature rejects, another delights in. Food which is nauseous to one tribe of animals, becomes, by that very property which makes it nauseous, an alluring dainty to another tribe. Carrion is a treat to dogs, ravens, vultures, fish. The exhalations of corrupted substances attract flies by crowds. Maggots revel in putrefaction." Neither can the astonishing changes of some of the insect tribe be regarded by a rational being without very considerable interest. "The wonderful metamorphosis undergone by the order Lepidoptera," says Swainson, "would be almost incredible, were it not familiarized to us from early childhood, that a crawling worm, ravenous of grass food, should voluntarily seek a retreat in the earth, or spin its own shroud; that such a change should come over it, so complete, as that not a lineament of its first form was retained; that in this state, after remaining a misshapen lump, to all appearance inanimate, it should suddenly burst forth, full of life and joy, and, with many-coloured wings, ascend into mid-air, and derive its only sustenance from the nectar of flowers;—all this, we say, is one of those miracles of nature, which, were it told of an insect that had never yet been seen, the world would not believe."

Description of the Plate of Noxious Insects.—Throughout this work we have made great use of the valuable treatise of Dr. Harris on destructive insects; but, as it is unaccompanied by plates, the reader who is unacquainted with the subject may be occasionally in doubt as to the aspect of those described. On this account we have devoted Plate 16 to the illustration of a few of the principal forms, both of destructive insects and those which prey upon them. The species figured are,

1. *Elaphidion putator*, oak pruner. See *ROVERS*, p. 205.
2. *Clytus flexuosus*, locust tree borer. See *BORERS*, p. 206.
3. *Criociris trilineata*. Potato-vine bug.
4. *Haltica striolata*, cucumber flea (magnified), p. 371.
5. *Phyllophaga quercina*, p. 172, 173.
- 6. *Hylobius pales*, which is very destructive to the pine forests of the south. The plum

weevil and grain weevil, as well as this species, belong to the *Curculio* family.

7. *Agrotis clandestina*, cut-worm.

8. *Egeria exitiosa*, peach tree borer, female.

9. *Gallerea cereana*, bee-moth, p. 168.

10. *Caravus Goryi*, which may be taken as a representative of a large family which feeds upon other insects, caterpillars, etc.

11. *Coccinella borealis*, which in its larva and perfect state, feeds upon the aphides so destructive to roses and other plants.

12. *Trogus fulvus*. The members of the extensive family (*Ichnemonidæ*) to which this species belongs, commit great havoc among caterpillars and grubs.

INSTEP. In farriery, a name given to that part of a horse's hind-leg which reaches from the ham to the pastern joint.

INSURANCE. One means of security against fire. The farmer being constantly surrounded by much combustible matter, should never, when possible, omit rendering himself safe by insuring his stock of every kind in some public office, instituted for this purpose.

In England, the legislature has wisely afforded very considerable facilities to the insurance of farming stock, which, by an act of Parliament, is exempted from duty. "The Farmer's Insurance Institution" of London insures it at 1s. 9d. per cent., without the average clause; thus easily repaired are the ravages of the incendiary, of accidental fires, and lightning.

INTRUMENT. The outer covering or skin of an animal: it is also used in the same sense as a synonyme for *Testa*, for the husk or exterior covering of seeds.

INVENTORY (Fr. *inventaire*; Lat. *inventarium*). A detailed account taken of any thing upon a farm. Inventories of the various kinds of farming stock should be taken annually, at the close of the year. See **BOOK-KEEPING** and **APPRAISEMENT**.

INVOLUCRE, or **INVOLUCRUM**. In botany, the bractes (or small leaves placed near the calyx, or the peduncle or pedicel) which surround the flowers or the umbels. *Involucels* are the partial involucre of umbelliferous plants. (*Paxton's Bot. Dict.*)

IRIS (from *iris*, the rainbow; alluding to the variety and beauty of the colours of the flower). This extensive genus has long been, as it still continues to be, a great favourite in the flower garden. "The sword-leaved sorts (says Sweet) do best in a light loamy soil, and increase freely by suckers from the roots or by seeds. The tuberous-rooted ones are more difficult to cultivate, and thrive best in a mixture of loam, peat, and sand, as does also the tribe to which *I. persica* belongs, as *I. alata*, *I. caucasica*, *I. reticulata*, &c. The common bulbous species do well in any garden soil, the more sandy the better." *I. tuberosa* is aromatic as well as emetic and purgative, and *I. versicolor* and *I. verna* are used in the United States as cathartics. (*Paxton's Bot. Dict.*) Two species of iris only are indigenous to England,

1. The yellow water iris, or flower-de-luce (*I. pseud-acorus*), which grows wild in ditches, pools, and rivers, and forms a handsome orna-

ment for the banks of ponds and streams, blowing from three to six large, bright yellow flowers in July. The root is horizontal, depressed, brown, very astringent; the stem 3 or 4 feet high; leaves erect, ribbed, grass-green. The disks of the larger segments of the flowers are pencilled with dark purple.

2. Stinking iris, or Gladwyn. Roast-beef plant (*I. fetidissima*). This species grows in groves, thickets, and under hedges, but it is rather rare. Dr. Withering, however, observed it to be very common in England in all the southwest counties. It is a perennial, growing to about 2 feet high; the leaves are dull green, exhaling, when rubbed, a scent compared to that of roast beef, to which it is no compliment. The flowers, which appear in May, are dull, pale purple, pencilled with dark veins. Seeds orange-coloured, polished. (*Eng. Flor.* vol. i. p. 48.)

Miller only mentions 19 species of cultivated irises, but there are now nearly 100 known species and varieties. Two or three only are much admired as ornamental flowers. The *I. xiphium* is a bulb from Spain, blowing blue, white, yellow, and violet flowers in June. The *Persian* iris blows a fragrant flower in March and April; plant the bulb in October, in a pot filled with equal quantities of fine mould and sand, and house it during frost. The dwarf iris is ornamental in clusters in a garden; it grows only three inches high, and blows in April. Part its roots in autumn. The *Siberian* iris blows in June, and likes a moist situation; it bears flowers whose falling petals are blue, and the upright ones dark purple; its stem is tall, and its leaves are narrow. *I. susiana*, or fleur-de-lis. The plant is tuberous rooted, loves a good soil, and should be removed every three years. It flowers handsomely in June, bearing varieties of pale blue, deep blue, and striped or bluish-white flowers. Its odour is feeble, but it is fetid. These are the most favourite kinds in gardens. The *I. florentina*, which is occasionally seen in our gardens, yields the orris root, which is the dried and peeled rhizomes of the plants. Orris root is prized chiefly on account of its odour, which resembles that of the violet. It is added on this account to tooth powders and hair powder. A hazardous custom prevails of giving the entire root to infants to gnaw during teething, from which fatal results have followed.

The wild flag, Colour-changing flax (*Iris Virginiana*), is common on the margins of ponds and in miry places in the Middle States. Dr. Bigelow remarks that the root of this is a violent emetic. Seven or eight other species of iris are enumerated in the United States. (*Flor. Cestrica.*)

IRON-WOOD (*Carpinus ostrya*). See **HORN-BEAM**.

IRRIGATION (Lat. *irrigio*, to water). In agriculture, the watering of the earth, to increase its productiveness. The term, however, is confined to that species of flooding which consists of spreading a sheet of water over a field or meadow, in such a manner that it can be easily withdrawn.

Irrigation, or the artificial watering of the

earth, chiefly to produce increased crops of grass, has been in use from a very early period. In Oriental countries, in fact, the heat of the climate is such, that in many situations the now productive soil would be absolutely sterile, were it not that the cultivator enriched his ground with a copious supply of water. The simile employed by Isaiah (i. 30), to indicate barrenness and desolation, is "a garden that hath no water." And that, in patriarchal times, they laboured hard to supply their grounds with water by means of various hydraulic machines, some of which resembled the water-wheels of the fen districts of England, and were worked by the feet of men, something after the style of the modern treadmill, is certain. Moses alluded to this practice when he reminded the Israelites of their sowing their corn in Egypt, and watering it with their feet (*Deut.* xi. 10; *2 Kings*, xix. 24), and in the sandy soils of Arabia the same system is still continued. (*Niebuhr*, vol. i. p. 121.) According to Dr. Shaw, the following is the modern mode of raising and using the water of the Nile for the purpose of irrigation in Egypt. "Such vegetable productions as require more moisture than what is occasioned by the annual inundation of the Nile, are refreshed by water that is drawn at certain times out of the river, and lodged in large cisterns made for that purpose. The screw of Archimedes seems to have been the instrument formerly made use of for that purpose, though at present the inhabitants either supply themselves with various kinds of leathern buckets, or else with a *sakiah*, as they call the Persian wheel, which is the most useful and generally employed machine. Engines and contrivances of both these kinds are placed all along the banks of the Nile, from the sea to the cataracts, their situations being higher, and consequently the difficulty of raising the water being greater, as we advance up the river. When their pulse, saffron, melon, sugar-canes, &c. (all of which are commonly planted in rills), require to be refreshed, they take out a plug from the bottom of the cistern, and then the water gushing out, is conducted from one rill to another by the gardener, who is always ready as occasion requires to stop and divert the current. In Egypt at the present day, according to Dr. Clarke, the water is sometimes raised for the purposes of irrigation by means of a wicker basket lined with leather, which is held by cords between two men, who, by this laborious means, swing it over the banks of the Nile into the canal which conveys it to the lands intended to be irrigated. A machine similar to the Persian wheel is still employed in China by the cultivators for the purposes of irrigation. This use of machinery for the purposes of watering might, in fact, in many situations, be advantageously employed in England to a much greater extent than is commonly believed. It is well known how many thousand acres of valuable land are profitably drained by means of the steam-engine. At this very period a public company is proposing to enclose and drain an arm of the sea in Lincolnshire, by the assistance of its gigantic aid. Yet how rarely, if ever, is that power employed

to irrigate the thirsty lands of England; lands of all others the most profitable, the best adapted for the formation of water meadows. The tracts to which I allude are those on a slope, as on the side of a hill; but these are rarely found in situations where a sufficiently copious supply of water can be constantly obtained for the purposes of irrigation. Yet the quantity thus required is not so large as to be beyond the power of the steam-engine to supply; thus, to sufficiently saturate a square yard of a calcareous sand soil with water to the depth of one foot, as in irrigation, requires about 30 gallons of water, equal to about 145,000 gallons per imperial acre. Now, that the steam-engine could readily and profitably supply this quantity of water may be concluded from several facts; thus, the two engines, one of 80, the other of 60 horses' power, which keep Deeping Fen, near Spalding, completely drained, when working, in 1835, only 96 days, of 12 hours each, raised more than 14,000,000 tons of water several feet. The district drained by them contains about 25,000 acres (*Brit. Farm. Mag.* N. S. vol. iii. p. 300), which would otherwise be a complete swamp. And it has been proved that, by a common condensing steam-engine, one bushel of coals will raise more than 50,000,000 lbs. of water one foot. In many situations, therefore, where, for the purposes of irrigation, good river water can be copiously obtained, and fuel is at a moderate price, I am confident that great results are yet to be obtained by the aid of mechanical power. For, by the steam-engine, the soils of all others the best adapted for irrigation, may be successfully brought into cultivation; for instance, the poor sands and gravels on the sloping banks of many of the English and Scottish rivers, many of whose waters, from being charged with organic matter, the carbonate and sulphate of lime, and various earthy substances, are excellent for the use of water meadows. The early employment of irrigation by the Egyptians and Chinese was most likely the result of the good effects which were observed to be produced by the overflowings of the Nile and the Chinese rivers; for, in the "Celestial Empire," irrigation has, it seems, been employed, according to their voracious historians, for a period long before that assigned to the flood. In Italy, especially on the banks of the Po, the cultivators of the earth have certainly employed this process for a period previous to the days of Virgil (*Georg.* lib. i. v. 106—9),—

Deinde satis fluvium inducit, rivosque sequentes—

and it is still carried on with a zeal and care worthy of the art they practise. M. P. Cato, the earliest of the Roman writers upon agriculture (150 years before Christ), in his ninth chapter, told the Italian farmers to "make water meadows, if you have water, and if you have no water, have dry meadows." The directions of Columella seem to have all the freshness of a modern age about them. He was the first who noticed the inferior nutrition afforded by the hay from water meadows. "Land," says he, "that is naturally rich, and is in good heart, does not need to have water set over it: and it is better hay

which nature, of its own accord, produces in a juicy soil, than what water draws from a soil that is overflowed. This, however, is a necessary practice when the poverty of the soil requires it; and a meadow may be formed either upon a stiff or free soil, though poor when water may be set over it; neither a low field with hollows, nor a field broken with steep rising ground, are proper; the first, because it contains too long the water collected in the hollows; the last, because it makes the water run too quickly over it. A field, however, that has a moderate descent may be made a meadow, whether it be rich, or so situated as to be watered; but the best situation is where the surface is smooth, and the descent so gentle as to prevent either showers, or the rivers that overflow it, remaining too long; and, on the other hand, to allow the water that comes over it quietly to glide off; therefore, if in any part of the field intended for a meadow, a pool of water should stand, it must be let off by drains, for the loss is equal either from too much water or too little grass." (*Col. lib. ii. c. 16.*) Pliny tells us that "meadows ought to be watered immediately after the spring equinox, and the waters restrained whenever the grass shoots up into stalk." (*Nat. Hist. lib. xviii. c. 27.*) When, after the fall of the Roman Empire, agriculture, in common with all other sciences, rapidly declined, a very remarkable exception to this melancholy result of slavery and despotism was presented in the case of irrigation, which was carried on and extended through the long period of the dark ages with equal zeal and success. This was more especially the case in Lombardy, where it was certainly prosecuted on a very bold and profitable scale long before 1037. The princes of Lombardy patronised and followed the example of the various religious establishments which then monopolized all the wealth and learning of the land, in extending the employment of water in all possible directions. The monks of Chiazevalle, in particular, were so celebrated for their knowledge of this branch of agriculture, and of hydraulics in general, that the emperor Frederick the First, in the 13th century, very gladly sought their advice and assistance. This system has ever been zealously and carefully extended and improved in every possible way. The waters of the chief rivers of the north of Italy, such as the Po, the Adige, the Tagliamento, and of all the minor streams, are employed in irrigation. There is no other country, which possesses an extent of rich water meadows equal to that of the Lombards. The entire country from Venice to Turin may be said to be formed into one great water meadow: yet the irrigating system is not confined to grass lands; the water is conveyed into the hollows between the ridges in corn lands, into the low lands where rice is cultivated, and around the roots of vines. From Italy the practice extended into the south of France, into Spain, and then into Britain. In the States of Lombardy, the water of all the rivers belongs to the state; in those of Venice, the government extends its claims to that of the smallest springs, and even to collections of rain water, so highly for the use of the cul-

tivator, is water of every kind valued in the north of Italy. It is necessary, therefore, in Lombardy, to purchase from the state the water taken from the river; this may be taken, by means of a canal, through any person's grounds, the government merely requiring the payment of the value of the land to the proprietor, and restraining him from carrying his channel through a garden, or within a certain distance of a mansion. The water is sold by the government at a certain rate, which is regulated by the size of the sluice, and the time the run of water is used; this is either by the hour, half-hour, or quarter, or by so many days at certain periods of the year; the right to these runs of water is regularly sold like other property. Arthur Young gives an account of the sale of an hour's run of water through a sluice near Turin, which produced, in 1778, 1500 livres. The rent of the irrigated lands in the north of Italy is, upon an average, more than one-third greater than the same description of land not watered. (*Com. Board of Agr. vol. vii. p. 189.*)

In Bengal, wells are dug in the highest part of their fields, and from this, by means of bullocks and a rope over a pulley, water is raised in buckets, and conveyed in little channels to every part of the field. No attempts at cultivation are here made without the assistance of water, obtained by some mode or other. (See INDIA, AGRICULTURE OF.) The art of irrigation was not confined to the Old World. The Mexicans practised it long before the days of Columbus; they collected the mountain torrents, and conducted their waters to their lands in proper channels, with much care and address. It was only towards the termination of the 17th century that water meadows were constructed in Britain upon any thing like a regular system. Of these, those in Wiltshire, which are amongst the most celebrated in England, especially those in the Wyley Bourn, were made between 1700 and 1705. Those of Hampshire and Berkshire were constructed about the same period, but they were at first formed very inferior to the modern noble water-meadow lands of those countries. Great improvements were made towards the conclusion of the 18th century, through the publications of G. Boswell on Meadow Watering in 1780, and of the Rev. T. Wright, of Auld, in Northamptonshire, whose writings appeared at intervals from 1789 to 1810. It is noticeable that the water employed for these celebrated southern meads is perhaps the most clear and swift flowing of all the English rivers; issuing from the chalk formation, it is equally copious and transparent. Some of the chief advantages, therefore, of irrigation may evidently be derived from almost any description of water; for it is proved by the good effects produced by the brilliant chalk-waters of the south of England, and the still greater fertilizing effect of those surcharged with organic matter, as in the Craigtintny meadows, near Edinburgh, that there is no water too bright, or too full of impurities, to be useless for the purposes of irrigation.

I propose, in this paper, to investigate the chemical properties of river water, and of the

effects produced by it in irrigation, adding a few remarks upon the practice of the best and most skilful cultivators of the water meadows of the south of England.

1. With regard to the composition of river water, there have been several chemical examinations; that of the Thames was analysed by Dr. Bostock, who found, in 10,000 parts, after most of its mechanically-suspended matters had subsided, about $1\frac{3}{4}$ parts of foreign substances, viz.:

	Parts.
Organic matters - - -	0.07
Carbonate of lime - - -	1.53
Sulphate of lime - - -	0.15
Muriate of soda - - -	0.02

In an equal quantity of the waters of the Clyde, Dr. Thompson found $1\frac{1}{8}$ part of solid substances, namely:

	Parts.
Common salt - - -	0.369
Muriate of magnesia - - -	0.305
Sulphate of soda - - -	0.114
Carbonate of lime - - -	0.394
Silica - - -	0.118

The water of the Itchen, in Hampshire, is one of the most celebrated of all the southern streams, for the use of the irrigator. I found, in 10,000 parts of water, about $2\frac{1}{2}$ parts of solid matter, viz.:

	Parts.
Organic matter - - -	0.02
Carbonate of lime - - -	1.89
Sulphate of lime - - -	0.72
Muriate of soda - - -	0.01

From an examination of the substances found in these streams (and they afford a pretty correct view of the contents of most others), the farmer will see that they all yield ingredients which are the food or natural constituents of the grasses. Thus, sulphate and carbonate of lime are found in most of them, and there is no river-water which does not contain, in some proportion or other, organic matter. To ascertain, therefore, whether pure water was alone able to effect all the magic effects of irrigation, it was necessary to employ other water than that of rivers, lakes, or even springs. Pure water, as obtained by distillation, therefore, has been tried as a supporter of vegetation, but it was found totally inadequate to the support of plants; they merely vegetated for a time, but they could not, by any means, be made to perfect their seeds. In this conclusion the experiments of Dr. Thomson, and of MM. Saussure and Hasenfratz, entirely agree. Pure water, therefore, notwithstanding the dreams of the Greek philosophers, and the celebrated deceptive experiments of Van Helmont with his willow tree, is not able to support the growth of the grasses. Van Helmont's tree, when he planted it in an earthen pot, weighed 5 pounds; the earth, previously dried in an oven, weighed 200 pounds; after 5 years it weighed 164 lbs., although it had been watered during that time with only rain and distilled water, and the earth had lost only two ounces of weight. Hence, said Van Helmont and his disciples, water is the sole food of plants. Bergman, in 1773, first pointed out the source of error. He showed, from the experiments of Margraff, that the rain-water contained a sufficient quantity of earth to account for the increased weight in

the willow, every pint of rain-water containing one grain of earth. Then, again, the earthen vessel (which was sunk in the earth) would, in this experiment, transmit its moisture impregnated with all kinds of soluble substances. And yet it has been shown that impure water, such as that from a sewer, or from a dunghill, is alone sufficient to sustain vegetation. This was clearly evidenced in the experiments of M. Lampadius; for he found that plants placed in a pure earth, such as silica or alumina, although they would not grow when watered with pure water only, yet, when watered with the liquid drainage of a dunghill, they flourished very luxuriantly, and this fact has been also proved in another way. It has been shown, by chemical analysis, that the quantity of solid or earthy matters absorbed by plants is in exact proportion to the impurity of the water with which they are nourished. Thus, equal quantities of some plants of beans, fed by distilled water, yielded—

	Parts.
Of solid matter or ashes - - -	3.9
Those fed by rain-water - - -	7.5
Those grown in garden mould - - -	12.0

These facts strongly confirm the conclusions of some of the most sagacious cultivators, that the chief advantages of irrigation are attributable to the foreign substances with which the water is charged; although, as I have elsewhere observed, almost every farmer has a mode of accounting for the highly fertilizing effects of irrigation; one thinks it *cools* the land, another, that it keeps the grass *warm* in winter. And this was Davy's opinion. He thought that a winter flooding protected the grass from the injurious effects of frost. He says, "Water is of greater specific gravity at 42° than at 32° , the freezing point; and hence, in a meadow irrigated in winter, the water immediately in contact with the grass is rarely below 40° , a degree of temperature not at all prejudicial to the living organs of plants. In 1804, in the month of March, I examined the temperature in a water-meadow near Hungerford in Berkshire, by a very delicate thermometer. The temperature of the air at 7 in the morning was 43° . In general, those waters which breed the best fish are the best fitted for watering meadows; but most of the benefits of irrigation may be derived from any kind of water."

Such were the opinions of Davy as to the fertilizing properties of water. It is to be regretted that the opportunities for agricultural observations of this great chemical philosopher were so few, for his valuable remarks were always cautiously made. He appears, however, as I have remarked elsewhere, never to have steadily investigated the chemical composition of river-water, with regard to its uses in irrigation, and, in consequence, knew little of the value of some of its impurities to vegetation. Thus, if the river-water contains gypsum (sulphate of lime), which it certainly does—if the water is *hard*, it must, under ordinary circumstances, on this account alone be highly fertilizing to meadows, since all grasses contain this salt in very sensible proportions; for, calculating that one part of sulphate of lime is contained in every two thousand parts of river-

water, and that every square yard of dry meadow soil absorbs only eight gallons of water (and this is a very moderate allowance, for many soils will absorb three or four times that quantity), then it will be found that, by every flooding, more than one hundred weight and a half of gypsum per acre is diffused through the soil in the water, a quantity equal to that generally adopted by those who spread gypsum on their clover crops, lucern, and sainfoin, as a manure, either in the state of powder, or as it exists in ashes. And if we apply the same calculation to the organic substances ever more or less contained in flood-waters, and allow only twenty parts of animal and vegetable remains to be present in a thousand parts of river-water, then we shall find, taking the same data, that every soaking with such water will add to the meadow nearly two tons per acre of animal and vegetable matters, which, allowing, in the case of water-meadows, five floodings per annum, is equal to a yearly application of ten tons of organic matter.

The quantity of foreign substances present in river-water, although commonly less, yet very often exceeds what I have thus calculated to exist in it. I have found it impossible, however, to give, from analysis, the amount which, under ordinary circumstances, is present in river-waters, with any tolerable accuracy, since the proportion not only varies at different seasons of the year, but a considerable proportion of the merely mechanically suspended matters subside, when the specimen water is suffered to rest. In my conclusions with regard to the theory of irrigation, I have found many excellent practical farmers concur. Thus, Mr. Simons, of St. Croix, near Winchester, considers that the great benefit of winter flooding for meadows is derived, in the first place, from the deposits made by the muddy waters on the grass; and, secondly, from the winter covering with water preventing the ill effects to the grass of sudden transitions in the temperature of the atmosphere. This gentleman is perfectly aware of the value of the addition of the city drainage of Winchester to the fertilizing qualities of the Itchen river-water, and of its superiority for irrigation after it has flowed past the city, having water-meadows both above and below the town; and he finds that, if the water has been once used for irrigation, that then its fertilizing properties are so materially reduced, that it is of little value for again passing over the meadows; and so convinced is he of this fact by long experience, that, having in this way long enjoyed the exclusive and valuable use of a branch of the waters of the Itchen for some grass land, a neighbour higher up the stream followed his example, constructing some water-meadows, and using the water before it arrived at those of my informant, who, in consequence, found the water so deteriorated in quality (though not sensibly diminished in quantity), that he had once thought of disputing the right with his more upland neighbour. The experience of other irrigators tends to the same conclusion. In the best-managed water-meadows of Hampshire, the farmer does not procure annually more than three crops of grass; yet in situations where a richer water is em-

ployed, as near Edinburgh, four or five are readily obtained. It is evident, therefore, that the chemical properties of water have a much greater influence in irrigation than is commonly believed. The quality of the water, therefore, employed for the purposes of irrigation, is of the first importance to be well understood by the farmer; and although many more modern discussions have taken place upon the subject, yet the definition which the great Lord Bacon gave, in his *Natural History*, of the advantages of "Meadow Watering," has never been excelled,—"that it acts not only by supplying useful moisture to the grass, but likewise by carrying nourishment dissolved in the water." This nourishment is, generally speaking, composed almost entirely of the animal and vegetable matters mechanically suspended or chemically dissolved in the water;—the fouler the water, the more fertilizing are its effects. The objection which has been sometimes urged to this explanation, by instancing the prejudicial effects of some very thick muddy waters (as those of the Humber) on meadow lands, is very erroneous; for, in those cases, the mud deposited on the grass did not consist of animal or vegetable matters, but of fine earthy particles, such as clay or chalk, substances of which the alluvial soil, on which the same flood waters had for ages occasionally deposited their earths, was in fact entirely composed, and to which, in consequence, any further supply was almost useless, the earthy slime merely covering the grass with mud, without adding a single fertilizing ingredient not already abounding in the soil. If, however, the soil is naturally deficient in any of the earthy ingredients contained in the water, then even such flood waters are ever found most fertilizing.

"The agency of water in the process of vegetation," says Mr. Stephens, "has not till of late been distinctly perceived. Dr. Hales has shown that, in the summer months, a sunflower, weighing three pounds avoirdupois, and regularly watered every day, passed through it or perspired 22 ounces each day, that is, half its weight. Dr. Woodward found that, in the space of 77 days, a plant of common spearmint increased 17 grains in weight, and yet had no other food than pure rain water; but then he found that it increased more in weight when it lived in spring water, and still more when its food was Thames water." (*Practical Irrigator*, p. 2.) And when speaking of the fact, that some irrigators think clear spring water equal to any, he adds (p. 24), "I would recommend to those who are of the same opinion, to inspect the irrigated meadows which are watered by the washings of the city of Edinburgh, where, I trust, they will find the superiority of muddy water to that of clear spring water most strikingly manifested."

Edinburgh has many advantages over the most of her sister cities; the large supply of excellent spring water is one of the greatest blessings to her numerous inhabitants, both in respect to household purposes and keeping the streets clean, as well as irrigating the extensive meadows situated below the town, by the rich stuff which it carries along in a state of semi-

solution, where the art of man, with the common sewer water, has made sand hillocks produce riches far superior to any thing of the kind in the kingdom, or in any other country.

By this water, about two hundred acres of grass land, for the most part laid into catch-work meadow, are irrigated; whereof 130 belong to W. H. Miller, Esq., of Craigtintny, and the remainder to the Earls of Haddington and Moray, and other proprietors. The meadows belonging to these noblemen, and part of the Craigtintny meadows, are what is called the old meadows, containing about 50 acres, have been irrigated for nearly a century. They are by far the most valuable, on account of the long and continual accumulation of the rich sediment left by the water; indeed the water is so very rich, that the tenants of the meadows lying nearest the town have found it advisable to carry the common sewer water through deep ponds, into which the water deposits part of the superfluous manure before it runs over the ground. Although the formation of these meadows is irregular, and the management very imperfect, the effects of the water are astonishing; they produce crops of grass not to be equalled, being cut from four to six times a year, and the grass given green to milch cows.

The grass is let every year, by public sale, in small patches of a quarter of an acre and upwards, and generally brings from 24*l.* to 30*l.* per acre per annum. In 1826, part of the Earl of Moray's meadow fetched 57*l.* per acre per annum.

About 40 acres of the Craigtintny lands were formed into catch-work water meadow before the year 1800, which comprises what is called Fillieside Bank old meadows, and is generally let at from 20*l.* to 30*l.* per acre per annum. In the spring of 1821, 30 acres of waste land, called the Freegate Whins, and 10 acres of poor sandy soil, were levelled and formed into irrigated meadow, at an expense of 1000*l.* The pasture of the Freegate Whins was let, previously to this improvement, for 40*l.* per annum, and the 10 acres for 60*l.* They now bring from 15*l.* to 20*l.* per acre per annum, but may be much improved by judiciously laying out 200*l.* more in better levelling that part next the sea, and carrying a larger supply of water to it, which might be easily done without prejudice to the other meadows.

This, perhaps, is one of the most beneficial agricultural improvements ever undertaken; for the whole of the Freegate Whins is composed of nothing but sand, deposited from time to time by the action of the waves of the sea. Never was 1000*l.* more happily spent in agriculture; it not only required a common sewer to bring about this great change, but a resolution in the proprietor to launch out his capital on an experiment upon a soil of such a nature.

Since the making of the Freegate Whins into water meadows, Mr. Miller has levelled and formed 40 acres more of his arable land into irrigated meadow, worth, before the formation, 9*l.* per acre per annum. It will only require a few years before these meadows will be as productive as the former; for it is evi-

dent that the longer water is suffered to run over the surface of grass land, the greater quantity of fertilizing substance will be collected; therefore, as the water is so very superior in quality to all other water, a speedy return for the capital laid out may be expected. The expense of keeping these meadows in repair is from 10*s.* to 15*s.* per acre per annum, which is more than double the expense of keeping water meadows in repair in general.

It by no means, however, follows, as a necessary result of any contemplated improvement in irrigation, that the water should previously undergo a chemical examination. There are many other modes by which the farmer can form a pretty correct conclusion as to the fertilizing properties of the water he proposes to employ.

"The surest proofs," says Mr. Exeter, "of the good quality of water (and the observations of this gentleman will be readily confirmed by the irrigators of the southern counties) as a manure, are the verdure of the margin of its streams, and the growth of strong cresses in the stream itself; and wherever these appearances are found, though the water be perfectly transparent, the occupier of the soil through which it flows may depend, in general, on having a treasure, if he is attentive to it; but that this is not invariably the case, and that there are instances where a good water will not improve the herbage of certain soils, is proved by the following account (and there are several other cases with which I am acquainted) of the meadows of Mr. Orchard, of Stokes Abbey, Devon. These two meadows are situated on the side of a hill, their aspect nearly south—the superstratum a fine rich loam, from 3 to 10 inches deep, on a substratum of strong yellow clay. No difference whatever can be seen by the naked eye, in either the upper mould or the substratum, or in the herbage growing on the surface of them; except that, in the lower part of one, a few rushes appear, in consequence of some small springs which rise near them, but the water from them is not sufficient to render any part of the land poachy. At the head of the two meadows is a large pond, formed by the collecting of some small runs of spring water rising near it, and which is also improved by the wash of a small farm-yard adjoining, which, of course, must add to its efficacy as a manure. When this water is thrown over one of the meadows, it produces the richest herbage in abundance, and this field is regularly mowed for hay; on the other meadow, though repeatedly tried, it produces no good whatever." (*Ann. of Agr.* vol. xxx. p. 206.)

This result is attributable to the superior tenacious, retentive quality of the substratum of the lower field, or of some chemical difference in the composition of the soil; and although almost any description of soil is adapted to the formation of water meadows, those of a heavy clay description are generally the most unsuitable, those of a light or peaty kind are better, and those with a sandy or very absorbent gravel substratum still more so. There are some of the most celebrated water meadows on the banks of the Kennet of this de-

scription, and many of the best on the banks of the Wiltshire Avon have a mass of broken, porous flints for a subsoil. Those near Edinburgh, irrigated by the city drainage, rest upon the sands thrown up by the sea.

It is evident, therefore, that it is as important an object in the construction of these meadows to secure a ready and rapid exit for the flood-waters, as to procure, in the first instance, a copious and fertilizing supply.

The farmer is generally well aware of the injurious effects to his meadows of suffering the water to remain too long on them. He watches, therefore, with much care, for the first indications of fermentation having commenced, which is evinced by the rising of a moss or scum to the surface of the water—putrefaction is now beginning in the turf, and he knows very well that if the water is not speedily removed, that his grass will be either materially injured, or entirely destroyed; he hastens, therefore, to open his water-courses. There are some soils in the vicinity of Standen, in Berkshire, however, of so porous a quality, that they need not any drains to empty the water-courses; and, in fact, in many instances, the farmer does not even require them: after a few hours all the water is absorbed by the soil; and yet these lands, with hardly 6 inches of mould above the gravel, are amongst the richest of water-meadows; the roots of the grasses penetrate readily into the gravel, and the earliest and sweetest grasses are produced on them.

Almost any description of grass will flourish under proper management in water-meadows. Those whose soils consist of peat resting on sand, or on sandy loam, with a substratum of chalk or gravel, generally produce the meadow foxtail (*Alopecurus pratensis*), the brome-grass (*Bromus arvensis*), and the meadow-fescue (*Festuca pratensis*), on the tops and sides of the ridges. The furrows and sides of the drains are usually tenanted by the creeping-bent, the hard-fescue, the rough-stalked meadow-grass, and the woolly soft-grass. In those water-meadows whose soil consists of a sandy loam on a clay subsoil, the chief grasses are commonly the creeping-rooted soft-grass, the crested dog's-tail, the meadow barley, and the sweet-scented vernal-grass. But some grasses change their appearance in a very remarkable degree, when exposed under favourable circumstances to the influence of the flood-waters. This fact is strikingly exemplified in the case of two small meadows situated at Orcheston, six miles from Amesbury, in Wiltshire, denominated, from their great produce, "the long grass meads." These, says Davis, "contain together only two acres and a half, and the crop they produce is so immense, that the tithe hay of them was once sold for 5 guineas." Much discussion took place amongst the Wiltshire farmers as to the nature of the crop of these meads, before it was at last shown that the greatest part of their herbage consisted of nothing else than the black-couch, or couchy-bent, the *Agrostis stolonifera*, one of the worst of the grasses or weeds which haunt a poor ill-cultivated arable soils.

It is a very general, as well as correct con-

clusion of the English farmers, that the grass and hay of water-meadows is not so nutritious as that of the permanent pasture lands. The difference, however, is not so great as is commonly supposed. The late Mr. George Sinclair determined this experimentally, and he is no mean authority with regard to all that relates to the grasses.

He obtained from the rye-grass (*Lolium perenne*), at the time of flowering, taken from a water-meadow that had been fed off with sheep till the end of April, of nutritive matter 72 grains; and from the same weight of this grass, taken from a rich old pasture, which had been shut up for hay about the same time, 92 grains. From the same grass from the meadow, that had not been depastured in the spring, 100 grains. And from the same grass from the pasture which had not been fed off, 120 grains. All the grasses, in fact, where their growth is forced by the application of either liquid or solid manures, are found to contain nutritive matter in diminished quantities: this, too, was determined by Sinclair. From 4 ounces of a very rankly luxuriant patch of rye-grass, on which a large portion of cow-dung had been deposited, he obtained of nutritive matter 72 grains. From the same quantity of the same grass growing on the soil which surrounded this luxuriant patch, he obtained 122 grains.

And, in a second trial, the same species of grass, on a soil entirely destitute of manure, afforded of nutritive matter, 95 grains. On the same soil, excessively manured, the grass afforded only 50 grains. In these experiments the plants were of the same age, and were examined at the same stage of their growth. (*Hortus Gram.* 384.)

With regard to the construction and management of water-meadows, there are many practical works of the highest authority to which the farmer has ready access; and, in the following observations, therefore, I shall merely very briefly paraphrase the accounts given by Mr. Davis and others, of the practice of irrigation in the southern counties. In this, however, even since the time that Davis wrote, there has been a great and steady improvement. The land is better levelled, the slopes more evenly preserved, the water-way, aqueducts, and hatches, better constructed, and in many of the more recent improvements, in the valley of the Itchen, in Hampshire, the sliding-water doors are regulated by a cogged wheel turned with a movable winch, so as to render them safe from alteration during the absence of the meadow-keeper.

The management of the Wiltshire and Hampshire water-meadows, as well as it can be briefly described, is as follows:—In the autumn the after-grass is eaten off quite bare, when the manager of the mead (provincially the *drowner*) begins to clean out the main drain, and the main carriage, and to "right up the works," that is, to make good all the carriages and drains which the cattle have trodden in, so as to have one tier or pitch of work ready for drowning. This is immediately put under water, whilst the drowner is preparing the next pitch.

In the flowing meadows this work ought to be done, if possible, early enough in the autumn to have the whole meadow ready to catch the first floods after Michaelmas; the water, being the first washing of the arable lands on the sides of the chalk hills, as well as the dirt from roads, is then thick and good; and this remark, as to the superior richness of the flood waters, is one that is commonly made in Berkshire and other parts of England. The length of the autumnal watering cannot be precisely stated, as much depends upon situations and circumstances; but if water can be commanded in abundance, the custom is to give meadows a "thorough good soaking at first," perhaps for a fortnight or three weeks, with an intermission of two or three days during that period, and continue for the space of two fortnights, allowing an interval of a week between them. The works are then made as dry as possible, to encourage the growth of the grass. This first soaking is to make the land sink and pitch close together, a circumstance of great consequence, not only to the quantity, but to the quality of the grass, and particularly to encourage the shooting of new roots, which the grass is continually forming, to support the forced growth above.

While the grass grows freely, a fresh watering is not wanted; but as soon as it flags, the water must be repeated for a few days at a time, always keeping this fundamental rule in view, "to make the meadows as dry as possible after every watering, and to take off the water the moment any scum appears upon the land, which shows that it has already had water enough."

Some meadows that require the water for three weeks in October, and the two following months, will not, perhaps, bear it one week in February or March, and sometimes scarcely two days in April and May.

In the catch-meadows, which are watered by springs, the great object is to keep the works very dry between the intervals of watering; and as such situations are seldom affected by floods, and generally have too little water, it is necessary to make the most of the water, by catching and rousing it as often as possible; and as the upper works of every pitch will be liable to get more water than those lower down, a longer time should be given to the latter, so as to make them as equal as possible. *Davis's Agriculture of Wiltshire*, p. 125—127.)

In Berkshire they first flood their water-meadows about Michaelmas; these are situated principally on the banks of the Kennet. The first flooding they deem the richest in quality: this they keep on the land for about four days, and they then dry them for about a fortnight, and after that the water is let on for three or four days more; those meadows which are the most readily dried are the most productive. There are none more so, in fact, than those which have a porous, gravelly, or broken flint bottoms, from which the flood-water readily escapes, almost without drains. They begin to feed their meadows with sheep about the 6th of April, and continue feeding till about the 21st of May, when the meadows are again flooded for a crop of hay; the land is

then flooded and dried alternately for three days until hay-time.

The number of acres of land in Wiltshire, under this kind of management, has been computed, and with a tolerable degree of accuracy, to be between 15,000 and 20,000. Some considerable additions, however, have been made to the water-meadows of the district since this calculation was made. (*Davis's Wilts.*, p. 122.) About the same number of acres are formed into water-meadows in Berkshire, and a still larger number in Hampshire. No one has attended more carefully to his water-meadows than Lord Western, on some of those situated on the London clay-formation in the Black-water valley, in Essex, a soil of all others, perhaps, from its tenacity, the least adapted to their successful formation, and his testimony is very important:—"There is an old adage," says his lordship, "that water is the best servant in agriculture, and the worst master. Water has in itself intrinsic value; distilled through chalk, lime, or marl, it acquires a portion of their qualities, though preserving the most perfect transparency, and, coming down in torrents and floods, it carries along the finer particles of earth and manure from the mountains, or higher grounds, into the valleys; hence, of course, it is that the valleys derive their fertility, and the value of the meadow has been originally created by an accumulation of wealth from the hills."

"In descending the Jura mountains, which divide France from Switzerland, the very first pasture you find on the descent evinces the value placed on the mountain floods by the inhabitants of those districts; and, accordingly, every stream is sedulously directed and conducted over the pastures in a most skilful manner. The very washing of the roads in hasty rains is also attended to and applied to the same purposes." This system of catching the uncertain flood-waters is known amongst farmers by the name of *catch-work*, and though highly valuable, yet they deem it infinitely less important to them than irrigation, which is watering (generally five or six times a year) from a certain and ever-accessible head of water, as a river, &c. And yet Lord Western's testimony is decisive in favour of even one *catch-flooding*; for he observes, when speaking of the expense of constructing the requisite little channels to disperse the flood-waters over the grass, "In many cases it will be trifling, in some cases considerable; but when the farmer reflects that one winter's flooding will do more in *many*, I may say in most cases, than thirty loads an acre of the best rotten dung manure that can be laid upon his grass lands, he can hardly shrink from some considerable expenditure." If, then, the effects even of a *catch-flooding* with water are so great, how infinitely superior are the advantages capable of being derived from a regular constant supply of the enriching foul waters, like those issuing from the drains of a large city, which is even now most successfully employed near Edinburgh, but worse than wasted in the case of London! Whatever may be the value, in an agricultural point of view, of the solid contents of the London sewers, yet to me the absolutely liquid

portion, for the purposes of irrigation, appear at least equally important.

Liebig informs us that, "in the vicinity of Liegen (a town in Nassau), from three to five perfect crops are obtained from one meadow, and this is effected by covering the fields with river water, which is conducted over the meadow, in spring, by numerous small canals. This is found to be of such advantage, that supposing a meadow not so treated to yield 1000 lbs. of hay, then from one thus watered 4500 pounds are produced. In respect to the cultivation of meadows, the country around Liegen is considered to be the best in all Germany."

There is no agricultural question, therefore, of more consequence, in a national point of view, than that of the improvement of the soil by the practice of irrigation; for, in its prosecution, all the rich, organic, and other matters diffused through the rivers, which would otherwise be carried into the sea, are saved to agriculture. This is not, therefore, a question like that attending most other modes of fertilizing the soil, merely transposing manure from one field or district to another; but it is the absolute recovery, as it were, from the ocean, of a mass of finely divided, enriching substances, constantly draining from the land. It is the effectual diversion of a stream which is ever steadily impoverishing all cultivated soils, and which unnoticed, and in too many instances deemed worthless, gliding into the ocean, is almost the only drawback to the steadily increasing fertility of our country.

There are papers on irrigation by Mr. J. Purdy, of Castle Acre, in Norfolk, *Com. Board of Agr.* vol. vii. p. 112; by Mr. D. Shank, of Wigtonshire, *ibid.* p. 170; by Mr. Beck, of Norfolk, *ibid.* p. 108; on the irrigation of Lombardy and Piedmont, by Don R. S. Coutinho, *ibid.* p. 189; in Aberdeenshire, *ibid.* vol. iv. p. 263; in Denbighshire, *ibid.* p. 266; by Mr. Eyres, of Norfolk, *ibid.* vol. vi. p. 328; by Professor Rennie, *Quart. Journ. of Agr.* vol. v. p. 24; on the fowl water irrigation of Edinburgh, *ibid.* vol. x. p. 256. (*Quart. Journ. of Agr.* vol. x. p. 558; *Stephens's Practical Irrigator*; *Brown's Rural Affairs*, p. 263; *Sinclair's Hortus Gram.* p. 382; *Davis's Wiltshire*; *Driver's Hampshire.*)

IRRITABILITY OF PLANTS. See **BOTANY**, **TEMPERATURE**, and **ACCLIMATATION OF PLANTS.**

ISNARDIA (named in memory of Anthony Isnard, member of the Academy of Sciences). These plants are mere weeds, or creeping aquatic herbs, growing in marshy situations.

The marsh isnardia (*I. palustris*) is the only indigenous species.

It is an annual, growing in ponds and watery places, blowing axillary, solitary, sessile, small, green, and inconspicuous flowers in July. The herb is floating, smooth, with numerous long filamentous roots. The stems are several, about a span long, simple, or slightly branched, leafy, bluntly quadrangular. The leaves are opposite, stalked, ovate, acute, entire, scarcely an inch in length, bright green, somewhat succulent, the mid-rib often red or purplish. (*Eng. Flor.* vol. iv. p. 264.)

The *I. Palustris* is common to America as

well as to Europe, and is found from Canada to the West Indies. In Pennsylvania another species is met with—the Alternate-leaved Isnardia (*I. alternifolia*), commonly called Bastard Loose-strife. The roots of both species are perennial.

Besides these, there are about a dozen additional species, as the genus is now constituted, in the United States. (*Flor. Cestrica.*)

ITALIAN RYE-GRASS. See **RYE-GRASS.**

ITCH. In farriery, a cutaneous disease. See **MANGE.**

IVY (*Hedera helix*). The name appears to be derived from *hedra*, a Celtic word signifying a cord; and the English name ivy is derived from *ivo*, a word in the same language signifying green.) A hardy evergreen climber, common everywhere in Europe, which is excellent as a screen planted against trellis-work. The common ivy is very often employed for covering naked buildings or trees, which latter it invariably kills. The stem is branched, either trailing on the ground and bearing 5-lobed white-veined leaves, but no flowers; or climbing, flattened and attached by dense tufted fibres, which serve for support, not nourishment; the flowering branches are loosely spreading, round, bearing ovate, undivided leaves. Umbels aggregate, green, many-flowered, their stalks covered with starry pubescence, and accompanied at the base by several small bracteas. The berry is the size of a currant, smooth, black, internally whitish and mealy, with seldom more than five seeds. The whole plant is somewhat aromatic; and a very fragrant resin exudes from the old stems when bruised.

IVY, AMERICAN, Virginia Creeper (*Ampelopsis hederacea*). Ivy-like ampelopsis. The stem of this climbing plant sometimes grows 30 or 40 feet long, branching diffusely, climbing fences, trees, and walls, and clinging to them by adhesive expansions at the points of the tendrils. The leaves are digitate in clusters of fives, on long stems. The plant is common in the United States in woodlands, fence-rows, thickets, &c. Sir J. E. Smith (in Rees Cyclop.) contends that this is a true *vitis*; but Dr. Darlington thinks, that although nearly allied to, it may be very properly separated from our grape vines. Two or three other species of ampelopsis are enumerated in the United States.

IVY, GROUND. See **ALEHOOF.**

IVY, IRISH (*Canatiensis*), is a fast-growing climber, with large lobed leaves, which soon covers walls and houses. It is propagated by layers, or slips taken off and planted where they are to grow.

J.

JACOB'S LADDER, BLUE OR GREEK VALERIAN (*Polemonium caruleum*). This plant is a common ornament of flower borders in rustic gardens, of no particular qualities, notwithstanding its name of valerian, derived perhaps from the leaves, which resemble those of some of the *Valeriana*. The root is fibrous, not creeping, herb nearly smooth, perennial, 1½ or

feet high; stems angular, leafy, hollow, often reddish, unbranched, paniced at the top; leaves alternate, of many elliptic-lanceolate, entire leaflets, with an odd one of nearly equal size. The flowers, which appear in June, are rather drooping, numerous, blue, occasionally white. All the species are of the easiest culture and propagation.

JERUSALEM ARTICHOKE. See **ARTICHOKE.**

JOHN'S WORT, or ST. JOHN'S WORT (*Hypericum*). The generic name is said to be derived from *uper*, and *eicon*, an image. The superior part of the flower represents a figure. The common name is derived from their coming into flower about St. John the Baptist's day. The most part of the species of this extensive genus are showy plants. The greenhouse and frame shrubby kinds do well in loam and peat, and young cuttings root freely in sand under a glass. The hardy shrubs are well fitted for the front of shrubberies, being dwarf and showy. They may be increased by divisions or seeds, as well as the herbaceous kinds, which thrive well in any common soil. The seeds of the annual species have only to be sown in the open ground in spring. Some of the species indigenous to Britain are as follows:—

1. Large-flowered St. John's Wort (*H. calycinum*). A shrub, growing wild in bushy places in the west of Ireland and Scotland. The root of this species is creeping, the stems shrubby, erect, 12 or 18 inches high, with simple, leafy, square branches, smooth like every other part. The flowers, which appear from July to September, are 2 or 3 inches wide, of a bright golden yellow, with innumerable reddish tremulous anthers. This plant is a great ornament to shrubberies and parks, and excellent as a shelter for game, bearing any cold of our climate.

2. Tutsan, or Park Leaves (*H. androsæmum*). This shrub is found in moist, shady lanes, thickets, and woods in Britain and Ireland, but not very general. It is rather taller and more branched than the preceding. The flowers, which appear in July and August, are an inch wide, yellow, with three sets of stamens, and as many styles. The leaves and other parts have an aromatic scent when rubbed.

3. Square St. John's Wort, or St. Peter's Wort (*H. quadrangulum*). This species is perennial, and common in moist meadows and thickets, and about the banks of rivers. The root is somewhat woody, creeping; the herb smooth, light green; stems several, from one to two feet high, erect, leafy, acutely quadrangular; leaves elliptical or ovate, obtuse, many-ribbed, veiny, full of minute, colourless, pellucid dots, and bordered with a more or less perfect row of dark-coloured ones yielding a blood-red liquor. The uppermost branches form a leafy dense panicle of numerous lemon-coloured flowers, about half the size of the last-described species.

4. Common perforated St. John's Wort (*H. perforatum*). This perennial species is met with abundantly in thickets, woods, hedges, and on dry banks. The root is woody, tufted, and somewhat creeping; the stem reaches to the

height of 18 inches, and is round and bushy in consequence of the much greater length of its axillary leafy branches. The whole herb is moreover of a darker green, with a more powerful scent when rubbed, staining the fingers with a dark purple, from the greater abundance of coloured essential oil lodged in the herbage and even in the petals: the leaves are very numerous, smaller than the last, elliptical or ovate, obtuse, various in width; the flowers are numerous, in dense, forked, terminal panicles, bright yellow, dotted and streaked with black or dark purple. This species is eaten by goats, cows, and sheep, but is refused by horses and hogs. As this plant was found to bleed at the slightest touch, it was supposed to have a vulnerary quality, and became the "balm of the warrior's wound," giving a blood-red colour to every composition, whether of a spirituous or oily nature, into which it entered. It contains resin, and the leaves give a good red dye to wool and oil.

5. Imperforate St. John's Wort (*H. dubium*). This species inhabits rather mountainous groves and thickets. The young radical shoots are bright red; the stem quadrangular in the upper part, but not winged or bordered; the petals and calyx are dotted and blotched with dark purple.

6. Trailing St. John's Wort (*H. humifusum*). This is a pretty little procumbent smooth species, with the lemon-like scent of *H. dubium* and *perforatum*, which tenants sandy or gravelly, heathy, and rather boggy pastures. The root is fibrous, stem compressed, prostrate; flowers few, somewhat cymose; leaves elliptical, smooth.

7. Mountain St. John's Wort (*H. montanum*). Though not an ostentatious plant, this species well deserves John Bauhin's epithet of "most elegant." The glutinous dark fringes of its calyx and bractees resemble the glands of a moss-rose; the stems are erect, round, smooth, about two feet high; the leaves ovate, naked, clasping the stem.

8. Bearded St. John's Wort (*H. barbatum*), which grows for the most part in bushy places in Scotland, on an herbaceous stem a foot or more in height, flowering in September and October: 9. Hairy St. John's Wort (*H. hirsutum*), flourishing in thickets and hedges, chiefly on a dry, chalky soil, stem two feet high: 10. Small upright St. John's Wort (*H. pulchrum*), met with very frequently in woods and bushy, heathy places, on a clay soil; stem 12 to 18 inches high: 11. Marsh St. John's Wort (*H. elodes*), stems procumbent, creeping. There are other species, which call for no detailed description.

The whole genus, says Mr. Nuttall, in his account of the American species, appears to possess active medicinal properties in common with *vismia*, which affords indeed much more abundantly a yellow and resinous gum, acting as a cathartic in doses of 7 or 8 grains. The *Vismia guttifera* of Surinam produces a kind of gamboge. 25 or 26 American species of hypericum are enumerated by botanists. The following are mentioned by Dr. Darlington as found in Chester county, Pennsylvania.

1. *Hypericum Virginicum*, or Virginia hypericum, having a perennial root, stem 18 inches to 2 feet high, whole plant of a purplish hue, flowering in July and August, the blossoms being of a dull orange colour. It is found in wet, low ground, though rare.

2. *H. punctatum*, or dotted hypericum, frequent in open woodlands and fields, flowers of a pale yellow colour, with numerous oblong black dots, appearing in July and August.

3. *H. perforatum*, or perforated hypericum, commonly called St. John's Wort. This plant has a perennial root and stem growing from 1 to 3 feet high. It is frequent in fields and pastures where it puts forth its rich clusters of yellow, or orange-yellow flowers, from June to October. This, says Dr. Darlington, is an introduced and pernicious weed. The plant has a resinous odour; and is believed to produce troublesome sores on horses and horned cattle, especially those which have white feet and noses, the skin of such being more tender, or irritable. The dew which collects on the plant appears to become acrid; as I have seen the backs of white cows covered with sores, wherever the bushy ends of their tails had been applied, after dragging through the St. John's Wort. A tincture of the flowers and leaves has been used, it is said, with good effect in some complaints of the stomach and bowels.

4. *H. quinquerivum*, or five-nerved hypericum. This is frequent in low grounds, along streams. Its root is supposed to be annual, and its slender stems grow 6 to 12 inches high; the flowers have very small petals of a yellow colour.

5. *H. Canadense*, or Canadian hypericum. This so much resembles the last mentioned species as to be regarded by some botanists as identical.

6. *H. sarothra*, broom-like hypericum, commonly called ground pine, netweed, and orange grass. This is frequent in sandy fields and along road-sides, where it puts forth yellow flowers in July and August. Its root is annual, the stem is slender and grows 4 to 8 inches high. (*Flora Cestrica*.)

JONQUIL. A species of daffodil, of which there are several sorts. The great jonquil and the odorous jonquil blow about the middle of March. The lesser or proper jonquil somewhat later. When they blow well and early they forebode a fine season.

JUDAS TREE (*Cercis*). This is a beautiful genus of ornamental trees, flowering early in spring, and looking very pretty planted singly on a lawn, or trained to a wall or trellis; they grow to the height of 20 feet, prefer an open loamy soil, and may be plentifully increased from seeds.

The species found in the United States is the *Cercis Canadensis* of botanists, commonly called red bud. In the Middle States, it is a small tree 15, 20, or 30 feet high, greatly admired for the clusters of small flowers, which in April clothe the limbs in purple before the leaves appear. The flowers are acid to the taste. It is the only species of *cercis* in the United States.

JUNE BERRY (*Mespilus arborea* of Michaux). With the exception of the maritime parts of

the Carolinas and Georgia, this tree, as Michaux informs us, is spread over the whole extent of the United States and Canada. But it is most multiplied upon the Alleghany mountains, and upon the elevated banks of the rivers which flow from them. In the northern section of the Union it is called wild pear tree, whilst in the Middle and other States it goes by the various names of wild service berry, June berry, snowy medlar, and shad-flower. The last name is derived from its blooming about the time the shad ascend the rivers (beginning of April), when it is quite a showy little tree. The flowers, which are white and pretty large, are arranged in pannicles at the extremities of the branches. As it blossoms early, so does it mature its fruit amongst the earliest trees of the forest. The largest tree, however, rarely yields more than half a pound. Long culture has been found to improve the fruit, both in size and quality. The berries are roundish, 3 or 4 lines in diameter, smooth, dark-red, and even purple when mature, pleasant flavoured, and not unwholesome. In Pennsylvania and the neighbouring states, it is generally found in moist and shady situations, especially along brooks and rivulets. In the western country, however, it grows in the midst of the forest among the oaks, walnuts, &c., and here reaches its greatest height, which does not exceed 35 or 40 feet, with a diameter of 10 or 12 inches.

JUNIPER (*Juniperus*, derived from the Celtic *juniperus*, rough or rude, in allusion to the stiff habit of the shrubs). This genus is too well known to need to be particularized here. All the species will grow in sandy loam, and some in any common garden soil. They are mostly raised from seed, though cuttings will strike when planted in a sheltered situation, under a hand-glass. The stimulating and diuretic powers of the savin (*J. sabina*) are well known. The fruit of *J. communis* are proverbial for the flavour they give to gin. (*Paxton's Bot. Dict.*) The species are all evergreen aromatic shrubs, with narrow leaves, either spreading and sharp-pointed, or closely imbricated, minute, and obtuse. The fruit is globular or oval, black or brown, with a glaucous efflorescence.

J. sabina is a native of the south of Europe, but it is cultivated as an evergreen in our gardens. The plant is a pyramidal shrub, with small, closely-adhering, glandular leaves, which exhale, when rubbed, a strong, heavy odour, and have a bitter, nauseous taste. By distillation they yield a large quantity of volatile oil, which has the odour and taste of the recent plant. Savin is a powerful acrid poison, irritating and vesicating the skin when it is applied to it. When swallowed in large doses, it causes vomiting, purging, and inflammation of the stomach and bowels.

The common juniper (*J. communis*) grows wild on hills and heathy downs, especially where the soil is chalky. Dr. Sibthorpe found it on Olympus and Athos, in Greece. It is, like all the species, a bushy shrub, with evergreen, linear pointed, glaucous leaves, dark green on the under disk. The flowers are axillary, small, sessile, male and female organs in separate flowers. The fruit, although called

a berry, is a *galbalus* or succulent cone. It requires two seasons to arrive at maturity. The dwarf alpine juniper (*J. nana*) is a variety of the *communis*. It grows upon lofty mountains, and is, as its name implies, more humble in its growth. These are the only indigenous species. The tops and the fruit are used in medicine as powerful diuretics. The former have a bitter, turpentine flavour and colour; the fruit is sweetish, with an agreeable, somewhat balsamic odour, depending upon a volatile oil, and a peculiar saccharine matter analogous to the sugar of the grape. The volatile oil is contained in cells in the shells of the seeds; hence, in making infusion of juniper, the seeds should be bruised. The infusion is made with an ounce of the bruised fruit and a pint of boiling distilled water. It is a useful beverage in some kinds of dropsies. The red cedar (*J. Virginiana*), is a hardy, handsome evergreen, native of North America, with dark foliage, producing a small blue berry-like fruit in May. It frequently attains to the height of a very lofty tree. See CEDAR, RED.

JURY (from the Latin *jurare*, to swear). A body of men sworn to decide a certain fact or facts according to the evidence produced before them.

This noble institution, like many others as dearly cherished by all lovers of freedom, commenced among the northern nations of Europe at a very early period. The early notices of this mode of trial remaining to us do not speak of its institution: and, in truth, it most probably originated in some rude form or other as soon as men began to dwell together in fixed habitations.

That trial by jury was employed by our Saxon ancestors from time immemorial is very certain, and over-industrious historians have wasted much time in fruitless endeavours to assign the honour of the first discoverer to the real author. Thus Stiernhook (*De Jure Sueonum*, l. i. c. 4), ascribes the glory to Regner, king of Denmark and Norway, who was the contemporary of our Egbert. Archbishop Nicholson carries the date of the invention back to Woden, the great captain, legislator, and god of the Northernmen.

Sir Edward Coke appears to have fancied that there is something in the very number twelve, in which the laws of God and man seem to delight; and he instances the twelve judges, twelve counsellors of state, twelve to wager the laws, twelve apostles, tribes, stones, &c. (*Coke on Littleton*, s. 234 b.)

Trial by jury is mentioned as early as the reign of King Ethelred, but not as a novel institution. (*Wilkins' Laws of the Anglo-Saxons*, 117.) And in Magna Charta it is mentioned more than once, and particularly ordained, That no freeman shall be dispossessed of his lands or goods, unless by the judgment of his peers; and amid all the long continued struggles of Englishmen for the liberty of the subject (from the days of King John down to the time of Fox and his declaration of the office of juries in libel cases), the preservation of the freedom of juries has ever been a darling object with English patriots.

K.

KALE, SEA (*Crambe maritima*), is found wild on the seashore on the southwestern coast of Great Britain, where the common people have from time immemorial been in the practice of watching when the shoots and leaf-stalks begin to push up the sand and gravel, in March and April, when they cut them off under ground, as done with asparagus, and boil them as greens. About the middle of the last century it was first introduced into gardens, and is now almost as universal as asparagus.

A light, moderately rich soil, on a dry substratum, suits it best; though in any dry soil it will succeed. A bed may be composed for it of one-half drift sand, one-third rich loam, and one-third small gravel, road stuff, or coal ashes; if the loam is poor, a little well-rotted dung or decayed leaves being added. The soil must especially be deep, so that the roots can penetrate without being immersed in water, which invariably causes their decay. Mr. T. Barton, of Bothwell Castle, has even found it succeed well on a pretty strong loam that had a loose bottom. The depth should not be less than 2½ feet; and if not naturally deep, it should be worked to it by trenching. If at all tenacious, this opportunity may be taken to mix with it drift or sea sand, so as to reduce it to a mouldy texture. If the soil be wet it must be drained, so that water never shall stand within three feet of the surface. If poor, well-putrified dung must be added; but decayed leaves are preferable (*Trans. Hort. Soc. Lond.* vol. i. p. 17), and sea-weed still more so. These precautions must all be particularly attended to, for upon the due richness and dryness of the soil not only depend the luxuriance and delicate flavour of the plants, but their very existence. Common salt, as might be anticipated, is found to be a very beneficial application, either applied dry, or by occasional waterings with a solution containing 4 or 5 ounces in the gallon, round every stool during the summer. As regards the situation, it cannot be too open or free from trees. Sea kale is propagated both from seed and slips of the root; the first is by far the best mode, for although it may be obtained from slips with greater certainty, yet the plants arising from seed are the strongest and longest lived; whilst the failure of seed, which is sometimes complained of, mostly arises from its being old, buried too deep, or some other extraneous cause. The seed may be inserted in drills from October, or as early in the spring as the ground can be brought into good condition. It is by much the best mode to leave the plants where raised, and with that intent, to guard against failure, inserting the seed in patches of 6 or 12 seeds, each 6 inches apart, and the patches 2 feet asunder. If, however, they are intended for transplanting, the seed may be sown in drills 12 inches asunder; in either case it must not be buried more than 2 inches below the surface; and it is a good practice, previous to inserting it, to bruise the outer coat of the seed, without injuring its vegetating power, as by this treatment the ger-

mination is accelerated. The plants will in general make their appearance in 4 or 5 months, never sooner than 6 weeks; but, on the other hand, the seed will sometimes remain 12 months before it vegetates.

The best time for increasing it by slips is in March and April. Rooted offsets may be detached from established plants; or their roots, which have attained the thickness of the third finger, be cut into lengths, each having at least two eyes. To plant the offsets requires no particular direction: the cuttings must be inserted in an upright position 2 or 3 inches beneath the surface. It is best to plant two together, to obviate the danger of failure, at 2 feet apart, to remain.

Whatever mode of propagation is adopted, the bed should be laid out 3 feet wide, and a 2 feet alley between every 2, in preference to the plan sometimes recommended of planting 3 rows in beds 7 feet wide, for in such the soil must be consolidated by the feet during the necessary grades of cultivation.

If the months of June and July prove dry, the beds should be plentifully watered. The seedlings require no other attention during the first summer than to be kept free from weeds, and, if they come up too numerous, to be thinned to 5 or 6 in each patch. When their leaves have decayed, and been cleared away about November, they must be earthed over an inch or two with dry mould from the alleys, and over this about 6 inches depth of long litter be spread, and thus left to stand the winter. In the following spring the litter is to be raked off, and a little of the most rotten dug into the alleys. When the plants have perfectly made their appearance, they must be thinned, leaving the strongest plant, or, as Mr. Maher recommends, the three strongest, at each patch; those removed being transplanted at similar distances if required; but it must be remarked that those transplanted never attain so fine a growth, or are so long-lived. In this second winter the earthing must be increased to 5 or 6 inches deep over the crowns, and the covering of litter performed as before. In the third spring, the litter being removed, and some dug into the alleys as before, about an inch depth of drift sand or coal ashes must be spread regularly over the surface. The sprouts may now be bleached and cut for use; for if this is commenced earlier, the stools are rendered much less productive, and much shorter lived. In November, or as soon as the leaves are decayed, the beds being cleared of them, the coating of sand or ashes removed, and gently stirred with the asparagus fork, they must be covered with a mixture of three parts earth from the alleys, and one part of thoroughly decayed leaves, to the depth of 3 or 4 inches. The major part of this is to be removed in the following spring, the beds forked, and the covering of sand renewed; this routine of cultivation continuing during the existence of the beds.

The above course is the one also pursued if the plants are raised from offsets or cuttings, as it is much the best practice not to commence cutting until they are two years old.

Blanching, as before observed, may commence the second spring after sowing. The most simple mode is that originally adopted, namely, to cover over each stool sand or ashes to the depth of about a foot; the shoots in their passage through it, being excluded from the light, are effectually bleached. But pots are by much to be preferred to these coverings. Common flower-pots of large dimensions may be employed, care being taken to stop the hole at the bottom with a piece of tile and clay, so as to exclude every ray of light.

Previous to covering the stools with the pots, &c., the manure laid on in the winter must be removed; and the operation should commence at the close of February, or at least a month before the shoots usually appear, as the shelter of the pots assists materially in bringing them forward. In 4 or 6 weeks after they are covered the plants should be examined, and as soon as they appear 3 or 4 inches high, they may be cut; for if none are taken until they attain a fuller growth, the crop comes in too much at once. In order to prolong the season of production, Mr. Barton recommends plants to be raised annually, so that every year a cutting may be had from a yearling crop, which comes in much later, and consequently succeeds in production the old established roots. The shoots should be cut whilst young and crisp, not exceeding 5 or 6 inches in height; the section to be made just within the ground, but not so as to injure the crown of the root. Slipping off the stalks is said to be preferable to cutting. The plants may be gathered from until the flower begins to form, when all covering must be removed. If, when arrived at the state in which broccoli is usually cut, the stalks and immature flowers are employed as that vegetable, they will be found an excellent substitute; and this greatly enhances the value of the plant, as broccoli does not stand the winter frosts in the Northern States, and can only be had when carefully protected; but this plant is sufficiently hardy to bear the frost without injury. It flowers about June, and produces abundance of seed on every stem, which ripens about the close of July or early in August.

To force sea kale, Mr. T. Baldwin, of Ragley, recommends that, on each side of a 3 foot bed, a trench is to be dug 2 feet deep, the side of it next the bed being perpendicular, but the outer side sloping, so as to make it 18 inches wide at the bottom, but 2½ feet at the top. These trenches being filled with fermenting dung, which of course may be renewed if ever found necessary, and frames put over the plants, the light is to be completely excluded by boards, matting, &c. Unlike the generality of vegetables, the shoots of forced sea kale are always more crisp and delicate than those produced naturally.

"To have this rare vegetable in perfection," says Bridgeman, "it should be cooked as soon as gathered. Let it be first soaked in water, seasoned with salt, for half an hour; then wash it in fresh water, and put it into the cooking utensil; keep it boiling briskly, skim clean, and let off steam. When the stalks are tender, which may be expected in from 15 to

25 minutes, according to size and age, take it up, dish it, and serve it up with melted butter, gravy, and such condiments as may be most agreeable to the palate." (*Gardener's Assistant.*)

KALE, THE WOBURN PERENNIAL.

See CABBAGE, BROCCOLE, &c.

KALI. A sea weed, from the ashes of which the alkali, called soda, is procured. See **KELP**, **SALTWORT**, and **GLASSWORT**.

KALMIA. American laurel. A North American genus of hardy shrubs, remarkable for the beauty of their flowers. The leaves are considered poisonous to cattle, and are particularly fatal to sheep. The honey gathered from the flowers is also charged with possessing deleterious qualities. The plants do best when grown in a peat soil, though they will grow in a very sandy loam; they may be increased by layers or seeds.

Mr. Nuttall describes five species of kalmia found in the United States:—1. *K. latifolia*, laurel, or calico bush, common from Canada to Georgia. The stem grows 3 or 4 to 10 or 12 feet high, with irregular, crooked, straggling branches. It frequents shaded banks and rocky hills, and blooms its beautiful flowers in May and June. The wood of this splendid flowering shrub is very hard, and is often used to make handles for small mechanical implements. A decoction of the leaves is sometimes used as a remedy for cutaneous diseases. (*Flora Cestrica.*)

2. *K. angustifolia*, or narrow-leaved laurel, commonly called sheep laurel, and dwarf laurel. The stem of this species grows about two feet high, being slender and somewhat branching. This pretty little species of laurel is thought to be particularly poisonous to sheep and other stock, when eaten by them. 3. *K. glauca*. 4. *K. cuneata*, found in swamps betwixt Camden and Statesville, South Carolina. 5. *K. hirsuta*, found constantly on the drier margins of open swamps, abundant around Savannah, Georgia.

KATY-DID. See **PLATYPHYLLUM**.

KELP, SEA-WEED, BARILLA, &c. I class these manures together, when treating of kelp, since it is to the presence of various salts of soda that sea-weed principally owes its fertilizing qualities, for when they are washed out, the residuum is nearly inert. Sea-weed has been analyzed by M. Gaultier de Claubry. In the *Fucus saccharinus* and in the *Fucus digitatus* (which is much used in Scotland as a manure) he found the following substances (*Thomson's Chem.* vol. iv. p. 298):—

Saccharine matter.	Muriate of magnesia.
Mucilage.	Carbonate of potash.
Vegetable albumen.	Carbonate of soda.
Oxalate of potash.	Hydriodate of potash.
Malate of potash.	Silica.
Sulphate of potash.	Phosphate of lime.
Sulphate of soda.	Phosphate of magnesia.
Sulphate of magnesia.	Oxide of iron.
Muriate of soda.	Oxalate of lime.
Muriate of potash.	

By burning these weeds the kelp and barilla of commerce is formed; the first of which has been often advantageously employed in Ireland and on the coast of Scotland as a manure. The Suffolk and the Kentish farmers, however, as well as some of the Scotch, employ the sea-weed in its freshest state, either ploughing it into the ground, or spreading it on the top of

their heaps of compost. The first plan, however, I have ever seen productive of the best effects; and in that conclusion I am supported by the experience of many excellent farmers.

The salt turf of the sea-shore has been long used in many parts of England as an excellent manure, especially for potatoes; and, according to Dr. Holland (*Survey of Cheshire*, p. 143), even the salt mud of the Mersey is extensively used for the same crop, at the rate of twenty tons per acre. "The ground thus manured not only gives a large produce of potatoes, but is in a state of excellent preparation for a succeeding crop of either wheat or barley. The adoption of this practice has increased very greatly the value of land about Weston."

There can be no doubt of the advantage of using the sea-weed, or sea-turf, in the freshest possible state, after it has been covered with the salt water, as by a spring tide; for if the salt water has been suffered to drain away from the weeds, and a partial decomposition has taken place, their value as a manure must be materially diminished. The Cornish farmers, when they fetch the calcareous sand from the sea-beach, are careful to obtain it as much wetted with the salt water as possible: and there are in the juices and other components of marine plants a variety of ingredients which must produce the most luxuriant effects upon vegetation growing at a distance from the sea; and their constituents are peculiarly noxious to the vermin with which all cultivated soils abound. If this conclusion be correct, then the mode adopted by the Isle of Thanet and Suffolk farmers, of collecting the sea-weed into heaps, and suffering it to putrefy, is decidedly wrong; for, by being thus decomposed, half its fertilizing virtues are lost to the soil. The common excuse for rendering dung putrid before it is spread, viz. that it is a necessary practice to kill the seeds of weeds, has no application here, for those of marine weeds will not grow on arable upland soils.

The use of sea-weed as a manure, in the isles of Jersey and Guernsey, has been very extensive from time immemorial. Thus, in a work upon Jersey, by the Rev. Philip Falle, published in 1694, he observes, that "Nature having denied us the benefit of chalk, lime, and marle, has supplied us with what fully answers the end of them in husbandry—it is a sea-weed, but a weed more valuable to us than the choicest plant that grows in our gardens. We call it *vraic* (*varec*), in ancient records *veriscum*, and sometimes *wrecum*, and it grows on the rocks about the island. It is gathered only at certain times appointed by the magistrate and signified to the people by a public crier on a market day. There are two seasons for cutting it, the one in summer, the other about the vernal equinox. The summer *vraic*, being first well dried by the sun on the sea-shore, serves for fuel, and makes a hot, glowing fire; but the ashes are a great improvement to the soil, and are equal almost to a like quantity of lime. The winter *vraic* being spread thin on the green turf, and afterwards buried in the furrows by the plough, it is incredible how with its fat unctuous substance it ameliorates the ground, imbibing itself into it, softening the

clod, and keeping the root of the corn moist during the most parching heats of summer. In stormy weather, the sea does often tear up from the rocks vast quantities of this weed, and casts it on the shore, where it is carefully gathered up by the glad husbandman."

The plants chiefly valued for making French varec are *Fucus vesiculosus*, *F. nodosus*, *F. serratus*, *Laminaria digitata* and *bulbosa*, *Himanthalia lorea*, and *Chorda filum*. Twenty-four tons of the sea-weeds make one ton of kelp. The Jersey and Guernsey Agricultural Society confirmed this account of the excellent effects of the ashes from sea-weed, in 1797, in their report to the English Board of Agriculture, when they observed—

"It is judged, that a chabot (half a bushel), strewed over a perch of ground in winter or the beginning of spring, will be a sufficient manure. Our labourers are unanimously of opinion, that it gives a full ear to the corn, and prevents it being laid—those who have any varech to sell may at all times get a chabot of wheat for a quarter or six bushels of varech." (*Com. to Board of Agr.* vol. i. p. 216.)

The fertilizing effects of sea-weed are not confined to the better description of soils; the poorest kind of heath lands are benefited by the application of this manure;—thus, Mr. John Sherriff, of Haddington, has described the effects of sea-weed, or sea-tang, as it is called in Scotland, on common heath or moor land, in the following terms: "Sea-weed, which is a capital manure for any land, may often be procured at little or no expense. Crops almost incredible of turnips, barley, clover, and rye, have, to the writer's certain knowledge, been obtained on an extensive tract of the most miserable benty wastes and poor rabbit warrens, by the powers of this manure; soils which, twelve years since, were not worth three shillings per acre. The bent was torn up by the common swing plough, burnt, and the ashes spread; the soil was then manured with the sea-tang, as much as could be ploughed in. Turnips were immediately drilled, and rolled to prevent blowing; this crop was succeeded by rye or barley, and that by red clover and rye-grass. On the clover stubble, and sometimes after the turnip crop, plenty of tang was again laid, the ley ploughed down, and sown with oats, barley, or rye, and frequently with turnips, which in this way have succeeded admirably on the ley with one ploughing." (*Com. to Board of Agr.* vol. iv. p. 122.) It is certain, from the experiments of the late Mr. Knight, that green manures of all kinds are an admirable manure; and it seems well established that the more the juice of the vegetables so employed is impregnated with saline matters, the more fertilizing are their effects: thus, in Bavaria, borage is very commonly cultivated for this purpose, and the reason assigned for the preference shown to this plant is, that it contains soda and other salts. (*Gardener's Mag.* vol. i. p. 203.)

I have no doubt that in many situations the sea-weed may be successfully cultivated on the sea-coast, expressly for manure; and it seems that for this purpose hardly any thing is required except placing stones on the shore, to

which the fuci can attach themselves, and in two years the crop may be cut. According to Mr. Jamieson (*Miner. of Scottish Isles*, vol. 2, p. 251), various kinds of stones have been employed in Scotland, as basalt, sandstone, and limestone, which last is the best adapted for the purpose, and after that the basalt.

There are also in many parts of the coast of Britain extensive tracts of land which it would be difficult to enclose, and yet these places are either already covered with a coarse turf, or might be so with a little management, and this turf, when cut and carted on to the light upland soils, is found almost invariably to be an admirable fertilizer;—for instance, when spread over land during the winter, and then turned into the soil, for potatoes, the crop is sure to be excellent. No description of fertilizer, perhaps, can be named, which *freshens*, as the farmers say, an over-cropped soil so much as a dressing of from 20 to 25 loads per acre of the turf from the sea-shore, soaked with sea-water; and no plant delights in fresh soil so much as the potatoe. It is, therefore, more than probable, that the exertions of the commonly cultivated corn crops are peculiar noxious to this plant; and it is certain that the potatoe, by the deposit which it leaves in the soil, renders it distasteful to the crop by which it is succeeded. Thus the wheat plant rarely looks well on soils where the potato has immediately preceded it. Saline fertilizers, in these cases, are sure to be serviceable, for they unite with, and neutralize the effects, as well as promote the decomposition, of the excretory matters which all plants deposit in the soil.

The chief fertilizing qualities possessed by barilla are attributable to the presence of soda. This alkali is found in all marine vegetables, and in most of those which grow on the sea-shore. It has been used in several experiments as a manure since the price of soda has been so much reduced; but these have not been conducted with sufficient accuracy to enable us to judge of its value as a fertilizer. What little has been done, promises well. Thus, it has been found, when a pound of soda is dissolved in 14 gallons of water, that this solution forms an excellent liquid manure for many culinary vegetables; for instance, the vegetable-marrow plant, when thus treated, has been found to flourish better in common garden mould than other plants growing on a dunghill. And, as I have remarked in another place, nature is here again our instructor: the fertile plains of Syria, and some of the most profusely luxuriant fields of the orientalist, abound in carbonate of soda. This alkali not only enters into the composition of many vegetables, but it promotes the growth of all, by preserving the moisture of the soil, and by accelerating the decomposition of the numerous organic substances found in all cultivated lands. The sewer water of towns and cities, which has been found so very rich and fertilizing as a dressing for grass lands, abounds with soda; for that is contained in the soap suds and other refuse washings which such drainage matters always convey. Soda has been found in very sensible proportions in the urine of the horse, by M. Fourcroy; and in that of the ass, by Mr.

Brande; and a small portion of this alkali is usually presented in the waste ashes of soap-makers, which many cultivators consider highly valuable as a manure.

As the use of kelp has been of late much greater than formerly as a manure, it will be useful for the cultivator to learn the proportion of alkali contained in the kinds usually met with in commerce, as determined by Mr. Jamieson (*Min. of Scottish Isles*, vol. ii. p. 248):—

	lbs.	oz.	lbs.
Barilla from Alicant, good	-	-	23 8 in 100
Teneriffe, bad	-	-	8 7
Kelp from Norway, indifferent	-	-	2 11
Shetland, indifferent	-	-	2 6
Lewis, indifferent	-	-	2 6
W. Highlands, much damaged	0	5½	
Arran	-	-	3 8
Isla, good	-	-	4 0
Mull, good	-	-	4 8
Morven, good	-	-	4 8
Skye, good	-	-	5 0
Leith shores	-	-	4 0

But, besides the alkali referred to, kelp contains iodide of potassium, bromide of potassium, and sulphuret of potassium; all of which probably exert considerable influence on vegetation. It is well known that seeds sown in pure sand, and watered with a solution of iodine, germinate very rapidly.

The residuum, when all the soda and common salt are extracted from the barilla, is principally earthy matters, which are of a very inert nature, and need not be regarded by the cultivator as possessing any peculiar fertilizing properties different from marl, which they much resemble in composition.

100 parts of these insoluble matters of kelp are composed of—

	Parts.
Sulphureted hydrogen and carbonic acid	- 14.00
Carbon	- 4.10
Sulphuric acid	- .47
Silica	- 12.30
Lime	- 32.60
Magnesia	- 18.50
Alumina	- 15.40
Iron	- .77
Loss	- 1.86
	<hr/> 100.

From the quantity of kelp produced on the shores of Scotland, and its reduced price since the peace, which again allowed the unrestricted import of Spanish barilla, and more especially since the discovery of a cheap mode of extracting soda from common salt, the application of kelp as a manure has engaged the serious attention of the farmers of that part of the island, and a committee was some time since appointed by the Highland Society of Scotland to report upon its pretensions; in much of that report, from which the following extracts are made, I cordially agree:—

“Your committee are unwilling to offer any theoretical opinion as to the way in which kelp may operate as a manure. From the quantity of alkali which it contains, it may naturally be expected to operate by rendering the animal and vegetable matter soluble, and a fit food for plants; but, from the series of facts to be noticed, kelp would seem to possess other qualities as a manure. Although it may be beneficially applied as a dressing by itself, yet the committee are at present inclined to think that,

with a view to raising of green crops, it would be better to mix it in compost with other substances. The selection of these must depend upon what the farmer can furnish; but the committee think that good earth or moss will form a good compost, and if to this mixture can be added a little vegetable or animal manure, a beneficial result can be relied on. In this way, a few tons of kelp would enable a farmer to extend his farm dung over at least four times the quantity of land.”

The relative value of kelp as a manure may be estimated from the following experiments, made in the neighbourhood of Edinburgh:—A field upon the estate of Inverleith, possessed by Mr. Hutchinson, was selected, which had been in wheat in the year 1828, hence it was in some measure in an exhausted state: upon one ridge of this field there was sown at the rate of 12 cwt. of kelp per acre; on a second, at the rate of 10 cwt. per acre; and on a third at the rate of 4 cwt. per acre. Two other ridges were manured with the best cow and horse dung, at the rate of 20 tons per acre; and the whole was sown with wheat late in the spring of 1829. The two ridges which had got the greatest quantity of kelp were equal to that which had the dung, and the ridge which had got the smallest quantity was decidedly superior to the others. Similar experiments were made upon the same field, by sowing barley after the previous crop of wheat; the result was, that the barley manured with the kelp was, according to the estimate of the tenant and his steward, a much heavier crop than after an application of horse and cow dung, and that the ridge with the smallest quantity of kelp appeared the heaviest crop.

A portion of the lands of Bangholm were manured with kelp of inferior quality, at the rate of one ton per acre, and the land sown with yellow turnip; the crop, upon examination, is considered to be fully equal to that part of the field which has been manured with dung. (*Baxter's Lib. of Agr. Knowl.* p. 406.)

Mr. Kerr, of Henfield, has given the result of his experiments on kelp, from which he is of opinion that “5 cwt. of kelp per Scotch acre will produce a manifest improvement on any crop.” (*Trans. High. Soc.* i. p. 320.) Care must, however, be taken not to apply too copious a dressing of kelp. Mr. Mackinnon, of Corry, draws the following conclusion from his experiments; he used the ashes of sea-weed burnt in a heap: “of the ashes thus manufactured, 20 bushels were allowed to the acre, and distributed in the drills. When the turnips sprouted, they had an unhealthy green or rather yellowish appearance, but after some time several patches in the field seemed to be growing luxuriantly, while others seemed to retain their sickly hue. Upon a careful investigation, it was discovered that wherever the ground was deepest, and the ashes of the sea-weed had been most mixed up with the soil, the turnips were best; and, on the other hand, that where the ashes, not being mixed up with the soil, came in contact with the seed, the turnips did not at all thrive. In clearing the ground the weeds were collected into heaps, and burnt upon the spot; and it was observed that on

the side of these heaps the turnips were very nearly as good as those on an adjoining piece of ground manured solely with dung." (*Ibid.* vol. iv. p. 246.) There is a good paper on the manufacture of kelp in *Quart. Journ. of Agr.* vol. ii. p. 927; and on mixing kelp with composts, peat, turf, &c., *ibid.* vol. iii. p. 556.

Every farmer has it in his power, even in the most inland situations, to procure soda for the use of his farm, by means of a mixture of two parts of lime and one part of common salt, and suffering the mixture to remain incorporated in a shady place, or covered with sods, in a dry state, for two or three months; a plan which I suggested some years since (*Johnson on Salt*, p. 32, 3d edit.), and which has been recently successfully adopted by Mr. Bennet, in Wiltshire. By this process a gradual decomposition takes place, chloride of calcium and soda are formed, the whole mass speedily becoming encrusted with this alkali. There is another advantage to be derived from the adoption of this process, besides the formation of the soda, viz. that the chloride of calcium is one of the most deliquescent or moisture-absorbing substances with which we are acquainted; and, in consequence, wherever it exists in a soil, the warmth of the sun has, in summer, much less influence upon it than it would otherwise have.

Mr. G. Irwin, of Taunton, bears testimony to the value of common soap-suds. "The portion of the garden invigorated by the soap-suds, only annually exhibits a luxuriance almost equal to anything this fertile neighbourhood can produce." The Rev. J. Falconer, when commenting upon this experiment, says, "This mixture of an oil and an alkali has been more generally known than adopted, as a remedy against the insects which infest wall fruit trees. It will dislodge and destroy the insects which have already formed their nests and bred amongst the leaves. When used in the early part of the year, it seems to prevent the insects from settling upon them. Mr. Speechly, the author of a treatise upon the Cultivation of the Vine, published in 1796, used this mixture with great success, although, from not having employed a garden engine, he applied the soap-suds awkwardly and wastefully. He directs it to be poured from a ladder, out of a watering-pot, over both trees and wall, beginning at the top of the wall, and bringing it on in courses from the top to the bottom."

Mr. Martin, of Warbleton, has recently used soda for turnips, half a cwt. per acre, previously to the last ploughing, thinking, as he observed, that it would destroy such insects as lie in the ground in an embryo state, or prevent their arriving at maturity so as to injure his crop. In respect to the use of soda on corn lands, he said he used it rather extensively last season, and that he had tried several experiments with it, both upon grass and arable land. That in a field of wheat, a very thin, poor, gravelly soil, he sowed one warp without any manure at all; on another warp adjoining, he used one cwt. per acre; and on a third warp he put 1½ cwt. per acre. The produce of eight rods on each warp was as follows: this was a land of a very bad description:—

	Per acre.
8 rods without manure, 7 gallons, or	17½ bushels.
8 rods with 1 cwt. soda per acre, 10½ gallons, or	26 bushels, 2 galls.
8 rods with 1½ cwt. soda per acre, 15½ gallons, or	38 bushels, 6 galls.

KENNEL (Fr. *chenil*, from *chien*, a dog). The hole of a fox or other wild beast. In rural economy, a habitation for dogs, especially those of the hound kind: it should be situated a good distance from the house. Large kennels require to be kept clean, well aired, and strewed with fresh straw to prevent the mange or other infectious distempers. Those readers who wish to acquire information on the management of the kennel will do well to consult *Blaine's Encyclopædia of Rural Sports*.

KERN-BABY (a corruption of corn-baby) was an image formerly dressed up with corn, carried before the reapers to their harvest-home.

KERNEL (Sax. *cýrnel*, a gland). In general this word signifies the substance within a shell; but it has different meanings, sometimes implying anything included in a husk or integument, as the seed of pulpy fruits, the grain of oats, &c. In horticulture the hardy fruits are generally arranged under the heads of *kernel fruits*, or pomes, including the apple, pear, quince, medlar, and service; *stone fruits*, as the peach, nectarine, almond, apricot, plum, and cherry; *berries*, as the mulberry, barberry, elderberry, gooseberry, currant, raspberry, cranberry, and strawberry; and *nuts*, as the walnut, chestnut, and filbert.

KIDNEY-BEAN, the kind of bean most cultivated in the United States, whereas the variety mostly cultivated in Europe is the horse-bean. See **BEANS**.

KIDNEY-VETCH (*Anthyllis*; derived from *ἄνθος*, a flower, and *ἔλας*, down, in reference to the flowers being usually covered with a soft or silky pubescence). The species are, for the most part, elegant and free-flowering plants proper for ornamenting rock-work. The hardy perennial and annual kinds thrive well in a warm situation and light soil. The greenhouse and frame kinds succeed best in sandy loam and peat; and increase plentifully from seeds, and sometimes from cuttings. (*Paxton's Bot. Dict.*)

The common kidney-vetch, or ladies' finger (*A. vulneraria*), is the only species indigenous to the British Islands. It is found growing wild in chalky or limestone countries, where the soil is dry and rather barren, and the herbage affords good pasturage for sheep. The root of this species is woody, the stems annual, round, hairy, leafy, mostly simple, ascending, about a foot high. The radical leaves are simple, elliptical, on long stalks, soon disappearing; the rest alternate, pinnate, with a terminal elliptical leaflet, and several pairs of opposite, small, lanceolate ones; all entire, smooth, and a little glaucous above, hairy, or rather silky, underneath and at the margin. The flowers, which are numerous, in a pair of crowded terminal heads, accompanied by figured bractæas, are usually yellow, rarely of a fine red. In Germany, according to Haller, the flowers are most frequently white. This plant formerly had the reputation of possessing some vulne-

rary properties, whence the specific name. (*Smith's Eng. Flor.* vol. iii. p. 269.)

KILN (Sax. *cýln*). A kind of furnace or stove for admitting heat, in order to dry substances of various kinds, as corn, malt, hops, &c. It also signifies a fabric or building constructed for the purpose of burning limestone, chalk, and other calcareous stones, into lime. Kilns are of various kinds, and formed in different ways, according to the purposes for which they are designed. See **HOPS**, **MALT**, **LIME**, **CLAY**, **KILN**, &c.

KILN ASHES. The ashes made in kilns where wood, straw, furze, &c. are burnt. These ashes are useful as manure for almost any kind of soil. They are found to succeed best when spread just before rain. See **ASHES**.

KIT. In some places a name given to a milking-pail or vessel in the form of a churn, with two ears and a cover, used to convey milk in.

KITCHEN GARDEN. A piece of ground laid out for the cultivation of fruit, herbs, pulses, and other culinary vegetables.

The kitchen garden is the most important object of the horticulturist's care, inasmuch as its productions, next to those of agriculture, tend most to the support of mankind.

It often affords the chief support of the cottager, and ought to be the constant attendant of his dwelling. Of more exalted mansions it is always an accompaniment, but it is much to be regretted that a more plentiful use of its products is not adopted in preference to grosser aliment.

The kitchen garden also has for its inmates many plants chiefly valuable as rendering other kinds of food more palatable, or as possessing sanative qualities. These last formerly far exceeded in number the edible plants. The subsequent more general employment of mineral medicines has reversed this state of our kitchen garden. The culture of aromatic herbs is also much less attended to since the introduction of spices. In selecting the site, and in erecting the enclosures, as well as in the after-preparation of the soil, the ingenuity and science of the horticulturist are essentially requisite. He will be called upon to rectify the defects, and to improve the advantages which nature affords; for it is very seldom that the natural situation of a mansion, or the plan of its grounds, allows him to construct it in the most appropriate spot.

The garden is best situated at a moderate elevation; the summit of a hill, or the bottom of a valley, is equally to be avoided. It is a fact, not very difficult of explanation, that low-lying ones are the most liable to suffer from blights and severe frosts; those much above the level of the sea are obviously most exposed to inclement winds. To determine the appropriate size of a kitchen garden is impossible. It ought to be proportionate to the number of the family, their partiality for vegetables, and the fertility of the soil. It may serve as some criterion to state, that the management of a kitchen garden occupying the space of an acre affords ample employment for a gardener, who will also require an assistant at the busiest periods of the year. In general, a

family of four persons, exclusive of servants, requires a full rood of open kitchen garden. It ought not to be larger than can be conveniently cultivated; and it is too large if its proprietor is induced to bring into it the culture of the field, for that neatness and fertility which is essential to the garden can be obtained by the use of the spade only.

A wall of brick or stone is the best fence; one of paling may be placed next in order. It ought to be set close, and kept in good repair, and not lower than 6 feet, that poultry may be effectually excluded. The form of the walks or divisions must depend upon local circumstances, but to some extent the following recommendations of Bridgeman (*Gardener's Assistant*, p. 7), may be carried out: "Form a border round the whole garden, from 5 to 10 feet wide, according to the size of the piece of land; next to this border, a walk may be made from 3 to 6 feet wide; the centre of the garden may be divided into squares, on the sides of which a border may be laid out 3 or 4 feet wide, in which the various kinds of herbs may be raised, and also gooseberries, currants, raspberries, strawberries, &c. The centre beds may be planted with all the various kinds of vegetables. The outside borders facing the east, south, and west, will be useful for raising the earliest fruits and vegetables; and the north border, being shady and cool, will serve for raising and pricking out such young plants, herbs, and cuttings, as require to be screened from the intense heat of the sun." The walks ought to be drained in some cases, and in all well gravelled. The edging or border may be of brick, which for a kitchen garden is preferable to all others, as it affords no shelter for slugs and vermin, is durable, and requires little labour to keep it in repair.

The order in which successive crops are grown on the same compartment has very considerable influence in prolonging the continuance of the soil in fertility. Some vegetables, as onions and carrots, are extremely impoverishing to the soil, whilst lettuces are but in a small degree prejudicial. It is, therefore, obvious, that a succession of exhausting crops should never be grown on the same bed, however plentiful manure may be, not merely because abundance is no excuse for a want of economy, but that fresh applied dung is not so immediately beneficial as those remains of organized matters, which, by long continuance in the soil, have become impalpably divided and diffused through its texture, and of which each succeeding crop consumes a portion. Those plants in general are the least exhausting which have the largest surface of leaves, and *vice versâ*, because the first are not only possessed of a larger proportion of aqueous, than solid matter than the latter, but also are enabled to obtain a greater quantity of their food from the atmosphere. It may be objected to many crops included by this rule, and especially to turnips, that they require a soil of extreme fertility; but this is only an apparent anomaly, for, although the turnip, for example, requires a rich soil, it is only because it requires a regular supply of moisture: neither will a tenacious soil therefore be beneficial.

on the contrary, a superfluity or deficiency, according to the season, being then afforded, decay or immaturity is induced.

There are many other contingencies which should regulate the rotation of crops. The roots of different plants strike in different directions, and to different depths; and, as their constituents vary, absorb different matters. Deep-rooted plants, therefore, should be succeeded by such as spread but a little below the surface; perennials always by annuals; crops left for seed, or those that are of a dry, solid texture, by such as are succulent and juicy; but, above all, the same species of plant should never be grown in successive crops upon the same ground. This is not even palliated by the excuse that manure is abundant, for, as Sir H. Davy observes, "though the general composition of plants is very analogous, yet the specific difference in the products of many of them prove that they must derive different materials from the soil; and though the vegetables having the smallest systems of leaves will proportionably most exhaust a soil of common nutritive matter, yet particular vegetables, when their produce is carried off, will require peculiar principles to be supplied to the land which produces them." (*Lect. on Agr. Chem.* p. 358.) It is known to every cultivator of soil, that land soon becomes tired of the same crop; in many instances, peculiar diseases are induced by the repetition. The most beneficial plan of rotation appears to be that where an exhausting and non-exhausting crop alternately succeed each other, for example,

Onions.	Turnips.
Lettuce.	Peas.
Carrots.	Potatoes.
Manure.	Manure.

Mr. Kelly, of Airthrey Castle, Scotland, says, that on poor ground the rotation he finds best is, 1st, celery; 2d season, cauliflowers, and red beet; 3d, onions; 4th, German greens or peas. By digging deep, and manuring abundantly for celery, the ground is brought into such fine tilth, that the whole rotation is often gone through without any further addition, and without failing in any of the crops.

A Hotbed will be found useful for forwarding several kinds of vegetables early in spring. In it tomatoes, egg-plants, peppers, early bush squashes, and cucumber plants may be raised, and planted out as soon as the danger of frost is over. The best material for a hotbed is fermenting stable manure, which may be mixed with a portion of cow manure or leaves, and turned over two or three times, at intervals of 5 or 6 days, before using. If dry, give it a little water at each turning. The frame may be made of strong boards or two-inch plank, about 1 foot high at front, and 1½ foot at back. The width from back to front may be about 6 feet, and the length of any number of sashes that may be required. The sashes may be glazed with small glass from 5 to 10 inches. The smaller sizes will answer every purpose, are cheaper, and not so liable to break. Having fixed upon the size of the frame, and a sheltered situation in which to make the bed, place a stake at each corner of it, allowing a few inches larger each way than the frame.

The manure must be well shaken up and thoroughly mixed, and, in building, the bed regularly beaten down with the fork or lightly trodden, and if at all dry, well sprinkled with water. If wanted for early forcing, the bed should be at least 4½ feet high; if for starting vegetables 2 feet will be sufficient. The frame and sashes may then be put on, and in three or four days 8 or 10 inches of good light earth may be put in, and the seed sown. Squashes and cucumbers will do best in pots. A pot of 4 to 5 inches in diameter will be large enough for three plants. Tomatoes, egg-plants, and peppers may be sown over the bed, and afterwards thinned to regular distances. Early cabbages, cauliflowers, celery, and lettuce may be raised in the same way, and afterwards planted where wanted. But should the management of the hotbed be attended with too much trouble or expense,

The Frame can be used with much advantage, as in it plants can be raised and kept safe from frosts long before they would bear exposure in the open air. The frame may be set on the ground on the south side of the fence, and if the earth is rich and light, or made so, the seeds may be sown broadcast over a space allotted to each kind, and afterwards thinned out to proper distances. Lima beans may be started in this way, and transplanted before they attain to any great size. The frame is also useful for preserving cabbage, cauliflower, and lettuce plants during winter, for planting in the spring; as well as cabbages, lettuce, and celery for family use. A few leaves or litter put among the vegetables will aid materially in excluding the frost, and a shutter and mat must be put over the sashes in severe weather.

Our object in this article is to give a condensed view of the common operations in the kitchen garden, as adapted to the United States, with a list of such varieties of the different species of vegetables as have been cultivated in this country, and can be had from the principal seedsmen in Boston, New York, and Philadelphia.* Several articles are omitted, which obtain a place in some gardens, but these are either thought not to deserve a place, or to belong more properly to field culture. Fuller information on any particular subject can always be found under the proper head in the alphabetical arrangement.

ASPARAGUS (*Asparagus officinalis*). Sow early in the spring; having previously soaked the seed in warm water for 24 hours, then drill it thinly, in rows sufficiently wide apart to admit the hoe; when two years old, transplant into permanent beds, which should be so situate as to cast off an excess of moisture, and having the soil prepared to the depth of two feet with plenty of manure under. A convenient width for the beds is four feet. The plants should be placed 12 inches apart in each direction; planted at least 4 inches beneath the surface; well manured at the time, and annually thereafter. If planted in rows, they should be 2½ feet apart. Common salt scattered over the bed in the winter operates favourably in im-

* In compiling this article, we would here acknowledge our obligations to the excellent catalogue of D. Landreth & Co. of Philadelphia.

proving the growth of asparagus. Meat pickle or brine is still better.

BEANS, ENGLISH (*Vicia faba*). Plant very early in the spring, in rows. Broad Windsor and Mazagan are the best varieties.

Bush Beans (*Phaseolus vulgaris*). The Early Six weeks, China red-eye, and Red speckled Valentine, are among the earlier; the Valentine, Mohawk, and Marrow are very superior varieties. They may be planted for the first and succession crops from the middle of spring till the close of summer; the usual mode of culture is in rows, two or three in a clump, at intervals of 10 or 12 inches.

Pole or Climbing Beans (*P. multiflorus*). The best varieties are the Lima, Carolina, White Dutch, Red and White Cranberry, and London Horticultural. The Limas are tender, and should not be planted till the close of spring. They may be forwarded by sprouting them in a hotbed, and transplanting them into hills 4 feet distant from each other. Poles 8 or 10 feet long should be put into the ground before planting, and (if of seed) 6 or 8 planted round each pole, as the seed is apt to rot in cold or damp weather. Thin them afterwards, leaving three or four good plants in each hill. The London Horticultural is an excellent variety, and may be used for the Lima in those districts where the Lima frequently fails to ripen. See **BEANS**.

BEEF (*Feta vulgaris*). The Turnip-rooted and Long Blood-red are generally esteemed the best for table use. The turnip-rooted is somewhat earlier than the long, and is equally good for winter use. Sow in drills from early in the spring till the commencement of summer. The plants should stand 6 or 8 inches apart in the drills, but the seed should be put in thick, to secure a full crop. A good plan is to drop several seeds together at proper distances, and when up remove all but the strongest.

Swiss Chard (*Feta cicla*), is much grown in Germany and Switzerland, and used as chard or asparagus. The laminæ or thin parts of the leaves, are eaten as spinach or put in soups; and the stalk or midrib is boiled, and eaten with melted butter or gravy like asparagus. The culture is the same as for the blood beet, but the leaves are much larger, and a greater space should be left between the plants on that account. See **BEEF**.

CABBAGE (*Brassica oleracea* var. *capitata*). The earliest variety is the Early York; next the Early Sugarloaf, and Landreth's large York; Early Battersea is late in the summer. The flat Dutch and Drumhead are for winter use, and red Dutch for pickling. Early and summer varieties are usually sown in seedbeds early in autumn, protected therein or in cold frames, during winter, and transplanted early in the spring. Where the climate is mild, and the land light and dry, they are planted in the autumn, in which case they head earlier than those put out in spring.

Should a supply of plants not have been obtained in autumn, sow in a hotbed very early in spring, or somewhat later, on a warm border in the open air. But let it be borne in mind that in no case can fine cabbage (especially the earlier kinds) be had, unless on heavily

manured and well-tilled land—heavy or strong loamy soil is best adapted to this crop.

For winter sorts, sow in a seedbed in the middle or latter end of spring, and transplant early in summer. To have these kinds to head early in autumn, sow at the same time as the early sorts. To preserve from the cabbage-fly, sow in boxes elevated two or three feet above the surface, and as soon as the plants are established, place them on the ground, lest the plants burn up. To keep them during winter, bury the stalk and part of the head with earth, over which, if the cold be severe, sprinkle straw, or put in a cold frame.

Savoys and Brussels Sprouts (*B. oleracea* var. *bullata*), are good for winter use, and become very tender after being touched by frost. Cultivate as winter cabbage.

Borecole, Kale, &c. (*B. oleracea* var. *acephala*), may be treated as winter cabbages. They are said by Bridgeman to be delicious when rendered tender by smart frosts; and to be valuable plants to cultivate, particularly in the Southern States, as they will there be in the greatest perfection in the winter months; they will also, if planted in a gravelly soil, and in a sheltered, warm situation, bear the winter of the Western States; and may be kept in great perfection in the Eastern States, if taken up before the frost sets in with much severity, and placed in trenches up to their lower leaves, and then covered with straw or other light covering. See **CABBAGE**.

Broccoli and Cauliflower (*B. oleracea* var. *botrytis*). Purple Cape broccoli is decidedly the best of many varieties. Sow in seedbeds in the middle of spring, and transplant and manage generally as winter cabbage. Early Asiatic cauliflower is sown in seedbeds in the beginning of autumn, kept in a cold frame during winter, and transplanted to very rich ground as soon as the frost ceases. Hand glasses or boxes put over them at night, when they are first put out, are useful. The late variety matures in autumn, and is sown at the same time, and managed like Cape broccoli. It is, however, not so sure to succeed as the broccoli, nor is it a better vegetable when obtained. See **BROCCOLI**.

CARROT (*Daucus carota* var. *hortensis*). The Early Horn is best for table use. The Long Orange is more productive. The Altringham produces great crops, and is suitable to raise for horses and cattle. Sow the seeds in the middle of spring, in a rich, sandy loam, well pulverized, in rows a foot apart, cover about half an inch deep, and thin the plants to 4 inches distance. Gather the crop soon after the first hard frost, and keep them in a cave or warm cellar. See **CARROT**.

CELERY (*Apium graveolens*). Sow the seed early in spring, in rich, mellow ground, and in a situation where the plants can be protected from the parching heat of the sun. It can either be sown broadcast or in drills, if in drills, they may be half an inch deep and 6 inches apart, that a small hoe may be worked between them. Plant out in July, in a piece of rich ground, in an open exposure, in trenches 8 or 10 inches wide, and allow the space of 4 feet between them. Dig each trench a spade deep, laying the earth equally on each side, and

put 4 inches of good rotten dung into the bottom; tread it firmly, and cover with an inch of soil from the sides, then plant a single row in the middle of each trench, leaving 7 or 8 inches between the plants. Give a plentiful watering, and shade with a board till they strike root. It may be grown also in beds, 4 feet wide, with alleys 4 feet between, prepared as above. Plant 4 rows in each bed, at from 6 to 8 inches apart, and water and shade as before. To blanch, earth up gradually in dry weather, as the plants progress in growth, repeating the earthing every 2 weeks, at which time care should be taken to gather up all the leaves neatly, and not to bury the heart of the plants. The earthing up may begin in September. See **CELERY**.

CORN, INDIAN (*Zea Mays*). There are several varieties used at table, but none are better than the common Sweet Corn.

CUCUMBER (*Cucumis sativus*). The Early Frame and Early Green Cluster are good varieties. The Long Green is chiefly used for pickling. As soon as the ground becomes warm in spring, plant in hills 6 feet asunder each way, putting a dozen seeds in a hill, and covering half an inch deep. Leave finally but three of the strongest plants. The ground must be rich and well manured. For very early use, sow in small pots in a hotbed; turn them into the open ground in May, taking care to protect them from the sun and late frosts. For pickling, plant in the end of June. See **CUCUMBER**.

EGG-PLANT (*Solanum melongena*). Sow in hotbed, or other protected place, very early in the spring, and late in the spring transplant into very rich ground, keeping the plants about two feet asunder. The seed requires much warmth to cause it to vegetate. See **EGG-PLANT**.

ENDIVE (*Chichorium endiva*). Sow at close of spring to middle of summer in shallow drills; when up an inch or two, thin out to stand a foot apart. In dry weather tie up to blanch as needed. See **CHICORY** and **ENDIVE**.

LEEK (*Allium porrum*). Sow in seed-bed middle of spring; when the plants are 4 or 5 inches high transplant into rows, setting them loosely and deeply into the soil, and leaving space to admit the hoe between them. See **LEEK**.

LETTUCE (*Lactuca sativa*). The Early Cabbage, brown Dutch, Royal Cabbage, Curled India and Tennisball are good, and stand the climate. Of the Cos varieties, which are very crisp and tender, but soon shoot to seed, the Egyptian Green Cos can be recommended. Sow in seed-bed from commencement to middle of autumn, protect the plants by a cold frame or with litter as they stand on the ground; early in the spring transplant them into rich ground. For a later supply, sow in drills from time to time during spring and summer; when up a few inches, thin out, leaving plants at proper distances. See **LETTUCE**.

MELON (*Cucumis melo*). The Citron, Persian, Nutmeg, and Murray's Pine-apple are good varieties of the canteleup or musk-melon. Plant in hills of rich, light soil, at the distance of 6 feet asunder, in the latter end of spring, putting 6 or 8 seeds into each hill, 2 inches distant

from one another, and half an inch deep. Thin out to 3 in each hill; draw the earth from time to time about the hills as high as the seed leaves. Pinch off the top at the first or second joint, as this will strengthen the plants, and cause them to fruit early. Grow no pumpkins or squashes near them.

MELON, WATER (*Cucurbita citrullus*). The Spanish and Mountain Sprout are good varieties. The Citron is cultivated for preserves. Cultivate as for canteleups, but let the hills be 7 or 8 feet distant.

OKRA (*Hibiscus esculentus*). Plant in good, rich ground late in spring, as it is a very tender vegetable. Make drills an inch deep, and 3 or 4 feet asunder, into which drop 2 or 3 seeds together, at intervals of about 8 inches, and cover them nearly an inch deep. Thin them out to 8 or 10 inches as the plants advance, and earth up 2 or 3 times.

ONION. See that head.

PARSLEY (*Apium petroselinum*). Sow in rows early in the spring. By soaking the seed in warm water some hours immediately before sowing, it will vegetate more speedily. It sometimes lies in the ground 2 or 3 weeks before vegetating.

PARSNIP (*Pastinaca sativa*). Sow early in spring, in good soil, deeply dug, making drills 18 inches apart. When the plants are 2 or 3 inches high, thin out to 6 or 8 inches apart.

PEA (*Pisum sativum*). Landreth's Extra Early, and Bishop and Russell's Early Dwarfs are the earliest varieties, and good of their kind. Dwarf Blue Imperial, and Dwarf Scimitar are much esteemed. Knight's Dwarf and Tall Marrowfats are late kinds, but superior to all others for flavour and productiveness. Tall and Dwarf Sugar or string peas are sweet, and productive; they are boiled without shelling, and served up as kidney beans. The dwarfs require sticks from 2 to 3 feet long, the others from 4 to 6, and a greater width between the drills.

PEPPER (*Capsicum*). Grossum or bell-shaped, Large sweet, and Squash or tomato-shaped, are used for pickling; the last variety is the best. The Sweet has a delicate taste, and is used as a salad. Sow in hotbed in March, and transplant; or in the open ground, late in spring, in drills 2 feet apart. When the plants are an inch or two high, thin them out to about 15 inches apart in the rows, and hoe them repeatedly.

POTATO. See that head.

RADISH (*Raphanus sativus*). Short-top Scarlet, Salmon, Red and White turnip-rooted, may be sown in the spring, as early as the ground can be worked. Yellow turnip-rooted and Summer White are best for summer use. White and Black Spanish for winter. Sow these at close of summer, or early in autumn, and when ripe store them in a cellar. For a succession in spring and summer, sow every two weeks. The ground should be light, rich, and well worked.

RHUBARB (*Rheum*). Tobolisk, Mammoth, and Giant, are the best varieties, and may be raised by dividing the roots early in spring, and planting them in rich, deep soil, in rows 4 feet asunder and 3 feet distant in the rows.

To raise from seed, sow late in autumn or early in spring. Young seedling plants require to be protected the first winter by soil. To force very early, cover with boxes or barrels surrounded and covered with horse manure. Gather before the leaves are fully expanded.

SALSIFY, or Vegetable Oyster (*Tragopogon porrifolius*). Cultivate as directed for carrot.

SEA-KALE. See **KALE**, **SEA**.

SPINACH (*Spinacia oleraceu*). Round Savoy-leaved, and Prickly seeded. May be grown either broadcast or in drills. For spring and early summer use, sow as early as the ground can be tilled, and afterwards at short intervals. For the autumn supply, sow at close of summer. For winter and early spring use, sow middle of autumn. The latter sowing will need a sprinkling of straw or long manure on the arrival of cold weather. Spinach is one of those vegetables for which the ground cannot be too rich; the stronger it is the more succulent will be the leaves, and of course the more delicate and tender.

SQUASH (*Cucurbita melopepa*). Early Bush, Early Crook-neck, Early Orange, Valparaiso, Winter and Canada Crook-necks. The three first are early varieties. The bush occupies but little room, and is best adapted for small gardens. Cultivate as directed for cucumber. The three last are winter varieties, and require more room.

TOMATO (*Solanum lycopersicum*). Sow in hot-bed in March or April, or in a warm border early in spring, and transplant, after settled warm weather, in rows 4 feet apart and about 3 feet distant in the row. They may be supported with brushwood, or trained to a trellis or fence.

TURNIP (*Brassica rapa*). Early White Dutch, Early Stone, Early Red-topped, are best for early garden culture. For winter use the Rutabaga, Yellow Stone, Yellow Aberdeen, and Dale's Hybrid, are excellent.

There is also a variety of aromatic and medicinal herbs cultivated in the kitchen garden, which are useful for many purposes. Of these, the Bene Plant, Sweet Basil, Carraway, Coriander, Sweet Marjoram, and Summer Savory are annuals, the seeds of which may be sown in the middle of spring, and thinned out to convenient distances.

Balm, Chamomile, Horehound, Hyssop, Fennel, Lavender, Mint, Pennyroyal, Rosemary, Rue, Sage, and Thyme, are perennials, and may be propagated by offsets or parting of the roots, and from seed sown in drills, and afterwards transplanted.

These are the most useful productions of the kitchen garden. The varieties named are believed to be the best, and such as are most certain, in the United States, to repay their culture. Those who desire to go extensively into the cultivation of vegetables, can consult the works of M'Mahon, Bridgeman, and Fessenden, for more minute details of the modes of culture and more extensive lists of varieties.

Much success in cultivating vegetables will depend on the rotation of crops. The same kinds should not be grown on the ground successively. The ground must also be kept rich, by the application of manure, well work-

ed, and above all kept clear of weeds. I ought always to be remembered that what will nourish a crop of weeds will produce a crop of useful vegetables; and no operation will tend more to produce luxuriant vegetation, and prevent the ill effects of drought, than the frequent use of the hoe.

For the compilation of the preceding article we are indebted to Mr. William Sinton, gardener to General Patterson, Philadelphia.

KNAPP, EARLY (*Knappia agrostidea*). It was named by Sir J. Smith in compliment to Mr. M. Knapp, a writer on British grasses. Of this, one of the least of the British grasses, only one species is known; although common on the coasts of France, it is very rare in England, but is found in maritime pastures, sometimes in Wales. It is an annual; root of many long, slender fibres; stems 1 to 3 inches high, erect, simple, slender, smooth, triangular, naked, except at the very bottom, where they are invested with the membranous sheaths of a few short, obtuse, channelled leaves. Stipules membranous, bluntish, cloven, but not deeply divided. Spikes solitary, simple, erect, of from 6 to 10 flowers, mostly sessile, alternate, erect; two or three of the lowermost only more or less stalked; their common stalks zigzag, slender, smooth, angular, but not excavated, as in the truly spiked grasses. Flowers, like the top of the stem, purplish. (*Eng. Flor.* vol. i. p. 84.)

KNAPWEED (*Centaurea*). This is a large herbaceous genus of plants, which Jussieu, after Tournefort, has divided into several, by the structure or termination of the calyx scales. Linnæus has kept it entire, and Decandolle has not disturbed it. Smith (*Eng. Flora*), also, makes one family of them. The following are the indigenous species known under the common name of *knapweed*. I have treated of other species under the heads **BLUE BOTTLE** and **STAR THISTLE**.

1. Brown radiant knapweed (*C. Jacea*). This grows in meadows where the soil is tenacious and moist. It is a perennial, flowering in August and September. The root is rather woody, with many long fibres. Stem solid, erect; a foot high, branched, angular, furrowed and roughish, leafy. Leaves, light green, rough, with short hairs; radical ones largest, stalked, toothed or pinnatifid; the rest scattered, sessile, oblong, or linear lanceolate, entire, or toothed near the base. Flowers large, numerous, radiant, light crimson, solitary at the tumid end of each branch, accompanied by a few leaves close to the calyx, which is brown; the calyx scales are membranous, torn. Linnæus says, the herb steeped in water, with alum, before the flowers expand, dyes silk of a fine yellow.

2. Black knapweed (*C. nigra*). This grows in pastures, and by road-sides, very common, flowering from June to August. In habit it is like the last, but the stem is taller, more bushy, more deeply furrowed, and rather less rough. The lower leaves are somewhat lyrate, with angular lobes; upper ones ovate; their colour always darker than that of *C. Jacea*. The flowers are also of a deeper crimson, commonly without any radiant or abortive florets. The flowers are occasionally white.

3. Greater knapweed (*C. scabiosa*). This is also a very common species, growing in the borders and ridges of corn-fields, and by waysides. The root is somewhat woody; stem about two feet high, erect, branched, angular, furrowed, leafy, smooth to the touch. Leaves dark green, slightly hairy on both sides, pinnatifid. The flowers, which blow in July and August, are terminal, stalked, solitary, large, and of a handsome crimson colour, rarely white; their radiant florets are large, each with five deep, long, and narrow segments. Calyx-scales ovate, green, somewhat downy, fringed with fine parallel teeth. The seeds are crowned with many reddish bristles; and after they are blown away, the calyx becomes reflex, and displays the silvery shining hue of its inside. (*Eng. Flor.* vol. iii. p. 463.)

KNAWEL (*Sceleranthus*, from *σκληρος*, hard, and *ανθος*, a flower; in allusion to the dry, juiceless calyx). These are dry, rigid herbs, which can only be considered as useless weeds.

The genus is European. There are 3 species, one of which, called *S. annuus*, is so abundantly naturalized in sandy, arable fields, as to appear native to some of the United States. (*Nuttall*).

1. The annual knawel, or German knot-grass (*S. annuus*), which grows commonly in dry, sandy soils and corn-fields, flowering in July. The root is small and tapering. The stems numerous, widely spreading, and partly decumbent; round, leafy, a little downy, branched, and many-flowered at the upper part. Leaves linear, acute, pale green, combined at the base by a membranous fringed border. Flowers small, green, nearly sessile, partly axillary, partly collected into dense forked tufts. Calyx of the fruit spreading, with taper, acute segments. The Swedes and Germans introduce occasionally the steam arising from a decoction of the knawel into their mouths, with a view to cure the toothache. Its leaves are astringent. Goats and sheep eat this plant, but cows totally refuse it.

2. Perennial knawel (*S. perennis*). This species is less common; it flowers from August to October, while the annual knawel blows in July. The root is woody, branched, with many decumbent or prostrate stems, 3 or 4 inches long. The whole herb is of a glaucous, glistening appearance, turning red with age, especially the stems. The leaves are more tapering, crowded, and curved, than in the foregoing. Segments of the calyx more obtuse, concave, and finally converging. In several parts of Europe the roots of this species are attacked by the insect called *Coccus polonicus* (*Linn. Syst.* vol. i. p. 741), which yields a fine crimson dye: it is said likewise to live on *S. annuus* and on some *Potentilla*. A good account of its economy is given in the *Upsal Transactions* for 1742, t. i. p. 51.

KNEE GRASS. A name sometimes given to the rough panic grass.

KNIGHT, THOMAS ANDREW, President of the Horticultural Society of London, F. R. S., &c., a distinguished vegetable physiologist and horticulturist, was born at Wormsley Grange, in Herefordshire, August 12, 1759. "My father," says Mr. Knight, in a late communica-

tion to me, "was a man of much learning and acquirements. Having great powers of mind, and living in an extremely quiet and sequestered spot, he was supposed by his ignorant neighbours, in their language, to know everything." He died at an advanced age, when Mr. Knight was an infant, and as evidence of the respect his knowledge obtained him, whenever in childhood his son sought for information upon any unusual subject, he was told that his father would have answered him, but that nobody now could. Being born in the midst of orchards, "I was early led," he continues, "to ask whence the varieties of fruit I saw came, and how they were produced; I could obtain no satisfactory answer, and was thence first induced to commence experiments, in which, through a long life of scarcely interrupted health, I have persevered, and probably shall persevere as long as I possess the power." Mr. K. was distinguished for his skill in producing hybrid plants, by impregnating the blossoms. We owe to him a debt of gratitude for many fine fruits.

He died May 11, 1838, in the 80th year of his age. The death of Knight was lamented by all men of science, for, as it was soon after well remarked by the Duke of Sussex, when addressing the Fellows of the Royal Society, "It would be difficult to find any other contemporary author, in this or other countries, who had made such important additions to the knowledge of horticulture and the economy of vegetation. (*Selection from his Papers*, p. 69.) To this interesting work a memoir of its author is prefixed.

Mr. Knight was author of the following works, besides numerous papers in the *Philosophical and Horticultural Transactions*:

1. A Treatise on the Culture of the Apple and Pear, and on the Manufacture of Cyder and Perry. London. 1797. 12mo. The 3d edition in 1808. 2. Some doubts relative to the Efficacy of Mr. Forsyth's Plaister, in renovating trees. London. 1802. 4to. 3. Report of a Committee of the Horticultural Society of London. London. 1805. 4to. 4. Pomona Herefordiensis, or a Descriptive Account of the old Cyder and Perry Fruits of Herefordshire. London. 1809. 4to. 5. A Letter on the Origin of Blight, and on raising Late Crops of Peas. This is appended to Sir J. Banks's Essay on the Mildew. London. 1806. 8vo. 2d Edition. (*G. W. Johnson's Hist. Eng. Gard.*)

KNOLL (Sax. *cnolle*). A little round elevation; the top of a hill or mountain.

KNOT-GRASS. The common oat-like soft-grass (*Holcus avenaceus*), from its bulbous roots is often called by farmers knot-grass; but in a botanical sense the following are the true knot-grasses.

This grass is preyed upon in Europe by a species of leaf-beetle (*Chrysomela polygomi*), and likewise in the United States by an insect scarcely to be distinguished from the European beetle. By these the knot-grass is completely stripped of its leaves two or three times in the course of a summer. This little beetle, says Harris, is about three-twentieths of an inch long. Its head, wing-covers, and body beneath are dark blue; its thorax and legs are dull orange-red; the upper side of its abdomen is also orange-coloured; and the antennæ and feet are blackish. The females have a very odd appearance before they have laid their eggs, their abdomen being enormously swelled

out like a large orange-coloured ball, which makes it very difficult for them to move about. I have found these insects on the knot-grass in every month from April to September inclusive. The larvæ eat the leaves of the same plant. (*Harris.*)

KNOT-GRASS, COMMON (*Polygonum aviculare*; from *πολυ*, many, and *γυνυ*, a knee; referring to the numerous joints of the stem). This common annual grass is in England found almost everywhere, in waste as well as cultivated ground, streets, paths, and barren sandy places. The root is fibrous, long, very tough, and somewhat woody, branched below, simple at the crown. Stems several, spreading in every direction, generally prostrate, much branched, round, striated, leafy at the numerous knots or joints. Leaves alternate, stalked, hardly an inch long, elliptic or lanceolate, entire, obtuse, single ribbed, smooth except at the margin; tapering at the base, very variable in width; their substance rather coriaceous; their colour grayish or glaucous, stipules membranous, acute, often red, with a few remote, brownish ribs. The flowers which appear from April to October are axillary, 2 or 3 together on simple stalks, small, seeds acutely triangular, of a shining black, the food of many small birds. It is common in the United States.

KNOT-GRASS, VALENTIA. A name by which the powdery sea-heath (*Frankenia pulverulenta*), is known in some districts.

KNOT-GRASS, WHORLED (*Illecebrum verticillatum*). This is an interesting dwarf perennial plant, which is not uncommon in marshy, boggy ground in Cornwall and Devonshire, flowering in July. The different species are pretty, may be grown in any soil, and increase from seed without difficulty. The root is creeping; herb smooth, branched, procumbent. Leaves small, ovate, acute, or sometimes spatulate, scarcely stalked, rather fleshy. Stipules intra-foliaceous, small, white, jagged. The flowers are small, white, or reddish, whorled, without bractes. (*Eng. Flor.* vol. i. p. 335.)

KNOT-WEED. See **PERSICARIA.**

KOHL-RABI. Bulb-stalked cabbage (*Brassica oleracea*, var. *caula-rapa*). This curious variety of cabbage is a native of Germany, where it is much cultivated, and whence it was first introduced into England by Sir Thomas Tyrwhitt. The stem is swollen like a tuber, and, when divested of the leaves, may readily be mistaken for one. The produce is nearly the same as that of Swedish turnips, and the soil that suits the one is equally good for the other. It may either be sown in drills, or raised in beds, and transplanted like cabbages; in this case the beds require to be made and sown the preceding autumn. Two pounds of the seed will produce a sufficiency of plants for one acre of ground. Hares are so fond of it, that, on farms where these animals abound, the culture of this plant is found to be impracticable. 3840 grains of the tubes of kohlrabi afford 105 grains of nutritive matter (*Sinclair's Hort. Gram.* p. 411). See **CABBAGE**, p. 247.

L.

LABELLUM (Lat.). In botany, the front segment of an orchidaceous or other flower; also the lower petal or lip.

LABOUR (Fr. *labour*; Lat. *labor*). In a general sense, labour implies the exertion of human strength in the performance of any kind of work.

Without entering into an abstruse treatise on the science of political economy, it may not be out of place to examine shortly the subject, for labour is the only source of wealth to the farmer; and having done this, I shall next inquire into the means by which labour may be rendered most efficient. Nature spontaneously furnishes the matter of which all commodities are made; but until labour has been applied to appropriate that matter, or to adapt it to our use, it is wholly destitute of value, and is not, nor ever has been, considered as forming wealth. Were we placed on the banks of a river, or in an orchard, we should infallibly perish of thirst or hunger, unless by an effort of industry we raised the water to our lips, or plucked the fruit from its parent tree. But this illustration is an extreme case; and it is more to our purpose to remark, that the mere appropriation of matter is seldom sufficient. In the vast majority of cases, labour is required not only to appropriate matter, but to convey it from place to place, and to give it that peculiar shape without which it may be totally useless, and incapable of administering either to our necessities or our comforts. The coal used in our fires is buried deep in the bowels of the earth, and is absolutely worthless, until by the labour of the miner it has been extracted from the mine, and brought into a situation where it may be made use of. The stones and mortar used in building our houses, and the rugged and shapeless materials that have been fashioned into the various articles of convenience and ornament with which they are furnished, were in their original state destitute alike of value and utility. And of the innumerable variety of animal, vegetable, and mineral products which form the materials of our food and clothes, none were originally serviceable, while many were extremely noxious to man. The labour that has subdued their bad qualities, that has given them utility, and fitted them to satisfy our wants, and to minister to our comforts and enjoyments, is plainly therefore the only source of wealth. "Labour," to use the words of Adam Smith, "was the first price, the original purchase-money, that was paid for all things. It was not by gold or by silver, but by labour, that all the wealth of the world was purchased." (*Wealth of Nations*, p. 14.) Those who observe the progress and trace the history of the human race in different countries and states of society, will find that their comfort and happiness have in all cases been principally dependent on their ability to appropriate the raw products of nature, and to adapt them to their use. The savage whose labour is confined, like that of the Australian, to the gathering of wild fruits, or of shell-fish on the sea

coast, is placed at the very bottom of the scale of civilization, and is in point of comfort decidedly inferior to many of the lower animals. The *first* step in the progress of society is made when man learns to hunt wild animals, to feed himself with their flesh, and clothe himself with their skins. But labour, when confined to the chase, is extremely barren and unproductive. Tribes of hunters, like beasts of prey, whom they closely resemble in their habits and modes of subsistence, are but thinly scattered over the countries which they occupy; and, notwithstanding the fewness of their numbers, any unusual deficiency in the supply of game never fails to reduce them to the extremity of want. The *second* step in the progress of society is made when the tribes of hunters and fishers devote themselves, like the ancient Scythians and modern Tartars, to the domestication of wild animals and the rearing of flocks. The subsistence of herdsmen is much less precarious than that of hunters; but they are almost entirely destitute of the various comforts and elegancies that give to civilized life its chief value. The *third* and most decisive step in the progress of civilization, in the great art of producing the necessaries and conveniences of life, is made when the wandering tribes of hunters and shepherds renounce their migratory habits and become agriculturists and manufacturers. It is then that man begins fully to avail himself of his productive powers. He then becomes laborious, and by a necessary consequence his wants are then, for the first time, fully supplied, and he acquires an extensive command over the articles necessary for his comfort as well as his subsistence. The importance of labour in the production of wealth was very clearly perceived by Locke. In his *Essay on Civil Government*, published in 1689, he has entered into a lengthened, discriminating, and able analysis, to show that it is from labour that the products of the earth derive almost all their value. "Let any one consider," says he, "what the difference is between an acre of land planted with tobacco or sugar, sown with wheat or barley, and an acre of the same land lying in common, without any husbandry upon it, and he will find that the improvement of labour makes the far greater part of the value. I think it will be but a very modest computation to say, that of the products of the earth useful to the life of man, *nine-tenths* are the effects of labour; nay, if we rightly estimate things as they come to our use, and cast up the several expenses about them, what in them is purely owing to nature, and what to labour, we shall find that in most of them *ninety-nine hundredths* are wholly to be put on the account of labour.

"There cannot be a clearer demonstration of any thing than several nations of the Americans are of this, who are rich in land and poor in all the comforts of life; whom nature having furnished as liberally as any other people with the materials of plenty, *i. e.* a fruitful soil apt to produce in abundance what might serve for food, raiment, and delight, yet for want of improving it by labour have not one hundredth part of the conveniences which might be enjoyed.

"To make this a little clearer, let us but trace some of the ordinary provisions of life through their several progresses before they come to our use, and see how much they receive of their value from human industry. Bread, wine, and cloth are things of daily use and great abundance; yet, notwithstanding, acorns, water, and leaves or skins must be our bread, drink, and clothing, did not labour furnish us with these more useful commodities; for whatever bread is more worth than acorns, wine than water, and cloth or silk than leaves, skins, or moss, that is solely owing to labour and industry; the one of these being the food and raiment which unassisted nature furnishes us with; the other provisions which our industry and pains prepare for us; which how much they exceed the other in value, when any one hath computed, he will then see how much labour makes the far greatest part of the value of things we enjoy in this world. And the ground which produces the material is scarcely to be reckoned in as any, or, at most, but a very small part of it; so little that even amongst us, land that is wholly left to nature, that hath no improvement of pasturage, tillage or planting, is called as indeed it is, *waste*; and we shall find the benefit of it amount to little more than nothing.

"An acre of land that bears here twenty bushels of wheat, and another in America, which, with the same husbandry, would do the like, are, without doubt, of the same natural intrinsic value (utility). But yet the benefit mankind receives from the one in a year is worth five pounds, and from the other possibly not worth a penny, if all the profit an Indian received from it were to be valued and sold here; at least, I may truly say, not one thousandth. It is labour, then, which puts the greatest part of value upon land, without which it would scarcely be worth any thing. It is to that we owe the greatest part of all its useful products; for all that the straw, bran, bread, of that acre of wheat, is more worth than the product of an acre of good land which lies waste, is all the effect of labour.

"For it is not barely the ploughman's pains, the reaper's and thrasher's toil, and the baker's sweat is to be accounted into the bread we eat; the labour of those who sell the oxen, who digged and wrought the iron and stones, who felled and framed the timber employed about the plough, mill, oven, or any other utensils, which are a vast number, requisite to this corn; from its being seed to be sown to its being made bread, must all be charged on the account of *labour*, and received as an effect of that; nature and the earth furnished only the almost worthless materials as in themselves. It would be a strange catalogue of things that industry provided and made use of about every loaf of bread before it came to our use, if we could trace them; iron, wood, leather, bark, timber, stone, bricks, coals, lime, cloth, dyeing drugs, pitch, tar, masts, ropes, and all the materials made use of in the ships that brought away the commodities made use of by any of the workmen to any part of the work; all which it would be almost impossible, at least too long, to reckon up."

Labour is the sole source of exchangeable value, and, consequently, of wealth. It is the talisman that has raised man from the condition of the savage; that has changed the desert and the forest into cultivated fields; that has covered the earth with cities, and the ocean with ships; that has given us abundance, comfort, and elegance, instead of want, misery, and barbarism. Labour, according as it is applied to the raising of raw produce, to the fashioning of that raw produce, when raised into articles of utility, convenience, or ornament, or to the conveyance of raw and wrought produce from one country or place to another, is said to be agricultural, manufacturing, or commercial. An acquaintance with the particular process, and most advantageous methods of applying labour in each of these grand departments of industry, forms the peculiar and appropriate study of agriculturists, manufacturers, and merchants.

In thus endeavouring to exhibit the importance of labour, and the advantages which its successful prosecution confers on man, it must not be supposed that reference is made to the labour of the hand only. This species, indeed, comes most under our observation; it is that, too, without which we could not exist, and which principally determines the value of commodities. It is questionable, however, whether it be really more productive than the labour of the mind. The hand is not more necessary to execute than the head to contrive. All the means by which labour may be facilitated and wealth increased resolve themselves, 1st, into the better division and combination of employment among individuals and nations; and 2d, into the more extensive or more judicious application of capital or stock in industrious undertakings.

The division of employments can only be imperfectly established in rude societies and thinly-peopled countries; but in every state of society—in the rudest as well as the most improved—we may trace its operation and effects. Even in the simplest business this co-operation and subdivision is required; neither hunting nor fishing, any more than agriculture or manufacture, can be advantageously carried on by solitary individuals. As society advances, this division of labour extends itself on all sides; one man becomes a tanner or dresser of skins, another a weaver, a third a smith, and so on. The wealth and comforts of all classes are, in consequence, prodigiously augmented. In countries where the division of labour is carried on to a considerable extent, agriculturists are not obliged to spend their time in clumsy attempts to manufacture their own produce, and manufacturers cease to interest themselves about the raising of corn, and the fattening of cattle. The facility of exchanging is the vivifying principle of industry; it stimulates agriculturists to adopt the best system of cultivation, and to raise the largest crops, because it enables them to exchange whatever portion of the produce of the land exceeds their own wants for other commodities contributing to their comforts and enjoyments, and it stimulates manufacturers and merchants to increase and improve the quantity, variety,

and quality of their goods, that they may thereby obtain greater supplies of raw produce. A spirit of industry is thus universally diffused; and that apathy and languor which characterize a rude state of society entirely disappear.

Besides that sort of division of labour which enables each individual in a united society to confine himself to a particular employment, there is another and most important branch of the division of labour, which not only enables particular individuals, but the inhabitants of entire districts, and even nations, to addict themselves in preference to certain branches of industry. It is on this *territorial division of labour*, as it has been appropriately termed, that the commerce carried on between different districts of the same country, and between different countries, is founded. The variations in the situation, soil, climate, mineral products, &c. of the different districts of an extensive country, render them more suitable for some than for other species of industry. A district where coal is abundant, which has an easy access to the ocean, and a considerable command of internal navigation, is the natural seat of manufactures. Wheat and other species of grain are the proper products of rich arable soils; and cattle, after being reared in mountainous districts, are most advantageously fattened in meadows and low grounds. Nothing can be more obvious than that the inhabitants of these different districts will be able, by confining themselves to those employments, for the prosecution of which they have some peculiar capability, to produce a much greater quantity of useful and desirable articles than they could do were they to engage indiscriminately in every possible employment.

Providence, by giving different soils, climates and natural productions to different countries, has evidently provided for their mutual intercourse and civilization. By permitting the people of each to employ their capital and labour in those departments in which their geographical situation, the physical capacities of the soil, their national character and habits fit them to excel, foreign commerce, or the territorial division of labour, has a wonderful influence in multiplying the products of arts and industry.

Having been led thus far into this fertile subject, I will conclude with some apposite and excellent observations by Dr. Paley:—“Every man has his work. The kind of work varies, and that is all the difference there is. A great deal of labour exists besides that of the hands; many species of industry besides bodily operation, equally necessary, requiring equal assiduity, more attention, more anxiety. It is not true, therefore, that men of elevated stations are exempted from work; it is only true that there is assigned to them work of a different kind: whether more easy or more pleasant may be questioned; but certainly not less wanted, nor less essential to the common good.” (*Brande's Dict. of Lit. and Art.*)

LABOURER. One who is employed in coarse and toilsome work. But, in agriculture, the term is applied to a person who performs the manual or most laborious part of

the business of a farm. The price of labour has at all times varied; and, as the poorer classes feel, with additional rigour, every evil arising from the pressure of the times, different expedients have been devised, with a view to alleviate their burdens, supply their wants, and render them more comfortable. From these investigations, it appears that, in the middle of the 14th century, the usual price of labour was 2*d.* per day, and wheat was sold at from 3*s.* 4*d.* to 4*s.* per quarter. In the middle of the 15th century the pay of a labourer per day was 3*d.*, and wheat cost from 5*s.* to 5*s.* 6*d.* per quarter. In the earlier part of the 16th century the price of labour rose to 3½*d.*, and that of a quarter of wheat to 7*s.* 6*d.* About the middle of the 17th century the pay of a labourer upon an average was (in Essex) 13*d.*, and corn had risen to 40*s.* per quarter. Towards the latter end of the 18th century the daily pay of a labourer was from 14*d.* to 18*d.* in the country, and from 2*s.* to 2*s.* 6*d.* in the metropolis, while the price of wheat was 48*s.* per quarter. The payment of *daily* wages, however, serves but imperfectly to ascertain the *real* price of labour, as a considerable portion of work is performed by the piece, so that a labourer in general earns from 3*d.* to 6*d.* per day more than by the common pay. The curious and philanthropic reader, who feels an interest in this popular inquiry, will be fully gratified by a perusal of Mr. Davies's *Case of Labourers in Husbandry Stated and Considered*, &c. 4to, 1795, p. 200; and Sir F. M. Eden's *State of the Poor*, &c., 3 vols. 4to, 1797. Mrs. Davies Gilbert, of Eastbourne, a lady whose active interest for the prosperity of agriculture, and the improvement of the condition of the labouring poor, may fairly (as has been justly observed) be set as an example for many country gentlemen to follow, urges most strenuously, in many publications (but particularly in the *Quart. Journ. of Agr.* vol. xii. p. 252), the advantages to be derived from manual labour, in preference to horse labour. In England, many benevolent persons of distinguished rank have also recently taken up the cause of the labourer, and formed themselves into a society, very appropriately named "the Labourer's Friend Society." They advocate strongly, and endeavour to promote more generally the system of home colonies for the cultivation of waste land. See ALLOTMENT and SPADE HUSBANDRY, FARM SERVANTS, WORKMEN, &c.

Farm labourers, being the most valuable class of men that a populous country possesses, should have every comfort provided for them that is compatible with their situation, and conformable to the general interest of the community. Their wages ought to be everywhere and at all times sufficient for the maintenance of themselves and families while in health, with a surplus to provide against the day of sickness, without their being under the debasing necessity of making application to their neighbours for relief. Persons so essentially useful to society should not merely support existence, but have the comforts of wholesome habitations, with sufficient spaces of ground to furnish them and their families

with changes of proper vegetable food without much expense.

LACTARY. A milk-house, dairy, or place where milk is kept. The term has been made to designate the whole establishment of a dairy. See DAIRY.

LACTIC ACID. This substance, in the opinion of Berzelius and some other chemists, exists in milk, and in larger proportion when it has become sour; but others imagine that it is the product of its decomposition. It was first recognised as a peculiar acid by Scheele, but he did not obtain it perfectly pure. It was afterwards observed by Berzelius in many animal fluids; and by Braconnet to exist with acetic acid in fermented rice-meal, wheat-paste, the juice of the beet-root, and other vegetable substances: he named it *nancéic acid*. It is formed, also, during the putrefactive process in some animal bodies. Lactic acid is a colourless, inodorous, syrupy liquid, and very sour. It may be so concentrated as to have a specific gravity of 1.215: it attracts moisture from the atmosphere, and dissolves in water and alcohol in all proportions. At 480° Fahrenheit, it is decomposed. When added to boiling milk, it is capable of immediately coagulating about 700 times its weight; but, when cold, it produces comparative little effect upon it: it also coagulates albumen. It has the property of dissolving fresh precipitated phosphate of lime; a property which is of great advantage in the animal economy, and might even be rendered useful in manures. The constituents of the lactic acid are, 6 parts of carbon, 5 of hydrogen, and 5 of oxygen. (*Penny Cyclopædia*, vol. xiii. p. 268.)

LACTOMETER (Lat. *lac*, milk, and *metrum*, a measure). A term applied to a glass tube for ascertaining the proportion which the cream bears to the milk of any particular cow, or the produce of a whole dairy. Lactometers of different kinds have been invented; the best is called "the four or five glass lactometer."

The principle of the instrument is, that if new milk is poured into glass tubes and allowed to remain, the division between the cream, which floats upon the surface of the milk, will be so evident that its depth may be easily measured; and should the milk from any cow produce more cream than that of another, the difference will be seen by the divisions or

marks on the glass tubes. The lactometer consists of 4 or 5 glass tubes, about half an inch diameter, and 11 inches long, fitted into an upright mahogany frame; each tube having a fine line drawn round it 10 inches from the bottom; 3 inches from the line downwards, it is graduated into inches and tenths of inches. At milking time each tube is to be filled up to the line with new milk. After standing 12 hours, the quantity of cream which floats upon the surface is shown by the scale of inches and tenths; each division will therefore represent one per cent. of the whole.

If the milk given by a cow at one meal is 1 gallon, or 8 pints, and the thickness or depth of the cream which floats upon it measures 14 divisions, multiply the number of pints, 8, by the depth of the cream, 14; the result will be that the produce of the cream of that meal is 112, or 1 pint $\frac{12}{100}$. Care must be taken to fill these tubes as soon as the pail is taken from under the cow, for if any delay takes place, some of the cream will have ascended towards the top. The milk should be taken from the middle of the pail, which is to be done by dipping a cream-pot below the froth. (*Journ. Roy. Inst.* vol. iv. p. 157; *Rees's Cyclo.* vol. xx.)

LADIES' FINGER. A name given to the common kidney-vetch (*Anthyllis vulneraria*), which, from its soft and downy nature, was supposed to possess vulnerary properties in stanching the blood of slight wounds. See **KIDNEY-VETCH.**

LADIES' MANTLE (*Alchemilla*). The species of this genus of plants are all astringent in their root, and somewhat mucilaginous. *A. vulgaris* is slightly tonic. Many of them are ornamental, and well adapted for planting in gardens near the front of borders, or for adorning rockwork. They succeed well in any common soil, if not over wet, and may be increased from seeds or divisions. The species indigenous to Britain are—

1. Common ladies' mantle (*A. vulgaris*). A perennial, growing in dry, rather mountainous pastures. The root is woody, with long fibres: stems from 4 to 8 inches high, more or less procumbent, alternately branched, round, hairy, leafy, terminating in numerous little corymbose clusters of green flowers, or smooth, almost capillary stalks. The radical leaves are numerous, on long footstalks, large, roundish, kidney-shaped, bluntly-lobed, plaited, serrated, of a fine green above; soft and hairy beneath. The stem-leaves are of the same form, but a great deal smaller; alternate, on short stalks, with a pair of large notched stipules to each. Horses, sheep, and goats, eat this vegetable; but it is not relished by cattle, and hogs totally refuse it.

2. Alpine ladies' mantle (*A. alpina*). A perennial plant growing on alpine rocks, especially in a micaceous soil. It is rather smaller in habit than the last species, and essentially different, not only in the silvery pubescence of the stalks, flowers, and backs of the leaves, but in the latter being separated to the base into 5 or 6 obovate lobes, closely serrated towards the extremity. Nothing can be more beautiful than the silvery splendour of their under sides, especially in exposed and barren

spots, when the leaves are agitated by the wind. No figure can do them justice. The upper surface is smooth and naked, of a fine green. This species is found on the mountains of New Hampshire.

3. Field ladies' mantle, or parsley piert (*A. arvensis*). This annual species will generally be found in England growing in sandy or gravelly fields, especially when fallow, as well as on heathy banks. The root is small and fibrous; stems numerous, about a finger's length, spreading or prostrate, round, leafy, hardly subdivided. Leaves flat, three-lobed, variously cut on short stalks. The whole plant is more or less hairy, and in flavour and scent approaches its natural ally, burnet. (*Smith's Eng. Flor.* vol. i. p. 223.)

LADIES' SLIPPER (*Cypripedium*, from *Cypris*, one of Venus's names, and *podion*, a slipper; hence the name Venus's or ladies' slipper). The species of this genus are remarkably handsome when in flower, and on that account deserve a place in every collection. They are all of the easiest culture. The hardy species succeed well in peat soil, either kept in a frame, or planted out in a shady border. The species, natives of America, require to be protected from severe frost and rain. The only indigenous species is the common ladies' slipper (*C. calceolus*), which is very rare, growing only in mountainous woods and thickets in the north of England. It is perennial, blowing large yellow, solitary, terminal flowers, without scent, in June. The stems are solid, 12 or 18 inches high, downy, bearing 3 or 4 large alternate, ovate, rather pointed leaves, clasping or sheathing at their base.—(*Eng. Flor.* iv. 51; *Paxton's Bot. Dict.*; see *Darlington's Flor. Cest.* 513.)

LADIES' SMOCK (*Cardamine*). An interesting genus of the simplest culture and propagation, natives of various countries, generally preferring watery situations. The native species are five in number:—

1. Daisy-leaved ladies' smock (*C. bellidifolia*). This perennial species grows in moist, grassy, lofty, alpine pastures. The root is rather woody, divided at the crown. Herb 2 or 3 inches high, unbranched, erect, bright green, smooth leaves, sometimes a little wavy or angular, the uppermost nearly sessile. Flowers few, corymbose, white, appearing in August. Style short, conical.

2. Impatient ladies' smock (*C. impatientis*). This annual species grows in shady, rather moist, rocky situations in the north of England; it is rarely met with in Scotland. The root is small and tapering; the herbage pale green; stem $1\frac{1}{2}$ to 2 feet high; leaves pinnate; leaflets lanceolate, mostly cut; stipules fringed. The flowers, which are numerous, and small, and white, appear in May and June. Pods erect, very slender, composing long clusters, and discharging their seeds with a crackling noise and great force on the slightest touch or concussion, by means of the revolute valves. The whole plant is disagreeably bitterish and pungent.

3. Hairy ladies' smock (*C. hirsuta*). Also annual in habit. This species is found very frequent in waste or cultivated ground, especially in moist, shady places; flowering fro

March to June. The root consists of many white fibres. The herb is variable in size and luxuriance, deep green, more or less hairy, rarely quite smooth; stem from 3 to 12 inches or more in height; leaves pinnate, without stipules; leaflets stalked, roundish, oblong, notched.

4. Meadow ladies' smock (*C. pratensis*). See CUCKOO FLOWER.

5. Bitter ladies' smock (*C. amara*). This is not a common species, but is found occasionally in watery places, by the sides of rivers and brooks. It is perennial, and before it flowers greatly resembles water-cress, but the taste is bitter and nauseous. The root is toothed, somewhat creeping; stems 1 to 2 feet high, more or less hairy, creeping at the base, with several radicles, and sometimes a few slender scions. Leaves pinnate, without stipules; leaflets of the lowermost roundish; of the rest, toothed or angular. Style obliquely elongated. Flowers, which appear in April or May, always white or cream-coloured, with violet anthers. (*Smith's Eng. Flor.* vol. iii. pp. 186—91.)

LADIES' TRACES (*Neottia*, a bird's nest, in allusion to the interwoven fibres of the roots). This is a pretty genus of orchidaceous plants. The hardy species will succeed well in chalky soil, or a mixture of loam, peat, and sand; they are all increased by divisions. (*Puxton's Bot. Dict.*)

There are in Britain only two indigenous species:—

1. Sweet ladies' traces (*N. spiralis*), which grows in open pastures, on a chalky or gravelly soil, or in meadows in various parts of England, flowering in August and September. The leaves are awned, all radical, on broad stalks, spreading, ovate, acute, ribbed, rather glaucous. Stalk a finger's length or more, viscid, and downy upwards, clothed with several sheathing, upright, pointed bractes. Spike spiral, of many crowded small white and highly fragrant flowers, in a single row, each with an ovate, tumid, pointed, downy, close bracte.

2. Proliferous ladies' traces (*N. gemmipara*). This species grows in marshes on the west coast of Ireland, and flowers in July. The root consists of two thick, fleshy, downy, annual, perpendicular knobs, each about 3 inches long, and one-fifth of an inch in diameter near its origin, tapering downwards to a blunt point. After flowering the root decays. Leaves 5 or 6, upright, broadly lanceolate, acute, three-ribbed, 3 inches in length. Foot-stalks broad, sheathing, near an inch long. Stalk erect, 2 inches high, sheathed more than half way up by the foot-stalks of the innermost leaves, and bearing in the upper part 2 or 3 lanceolate, smooth, upright bractes. Spike an inch long, ovate, dense, erect, of about 18 white flowers in 3 rows, twisted round in a very remarkable way, and each accompanied by a smooth, lanceolate bracte, as tall as itself. The outside of the flowers and capsule are downy; every other part of the herb is smooth. Buds destined to flower the following year are formed among the leaves, at the bottom of the flower-stalk. In the spring, each bud puts forth a pair of oblong

knobs and becomes a separate plant. (*Smith's Eng. Flor.* vol. iv. p. 35.)

LADIES' TRACES. Ladies' hair or quaking-grass. See BRIZA MEDIA.

LADDER. A framework of steps between two upright pieces. Ladders of various length are essential requisites on a farm, whether for use in repairs to buildings, for reaching stacks, or in cases of fire.

"Garden ladders are of three kinds: the *common wall tree ladder*, which differs from those used in other arts in having two pieces of 10 or 12 inches in length, projecting at right angles from the upper end, the use of which is to avoid injuring the trees, by keeping the top of the ladder at a small distance from the wall, and thus admit of the operation of nailing. The *orchard ladder* consists of a frame on low wheels, as a basis for several ladders which fit into each other, and are capable of being hoisted up by machinery, so as a person near the extremity of the ladder may have access to any part of a tree with convenience, either to prune it or gather the fruit.

The *three-styled*, *forked*, and *double ladders* are also well adapted for the ordinary purposes of gathering fruit or pruning. The *rule-joint ladder* is used for working on curvilinear roofs either of glass, or domes of lead, stone, &c., which require panes renewed or trees nailed. Such ladders are particularly useful for repairing the roofs of hothouses and greenhouses. The *step-ladder*, instead of round rods on which to place the feet, has steps or boards, an improvement essentially necessary where much work is to be done, because less fatiguing to the feet. Such ladders have a back or fulcrum, by which they stand independently of any other object, and which is removable at leisure by drawing out an iron bolt." (*Loudon's Enc. of Gard.* p. 290.)

LADY BIRDS, or LADY BUGS. Familiar names applied to small hemispherical beetles, scientifically denominated *coccinella*. These little beetles are generally yellow or red, with black spots, or black, with white, red, or yellow spots; there are many kinds of them, and they are very common and plentiful insects, and are generally diffused among plants. They live, both in the perfect and young state, upon plant-lice, and hence their services are very considerable. Their young are small flattened grubs of a bluish or blue-black colour, spotted usually with red or yellow, and furnished with six legs near the forepart of the body. They are hatched from little yellow eggs, laid in clusters among the plant-lice, so that they find themselves at once within reach of their prey, which, from their superior strength, they are enabled to seize and slaughter in great numbers. There are some of these lady-birds, of a very small size, and blackish colour, sparingly clothed with short hairs, and sometimes with a yellow spot at the end of the wing-covers, whose young are clothed with short tufts or flakes of the most delicate white down. These insects belong to the genus *Scymnus*, which means a lion's whelp, and they well merit such a name, for their young, in proportion to their size, are as sanguinary and ferocious as the most savage beast of prey. I have often seen one of these

little tufted animals preying upon the plant-lice, catching and devouring, with the greatest ease, lice nearly as large as its own body, one after another, in rapid succession, without apparently satiating its hunger or diminishing its activity. (*Harris.*) See **APHIS**.

LAIR. Provincially, land in a state of grass or sward. (See **LAY**.) Also employed in some countries, to signify soil and dung. Lair is used sometimes to express the couch or resting-place of a boar or wild beast, or of cows in dairies.

LAMA, or **LLAMA**. See **ALPACA**.

LAMB'S LETTUCE. See **CORN SALAD**.

LAMB'S QUARTERS. A name given to wild or mountain spinach. (*Chenopodium album.*) See **GOOSEFOOT**.

LAMB SKINS (Germ. *Lammfelle*). The value of lamb skins varies according to the fineness, brilliancy, and colour of the wool. Black lamb skins are more generally esteemed than those of any other colour. English lamb skins are seldom to be met with perfectly black; but since the introduction of merino sheep into England, many of the white fleeces have, in point of quality, arrived at a pitch of perfection which justly entitles them to be ranked with some of the best fleeces in Spain. The importation of lamb skins is immense, having amounted on an average in 1831, and 1832, to 2,365,635. Eight-tenths of the whole quantity are supplied by Italy. They are most used in the glove manufacture. (*McCulloch's Com. Dict.*) See **WOOL**.

LAMENESS. In farriery, an affection in the feet or limbs in horses and other animals, by which motion is rendered less perfect. In the horse, it is brought on from various causes—sprains, over-exertion, diseases of the foot, &c. The muscles of the shoulder are occasionally sprained, and in this case the animal cannot lift his foot without great difficulty, indeed he will be observed to drag his toe along the ground. In this case few local measures can be adopted. The horse should be bled from the vein on the inside of the arm, fomentations applied, and a dose of physic given. In this, as in most other cases of lameness, quiet and rest are essential to the restoration of the animal. (*The Horse*, p. 229.)

LAMMAS DAY. In the English calendar, the 1st of August. Dr. Johnson supposes this term to be a corruption of *lattermath*, which signifies a second mowing of grass. Others derive it from a custom which once prevailed in some parts of England, of bringing a lamb alive on this day into the church at *high mass*. Others again derive it from a Saxon term signifying *loaf mass*, so named as a feast of thanksgiving for the first-fruits of the corn. (*Brande's Dict. of Lit. &c.*)

LAMP BLACK. A colouring substance which is in very general use for several purposes. The finest lamp black is produced by collecting the smoke from a lamp with a long wick, which supplies more oil than can be perfectly consumed, or by suffering the flame to play against a metalline cover, which impedes the combustion, not only by carrying off part of the heat, but by obstructing the current of air. Lamp black is prepared, however, in

a much cheaper way for the demands of trade. The dregs which remain after the purification of pitch, or else small pieces of fir wood, are burned in furnaces of a peculiar construction, the smoke of which is made to pass through a long, horizontal flue, terminating in a close boarded chamber. The roof of this chamber is made of coarse cloth, through which the current of air escapes, while the soot remains. (*Ure's Dict.*)

LANCEOLATE. In botany a term used to describe leaves which are oblong and gradually tapering towards each extremity, or shaped like a spear or lance.

LANCEWOOD (*Guatteria*, in honour of J. B. Guatteri, an Italian botanist, and once professor at Parma). This is a splendid genus of evergreen shrubs, succeeding in a mixture of loam, peat, and sand. They are natives of warm climates and require stove culture. Young plants are readily obtained by cuttings raised in sand under a glass in heat. (*Paxton's Bot. Dict.*)

LAND (Germ.), in the widest acceptation of the word, is used to denote the solid matter of which the globe is composed; in contradistinction to the liquid matter or water (see **GEOLOGY**): but in its most restricted signification it is confined to *arable ground*. The latter is the legal meaning of the term; and in this sense it is used in all original writs, and in all court and formal pleadings.

LAND-DITCHING, or hollow draining as it is sometimes termed, is chiefly practised in England in the counties of Essex and Herford. It consists in digging both main and side drains, similar to those generally adopted in draining land: the former are usually made from 22 to 24 inches, the latter from 20 to 22 inches in depth. The soil is previously ploughed, and the length to which the main drains may be protracted without a vent, depends upon the situation of the land. When the land has a regular declivity, the most proper method will be to carry off as much water as possible, by means of side drains; but if the ground be irregular, it will be requisite to form additional main drains, so that every advantage may be derived from the valleys, into which the latter must often be conducted to a considerable extent.

The length of the side drains varies according to the elevation of the soil; in general they need not be more than one rod apart from each other; though in very loose or porous grounds, they may be dug at a distance of one rod and a half. When the trenches are cut to a sufficient depth, they are filled up and covered in the usual manner with straw and bushes. The expense of this method of draining is computed in England to be nearly 3*l.* per acre.

Land-ditching not only carries off the water from wet or marshy soils, but also meliorates stiff loamy clays, which being thus better enabled to resist the long continuance of moisture on their surface during the winter, promote vegetation very early in the spring, and the grass is rendered of a superior quality. The weeds, &c. change their colour, and are totally divested of their rankness; the corn also increases both in quantity and weight. Another important advantage arising from this practice is, that

It will admit of the soil being ploughed at an earlier period of the spring and later in autumn; while it may be tilled with greater facility, and kept clean from weeds at a very small expense.

LANDLORD. One who owns lands or houses, and has tenants under him. See **TENANT, CUSTOMS OF COUNTIES, LEASE, AGREEMENT, &c.**

LANDMARK, signifies in a general sense any thing by which the boundary of a property is defined. In ancient times the correct division of lands was an object of great importance; and various means were adopted to give distinctness and permanency to the boundaries of every man's property. Stones and hillocks were the most usual landmarks. The importance of this subject among the Israelites particularly, may be judged of from the denunciation of Moses, "Cursed be he that removeth his neighbour's landmark."

LANDSCAPE GARDENING. The art of laying out grounds so as to produce the effect of a natural landscape. Its principles are the same as those upon which the landscape painter proceeds in composing a picture; and though it is an art of which, like many others, everybody thinks he is a judge, it requires to be properly practised, and the possession of powers of a much higher order than fall to the lot of most men. Mr. Brown, commonly called Capability Brown, was the first who practised the art in England, so as to render himself worthy of the name of artist. To lay down the principles of this art here would be quite impossible; but this general observation contains the sum of them; let selected and beautiful nature be constantly your model, and success must follow. *Loudon's Enc. of Gardening*, and *Downing's Landscape Gardening*, recently published in New York, may be consulted with advantage by those desirous of practising the art.

LANDSLIP. A portion of land that has slid down in consequence of disturbance by an earthquake, or from being undermined by the action of water or other means.

LAND SPRINGS. Land springs are sources of water which only come into action after heavy rains; while constant springs which derive their supplies from a more abundant source, flow throughout the year. All springs owe their origin to rains. In the case of land springs, the water when it sinks through the surface, is speedily interrupted by a retentive stratum, and there accumulating soon bursts out into a spring, which ceases to flow a short period after the cause which gave it birth has ceased to operate; but the water which supplies constant springs sinks deeper into the earth, and accumulates in rocky or gravelly strata, which become saturated with the fluid.

LAND STEWARD. A person who has the care of a landed estate, and whose duties vary in different countries, according to the mode in which landed property is managed. In England, where the landlord very commonly undertakes to keep the buildings and fences of his tenants in repair, the duties of the land steward are constant and multifarious; while in Scotland, where the buildings and fences are kept in repair by the tenant, the duties of the steward are limited to receiving the rents, and see-

ing that the covenants of the leases are duly fulfilled. In many parts of the Continent, and particularly in Italy, where the landlord is a partner with his tenant, and shares the produce with him, the duties of the land steward or *fattore*, as he is there called, are much more onerous than in Britain. See **BAILIFF.**

LAND TAX. In England, a branch of the public revenue, which was first raised in its present form in 1692. The rate at which this tax is charged is 4s. in the pound on the annual value. The amount which it yielded to the exchequer in 1837 was 1,192,635*l.* (*Penny Cyclo.* vol. xiii. p. 300.)

LARCH TREE (Lat. *larix*; It. and Span. *larice*). The larch is one of the most valuable exotics which has been introduced into Britain. In the north of Scotland it has been grown to a great extent, cultivated with particular attention; and found to be one of the most profitable of all trees to the planter, provided the land be well drained, but it will not succeed in swampy situations. It grows with great rapidity, is subject to very few accidents, transplants with but little risk, and produces timber of great excellence and value, not only for domestic but for naval purposes.

In bridges, dock-gates, mill work, and especially in mill axles (where oak only used formerly to be employed), larch has been substituted with the best effect. The small larch is useful for agricultural implements, gates, upright palings, rails, and hurdles. Boats built of larch have been found sound when the ribs made of oak 40 years old were decayed. A fine frigate of 36 guns, named the Atholl, was launched at Woolwich in 1820, built entirely of larch, the growth of the Atholl plantations. It is also very useful for staves for casks.

1. The common larch fir or white larch (*Abies larix*). The leaves of all the species are clustered, and deciduous. The cones vary: in the common larch they are ovate, oblong, blunt; and the flowers are pink. In mountainous districts in Scotland the Duke of Atholl planted this species in immense quantities, having had nearly 9000 acres in cultivation with the larch alone. We are told by Dr. Anderson that his grace planted 200,000 every year; and in the winter of 1819 and the following spring no less than 1,102,367 were planted on 556 acres, at 2000 per Scotch acre. The late Earl of Fife also planted 181,813 in Morayshire. Goodwood, the property of the Duke of Richmond, was probably the first place at which the larch was planted as a forest tree, and even there it was only in small numbers. A few years after, viz. in 1738, it was introduced into Scotland by a Mr. Menzies. About 1740, James, Duke of Atholl, commenced planting larches around Dunkeld House and Atholl House, the two residences of his grace; and great attention having been paid to these nurseries by his grace's successors, the plantations have amazingly increased. A very detailed account of the plantations on the Atholl estates, and experiments on the wood, will be found in the 3d vol. of the *Prize Essays* of the Highland Society, p. 165, drawn up from papers and documents communicated by his grace's trustees. In a communication to the

Board of Agriculture in February, 1812 (vol. vii. p. 273), the Duke of Atholl, speaking of the advantages to be derived from a more general culture of the larch, says, "The lower range of the Grampian Hills, which extend to Dunkeld, are in altitude from 1000 to 1200 feet above the level of the sea; they are in general barren, and are composed of mountain schist, slate, and iron-stone. Up to the highest tops of these, larch grow luxuriantly, where the Scotch fir, formerly considered the hardiest tree of the north, cannot rear its head. In considerable tracts, where fragments of shivered rocks are strewn so thick that vegetation scarcely meets the eye, the larch puts out as strong and vigorous shoots as are to be found in the valleys below, or in the most sheltered situation." And it further appears from a report of that nobleman to the Horticultural Society (*Trans.* vol. iv. p. 416), that in situations 1500 to 1600 feet above the level of the sea, he has felled trees 80 years old that have each yielded six loads of the finest timber. The growth of larch is not, however, confined to Scotland; but much land has been planted in the northern counties of England. The Society in London for the Encouragement of Arts and Manufactures, so long ago as 1783, offered premiums for the planting of larch. A gold medal was offered to those who should plant within any one year 5000 larches from two to four years old at a distance of 5 feet asunder; and a silver medal to any one who should plant 3000 larches at the same distance. This premium only contemplated making plantations solely of the larch. The first claimant for the premium was the Bishop of Llandaff, who had by that time planted 48,500 larches on 18 acres of the high grounds near Amble-side in Westmoreland, at a distance of 4 feet from one another. Immense numbers continued to be planted annually up to the year 1805, from which year to 1816, no candidates appeared to claim the premium, in consequence of the severe blight which affected the larch trees in England for some years; and which preventing the formation of the cones, deprived the growers of larch plants of the usual supply of seed.

There is no account given of the height at which these larches were planted. Had they been placed at a considerable elevation above the level of the sea, they would have probably escaped the contagion of the blight. In the account of the Dunkeld larch plantations, the late Duke of Atholl conceived that he had introduced three great improvements in the planting of the larch, when it was to be raised for useful timber. These improvements were the planting it at a high elevation on the mountain side, in a region in which no other kind of timber tree would grow to perfection in this country; the inserting the tree in the soil at an early age, not exceeding two years old in the seed-bed; and the notching the small plants into the ground by a peculiar instrument at wide intervals, not nearer than $5\frac{1}{2}$ feet to each other; for, if planted close, they exhaust the soil, and prevent its being nourished by the annual deposition of spines, on account of the closeness of the trees.

In 1820 the gold medal was awarded to the Duke of Devonshire for planting 1,981,065 forest trees, 980,129 of which were larch. Besides these instances of the planting the larch *alone*, there are many others in England in which they were planted along with other trees; but as they would probably be so planted merely as nurses to the hard timber, such plantations cannot be considered as interesting experiments, in regard to the value of the larch as timber. From the foregoing details, however, we find that, mainly under the auspices of the Society for the encouragement of Arts and Manufactures, 1,407,036 larches were planted in England in 37 years. It is singular that so much elevated barren land in the counties of Hants, Sussex, and Kent should be suffered to remain unplanted with this and other timber, which would find a ready sale in the neighbouring government yards.

Plantations that are formed *exclusively* of larch destroy the heath and all other vegetables; but after a few years a fine grass springs up which is so valuable for grazing, that it has been let from 10s. to 5l. per acre for this purpose, which, previously to its being planted, would not bring as many pence.

Three varieties of the common larch are mentioned by botanical writers; one remarkable for the young cones being pale green instead of crimson, and erect, not drooping. A second has a weeping habit, with pendulous branches, but is distinct in botanic characters from the black larch (*Laryx pendula*) of North America; both these varieties are natives of the Tyrol. The third sort is of a slow, stunted growth, and an inelegant appearance, leafing early, and very subject to injury from spring frosts. The bark is cinereous, not yellowish brown. It was raised by the Duke of Atholl from seed, procured at Archangel in 1806. Both in its appearance as a tree, and its value as timber, this Russian larch is much inferior to the common larch. From the boiled inner bark, mixed with rye flour, and afterwards buried a few hours in the snow, the hardy Siberian hunters prepare a sort of leaven, with which they supply the place of common leaven when the latter is destroyed, as it frequently is by the intense cold to which hunters are subject in the pursuit of game. The bark of the larch is nearly as valuable to the tanner as oak bark; this valuable property was first discovered by Mr. T. White in 1812. (*Com. to Board of Agr.* vol. vii. p. 278.) The larch also produces the substance called Venice turpentine, which is of considerable use in medicine, and flows in abundance when the lower part of the trunk of old trees is wounded or tapped between the months of March and September. When forests of larch in Russia take fire, which sometimes happens, a gum issues from the medullary part of the trunks, during the combustion, which is called *Orenburgh gum*. A saccharine matter, also, resembling *manna*, and called *manna of Briunçon*, exudes from the larch in June; and another sort of manna is exuded from its leaves in the form of a white, flocculent substance, which finally becomes concreted into small lumps. From the inner rind or bark of the larch the Russians manufacture

fine white gloves, not inferior to those made of the most delicate chamois, while they are stronger, cooler, and more pleasant for wearing in the summer.

The larch is propagated by seed, which is generally ripe in September and December, when the cones may be collected and carefully dried, and put away till April, which is considered the best time for sowing. The most proper season for felling the larch is July.

2. The red larch fir (*A. microcarpa*). In this species the cones are oblong, small, thin; scales erect, close pressed, the upper ones much smaller than the lower. It is a graceful tree, with much of the habit of the common larch, from which, however, its very small cones, of a bright purple, readily distinguish it. It is a native of North America. This is by no means so well adapted to the planter's purposes as the common larch. According to the Duke of Atholl, trees when 50 years old do not contain one-third as many cubic feet as the common larch. The wood is so heavy that it will scarcely swim in water.

3. The black larch fir (*A. pendula*). Cones oblong, with numerous spreading scales, which gradually diminish from the base to the apex of the cones. Branches weak and drooping. The leading shoot will often begin to droop at the height of 15 or 20 feet from the ground, and after gradually acquiring a horizontal direction, will bend towards the earth, so as to form a natural arch of great beauty. This species is also a native of North America, where it is found growing on a rich clay soil, mixed with sand, in cold, mountainous districts. When cultivated in Britain it is an elegant tree, having a good deal of resemblance to the common larch, but being of a brighter green colour, and much more graceful. The wood is less valuable than the common larch.

There is a report (*Trans. High. Soc.* vol. v. p. 391), by Mr. Lawson on larches raised by him from seed imported from the Tyrol, which being the native country of the larch, is supposed to mature the most perfect seed.

The larch is affected with many diseases in Britain. Some of these have been supposed to arise from a constitutional weakness engendered in the tree from the seed not having been perfectly ripened. The reader's attention may be drawn to several valuable treatises on the diseases of the larch, distributed through the volumes of the *Trans. of the High. Soc. of Scotland*, &c. In the *Quart. Journ. of Agr.* there are also some able papers, "On the probable Cause of the Diseases of the Larch in Great Britain," by the late M. Decandolle (vol. v. p. 403); "On the Diseases of the Larch in the South of Scotland," by Mr. Webster (*Ibid.* p. 535); "On the Rot in Larch," by Mr. Gorrie (*Ibid.* p. 537); and some remarks on the foregoing papers (*Ibid.* p. 574); "On the Canker in Larch," by Mr. Drummond, vol. ii. p. 221. (*Penny Cyclo.* vol. i.; *Quart. Journ. of Agr.* vol. iii. p. 794; *Brit. Husb.* vol. iii.) See **CANKER**, **FIRS**, and **PINLS**.

LARCH, AMERICAN. See **HACKMATAK**.

LARD. The melted fat of the hog, which is much used for domestic purposes and in cookery, for ointments, pomatums, and other pur-

poses. Pure lard has little or no taste, and no odour; its melting point is about 97° Fahrenheit. When long exposed to the air it attracts oxygen, and becomes rancid; whilst a portion of carbonic acid is evolved. Lard is a compound of a solid, firm fat, *stearine*, and a semi-fluid substance termed *elaine*, in the proportion of 38 of the former to 62 of the latter.

Most fats and oils, whether of animal or vegetable origin, are composed of these two ingredients, upon the relative proportion of which their consistence respectively depends. They may be obtained separate by the action of boiling alcohol, which on cooling deposits the *stearine*, and yields the *elaine* upon evaporation. Another method is to compress fat, or oil congealed by cold, within the folds of bibulous paper. The *elaine* is absorbed by the paper, and may be separated by compression under water; the *stearine* remains.

Elaine resembles oil in appearance, is colourless when pure, congeals at 20° Fahrenheit, may be evaporated unchanged *in vacuo*, has little odour and a sweetish taste, is insoluble in water, but soluble in boiling alcohol, and consists of carbon, oxygen, and hydrogen.

Stearine is white, concrete, fusible at 111° Fahrenheit, volatilizable unchanged *in vacuo*, partly volatilized and partly decomposed when heated in a retort, insipid, inodorous, slightly soluble in alcohol, insoluble in water, and composed, like the former principle, of carbon, hydrogen, and oxygen.

Exposed to the air, lard absorbs oxygen and becomes rancid. It should therefore be kept in well-closed vessels, or procured fresh when wanted for use. In the rancid state it is irritating to the skin, and sometimes exercises an injurious reaction on substances mixed with it. Lard should never be used when it becomes rancid. See **FAT** and **ADERS**.

LARD OIL. In the United States, where swine are raised so abundantly, oil is now very extensively separated from lard. Its close connection with the question of disposing of the agricultural products of the Union, and especially of the Western States, forms a reason for giving it an extended consideration. Several large factories for the manufacture of this oil have been some time in operation in Cincinnati, and thousands of gallons are daily prepared for home consumption and exportation. It is also carried on at Cleveland, Ohio; Chicago, Illinois; Burlington, Iowa; Hannibal, Missouri; and other places both in the Western and the Atlantic States.

It is considered much superior to olive or sperm oil for machinery and for the manufacture of woollens, &c. It can be furnished also at half the price, and therefore it will doubtless supersede that article of import. As it contains less *stearine* than other oils, it is found much better for combing wool, for which purpose a single factory wished to contract for 10,000 gallons from one establishment. It is also undergoing trial in England; and, if it succeeds, of which there can scarcely be a doubt, large orders for it may be expected, or at least the American lard itself, which pays a less duty, will find a ready market.

Repeated experiments have shown that for

the purpose of combustion, no oil is superior. It is important, in trying it with this view, to obtain a good article, manufactured from good lard, and not from the dark-burned, which creates smoke and clogs the flame. For want of sufficient care in this respect, some have no doubt met with disappointment in their attempts to substitute this oil for sperm oil in their lamps.

The following are given as the relative constituents of lard oil and sperm oil, in 100 parts of either:—

	Carbon.	Hydrogen.	Oxygen.
Lard oil	79.03	11.422	9.548
Sperm oil	79.05	11.6	8.9

It will thus be seen that the difference in carbon is only 3.00; about the same in hydrogen; while in oxygen it is about 4.10 in favour of the lard oil. The large quantity of carbon proves that it may be relied on as a material for giving light, as it is well known that whenever carbon predominates in an animal oil, the article is capable of a high degree of luminous power. Experiments have been made which have shown results in favour of lard oil. About 60 lbs. in 100 of good lard, in tallow only 28 is oil; and the processes of manufacture resorted to show that it may be made a profitable business. Large orders have already been executed at the West for this oil, to be used in the Eastern States. The heat of lard oil for the blow-pipe has been found to be much greater than that of sperm. Lard itself melts at 82° to 97° of Fahrenheit; its specific gravity at 60° is 0.939. Lard crystallizes in small globules; sperm in flakes or scales. It is soluble in boiling alcohol. The proportion is 80 gallons of lard to 1 of alcohol. The application of stearine for candles promises greatly to reduce the price of that article, so that candles equal to spermaceti may eventually be reduced to 12½ cents per pound.

As the capillary attraction of the lard oil is not so great as that of sperm, it is recommended that the form of the lamp should be such as to bring the bulk of the oil as near to the point of combustion as possible.

It is also recommended that the tube should be filed thinner at the top where the wick is inserted, to prevent the escape of heat. Various lamps have been constructed for burning lard as well as lard oil, which have been found to answer very well. The burning of this oil has been introduced with entire success into the light-houses on Lake Erie. An objection has been made against lard oil, that it is not capable of being preserved in a liquid state in cold weather; but by a process similar to that by which the winter sperm is prepared, lard oil can be made which will not chill at 30° of Fahrenheit.

The importance of this application of lard can scarcely yet be realized. Vast quantities of the oil can be manufactured at the West. Indeed, there is hardly any assignable limit to the power of production of the article, so that, while the demand continues, the business may be conducted profitably. The immense herds of swine which can be suffered to range over the lands adapted to them, and gather their food from mast as well as the surplus of corn, wheat, potatoes, &c., on which they may be

sustained, admit of the manufacture being carried on to almost any extent.

The proportion of lard to the whole hog is about 60 per cent., after taking out the hams and shoulders, or taking out the hams only; the estimate for hogs of the best breeds, and so fed as to produce the greatest quantity of fat, is 70 per cent. As the object is not in this case to make pork for food, the objection against those species of nuts, and other modes of feeding which render the animal more gross and oily, is obviated; and it has been proposed to feed out oil-cake to swine, to increase the proportion of oil.

By a new process of steaming, a very simple method described by Mr. Stafford, it appears that the whole of the lard or oily matter in the hog, or of tallow in cattle, may be obtained; while the danger of burning (common in other modes) is avoided, the consumption of fuel lessened, and the degree of pressure required not so great as otherwise. It will be recollected that, while conducting the manufacture of lard, the other parts of the animal, as the hams and shoulders, may be turned to profit. Besides these, also, the hides may be tanned by a cheap process; and the bones, which are worth half a cent per pound, may be calcined and made into animal carbon, for which they are said to be worth, in this calcined state, 2½ cents per pound. (*Ellsworth's Report.*)

LARKSPUR (*Delphinium*, from *delphin*, a dolphin, in reference to the supposed resemblance in the nectary of the plant to the imaginary figures of the dolphin). All the species of larkspur are showy, and valuable as border flowers, especially *D. ajacis* and *D. consolida*, both of which are universally grown among the border annuals. The herbaceous and perennial kinds are increased by divisions or seeds, and the annual and biennial kinds merely require sowing in the open border, where they will flower and seed freely. The field larkspur (*D. consolida*), grows wild in sandy or chalky corn-fields in England, and is regarded as a simple astringent. In gardens this species is called the branching larkspur, and attains the height of 3 or 4 feet, blowing vivid blue flowers.

D. Grandiflorum is a hardy and beautiful perennial, blowing dark blue flowers in July and August. It loves a dry soil, and open situation.

The bee larkspur is a beautiful perennial, blowing bright blue flowers in July and August. Sheep and goats eat the wild larkspur, horses do not relish it, while cows and swine totally refuse it. Bees are remarkably attached to its flowers, which are likewise gathered by the country people of Germany, cut small and mixed with tobacco, to improve its flavour.

LARVA (Lat. a mask). A term applied to that state, in which an insect exists, immediately after its exclusion from the egg, and which precedes the pupa state. The animals commonly called *grubs*, *maggots*, and *caterpillars*, are larvæ. Grub appears to be a general term analogous to larva; the term maggot is most generally applied to the larva state of dipterous insects; and caterpillar, in the most common acceptance of the term, is used to de-

signate the larva state of lepidopterous insects. These terms, however, are used in a very vague manner. (*Penny Cyclo.* vol. xiii. p. 338.)

LAST. An uncertain quantity, varying in different countries, and with respect to various articles. The following quantities of different commodities generally make a last:—12 dozen of hides or skins; 12 barrels of meal; 10½ qrs. of cole seed; 10 qrs. of corn or rape seed (in some parts of England 21 qrs. of corn go to a last); 12 sacks of wool, 1700 lbs. of feathers or flax. (*M'Culloch's Com. Dict.*)

LATHYRUS (from *la*, augmentative, and *thouros*, any thing exciting, in allusion to the medicinal qualities of the seeds). This genus belongs to the natural order Legumineæ. It consists for the most part of very handsome plants when in flower, well adapted for arbours or shrubberies, where they must be supplied with branches to support them, as they climb by means of tendrils terminating the footstalk, and sometimes without tendrils. Any common soil suits them; they are increased by seeds, and some of the perennial kinds by dividing the roots.

The yellow vetchling (*L. aphaca*) is an annual, flowering in June. The plant is glaucous, without any true leaves or leaflets, except near the root. The flowers are solitary on long stalks, small, drooping, lemon-coloured. The pod is an inch in length, nearly cylindrical, smooth, and containing six seeds, which produce intense headache if eaten in any quantity, while the roots of *L. tuberosus* are said to be wholesome food. (*Paxton's Bot. Dict.*) See **VETCHLING**.

Crimson vetch (*L. nissolia*) is also an annual, flowering in May. It is destitute of tendrils, it has a grass-like form, and bears beautiful crimson flowers, variegated with purple and white. The pod is long and the seeds numerous.

There are five other species of lathyrus: namely, *L. hirsutus*, *L. pratensis*, *L. sylvestris*, *L. palustris*, and *L. latifolius*, which is the only one of importance as a garden flower.

Broad-leaved, everlasting pea (*L. latifolius*) is a perennial, flowering in July and August. The herb is glaucous, the stem winged, the leaflets broadly elliptical, bluntish, three or five ribbed, and the tendrils in five branches. The stipules are ovate in their upper part, and broader than the stem. The flowers are large, handsome, of a fine rose colour, and in tufts of five or ten. The legume is long, compressed, and narrow. It is one of the most showy of the herbaceous species of the pea tribe; and well adapted as an ornament to cottages.

Several American species of lathyrus are enumerated by Nuttall, among which are, *L. myrtifolius* found near Philadelphia. *L. venosus*, with about five pair of leaflets. This grows on the declivities of shady hills, and is common in the Alleghany mountains. *L. polymorphus*, with naked quadrangular stems, and four or five pair of leaflets. This is found on the grassy alluvial plains of the Missouri from its confluence to its sources. The flowers are as large as those of the *Pisum maritimum*, and of a fine purple, variable however in size. (*Nuttall's Genera.*) See **EVERLASTING PEA**.

LAUREL (from the Celtic word *blaur* the *b* is dropped, signifying green, in allusion to the foliage of the plants). This is a very handsome and interesting genus of plants: among the most interesting and valuable of the hardy kinds, is the bay tree (*L. nobilis*), which is injured by severe frost. (See **BAY TREE**.) *L. benzoin*, *L. sassafras*, and several others are deciduous, and in some situations attain a great size. They may be increased by layers or cuttings of the roots. The bark of *L. benzoin* or *spice wood* is stimulant and tonic, and in North America it is used in intermittent fevers. In the *L. fatens*, an acrid red or violet juice is particularly abundant. All the species are more or less aromatic and stomachic.

The Portugal laurel (*Prunus lusitanica*), is a beautiful evergreen, which grows from 10 to 15 feet high, blowing handsome spikes of white flowers in June and July. It forms a round head, and is very ornamental upon lawns.

The Alexandrian laurel (*Ruscus racemosus*) is a dwarf evergreen shrub, growing about two feet high, and blowing a yellow flower, succeeded by beautiful red berries. See **KALMIA**, **CHERRY LAUREL**, and **SPURGE LAUREL**.

LAURESTINE, *Lauristinus*, or *Wild Bay* (*Viburnum tinus*, said to be derived from *vico*, to tie; because of the pliability of some of the branches). All the species of *viburnum* are very elegant, rather early-flowering shrubs. The hardy kinds are well fitted for planting in ornamental shrubberies. They are increased by layers or by cuttings planted under a glass in a shady situation. The berries are violently purging, but become eatable after fermentation, and are made into a sort of cake by the North American Indians. See **GUELDER ROSE**.

LARUS (*Sassafras*, *spicewood*, &c.). This extensive genus of shrubs and small trees, which afford the cinnamon, the cassia, and the camphor of commerce, is for the most part confined to the tropical and temperate latitudes. One species (*L. nobilis*) is found in Europe; five in Japan; India affords three of the most important species, long celebrated as spices; in the Canary islands there are two, the tropical regions of America afford no less than 21, amongst the most remarkable of which is *L. caustica* of Chili, being poisonous, and the *L. Persea*, called avocado, and alligator-pear, producing a large and very grateful fruit formed like a pear.

In the Southern States two species are found, one called *L. catesbæi*, and the other *L. Carolinensis*, or Red Bay. This last, which flowers in July, Mr. Nuttall says he has met with as far north as Sussex county, in the state of Delaware. The whole plant is aromatic. See **SASSAFRASS**, **RED BAY**, **CAMPHOR TREE**, **SPICEWOOD**, &c.

LAVA. The substances which flow in a melted state from a volcano. They vary considerably in texture and composition.

LAVENDER (*Lavandula*, from *lavo*, to wash, in allusion to the use formerly made of its distilled water in baths, on account of its fragrance). The hardy kinds are the only plants of this genus worth cultivating.

Common garden lavender (*L. vera*) is well

known and much esteemed for the fragrance of its flowers, and the volatile oil which they yield by distillation with water. It is cultivated in great abundance for the London market, at Mitcham in Surrey. A very poor and light gravelly soil is best suited to this plant, being in such more fragrant, longer lived, and more capable of enduring severe weather than in a rich soil. In rich or moist soils it grows luxuriantly, but is in general destroyed during the winter. The situation cannot be too open. It is propagated by slips and cuttings of the current year's shoots, which may be planted in May and June, as well as by cuttings of those which are a year old; these are to be planted in March, April, and early in May. Both slips and cuttings must be from five to seven inches in length, these, after being stripped to half their length of the lower leaves, are to be planted to that depth either in a shady border, or in any compartment, to have the shade of a mat during mid-day until they have taken root, in rows six inches apart each way. Water must be given in moderate quantity every evening until fully established.

Having attained sufficient strength, they may be moved to their final stations in September or October, which is the season to be preferred if the soil is not light and dry on which they have been raised; or they may be left until the succeeding spring. If it is grown in considerable quantity for medicinal purposes, which is the only claim it has to a place in the herbary, it must be planted in rows two feet apart each way, otherwise, only detached plants are inserted along the borders. The only after-culture required is the occasional employment of the hoe, the decayed spikes and branches being removed in autumn, and the surface gently stirred with the spade in the spring.

The flowers are ready for gathering either to dry or for distillation, in July or the end of June. The flowers are used as excitants and carminatives in medicine, in the form of tinctures. The oil is an agreeable perfume, and one or two drops rubbed up with sugar and mixed in water forms a useful draught in nervous headache and hysteria.

LAVENDER, SEA. See **THRIFT.**

LAWN. A space of ground covered with grass, kept short by mowing, and generally situated in front of a house or mansion, or within the view from such. Lawns, when once established, require only to be kept neat by the ordinary routine of rolling, mowing, and sweeping, except keeping the surface perfectly even, by making up small hollows with screened mould early in spring. When lawns become worn out, a top dressing of any finely divided manure will refresh them; malt dust applied in October is excellent for this purpose; and at the same time an additional quantity of grass seed may be sown.

LAY. A term applied to land in the state of grass or sward. This kind of ground is frequently distinguished into such as has been long in the state of sward, and such as is newly laid down to grass, or into old and new lays. The proper method of managing the latter is of great importance to the farmer, and which Young thought should be by keeping them per-

fectly free from stock for the following autumn and winter after their being laid down, when, in the spring, they will afford a growth of young grass highly valuable for sheep, with which they should only be well stocked, and kept down then, and during the following summer. Nothing, in his opinion, being more pernicious than mowing a new lay, as directed by certain authors. They may, he thinks, have succeeded in spite of such bad management, but never by it.

LAYERING. In gardening, an operation by which the propagation of plants is effected by laying down or bending the shoot, so that a portion of it may be covered with earth. A shoot so operated on is called a *layer*, and the point which furnishes the layers bears the name of *stock*. Some plants are so much disposed to emit roots that if their branches happen to come in contact with the earth they immediately begin to strike. Plants so situated as to render it impossible to bend their branches to the ground, may nevertheless be layered by having their shoots introduced into a pot or box of soil elevated to them, and supported in a convenient position. This is a common practice among the Chinese who cause branches of trees to root in this manner by partially ringing them, and covering their parts so ringed with a ball of clay, which is kept moist. (*Penny Cyclo.*)

LEADWORT (*Plumbago*; from *plumbum*, lead). A genus of pretty free-flowering plants, growing in any common soil, and increased readily by cuttings. The root of *P. europæa*, it is said, when chewed, will cure the toothache.

LEAF (Sax.). The well-known fine membranous part of a tree or plant, which is put forth and unfolded in the spring, and which in some trees falls off in the autumn. "The leaf," says a writer in the *Penny Cyclopædia*, "is an expansion of the bark of a plant, from whose axil a leaf-bud is developed: but this opinion is hypothetical. The leaf is usually thin, and traversed with one or more veins, composed of woody and vascular tissue; sometimes it is fleshy, and occasionally cylindrical, or nearly so." The functions of the leaf being at once that of respiration, digestion, and nutrition, its surface is covered with stomata, or breathing pores, which communicate with minute hollow chambers in its interior. It is in the leaf that all the peculiar secretions of a plant are prepared out of the under sap which the roots obtain from the soil, and which, carried up to the leaves, is exposed to the air, and undergoes the action of the vital chemistry which converts it into the proper juice. It is then returned to the stem, and forms the different secretions of the plant, as resin, starch, sugar, gum, &c. A leaf is either united to the stem by means of a petiole, or stalk, or it is sessile—that is to say, seated on the branch without an intermediate stalk; the veins pass through the petiole before they can expand into the broad or green part forming the blade of the leaf. Some leaves are furnished with an appendage, which in grasses is a thin membranous body arising from the base of the lamina, and in palms is a coarse net, formed, it is said, of tissue belonging to the veins of the leaves. When leaves

have but one blade, they are simple, as in the apple; but when there is more than one blade, each seated on a ramification of the petiole, a leaf is called compound. Of these, and of the external form of the leaf, there are endless modifications. Between 200 and 300 are enumerated by Bischoff.

The distinction of leaves made by those who have written on botany are the following: a simple leaf is that which is not divided to the middle. A compound leaf is divided into several parts, each resembling a simple leaf, as in liquorice, &c. A digitate leaf is a leaf divided into several parts, all of which meet together at the base, as in hemp, black hellebore, &c. A trifoliolate leaf is a compound leaf, consisting of three leaflets, as the trefoil, &c. A quinquefoliate leaf is a leaf consisting of five leaflets, as in *Hedera quinquefolia*. A pinnated leaf is a compound leaf divided into several parts, each of which is called a leaflet, placed along a middle axis, either alternately or by pairs. When the axis is terminated by an odd leaflet, it is said to be unequally pinnated; and equally pinnated when it is not terminated by an odd leaflet, as in the cassia; when the leaflets are all nearly of the same form and bigness, it is called an uniform pinnated leaf, as in the liquorice; when they are not so, it is said to be difform, as in the agrimony. A winged leaf is a pinnated leaf, with an intervening membrane. A ramose leaf is that which is still farther divided than the pinnated leaf, as in the osmund royal, female fern, &c. An entire leaf or lobe is that which has no division on its edges, as in the apple-tree, &c. A sinuated leaf is that which is cut about the edges into several long segments, as in common mallows. A serrated leaf is that which is cut about the edges into several acute segments, resembling the teeth of a saw, as in the nettle, &c. A crenate leaf is that which is cut on the edges into several obtuse segments, as in betony, &c. A lacinated or jagged leaf is that which is cut on the edges into several pretty deep portions in an irregular manner, as in the horned poppy, &c.

All the experiments which have been made, in order to show how serviceable the leaves of trees and plants are to their well-being, have proved that when the plants have been divested of their leaves, or their leaves have been eaten or cut during their growth, they have been remarkably weakened or destroyed. If the leaves of plants be the means by which their juices are prepared for their support, as has been just stated, it should teach us not to pull or cut off the leaves of trees or plants on any account, while they retain their verdure, and are in health, as they may be greatly injured thereby. Hence, probably, the error of the common practice of feeding down wheat in the winter and spring with sheep, as, by so doing, the stalks may in many cases be rendered weak, and the ears shorter, the grains of corn not being so plump and well nourished as when it is not fed down upon the ground. It is well known, too, that in grass which is often mowed, the blades are rendered finer in proportion to the frequency of mowing; so that, though this may be a desirable thing in lawns,

&c., where regard is had to the produce, it should certainly be avoided.

The leaves of trees or plants, where they can be collected in large quantities, as in parks and woods, may be highly useful in augmenting the manure heaps of the farm.

Mr. Young, in his Calendar, recommends that, in wooded countries, all the leaves that can be had at little expense, should be raked up in October, and carted to the yards and standing folds, for littering and making them into dung: he did it, he said, at 3*d.* per one-horse cart load. They do not rot easily, but that is, he thinks, no objection to them; they are a sponge to be saturated with urine, and if not touched previously to carting on to the land, will convey to the field much of what might otherwise be lost; and they are extremely useful in aiding the main object of bedding the yards in the autumn and winter season.— See BOTANY.

LEAF-BUDS. Rudiments of young branches, made up of scales imbricated over each other, the outermost being the hardest and thickest, and surrounding a minute axis, which is in direct communication with the woods and cellular tissue of the stem. When stimulated by light and heat they extend into branches; or if artificially removed from the plant that bears them, they are capable of multiplying the individual from which they have been taken. In this case, however, the individual is not a progeny as from seed, but merely an extension of the parent.

LEAFLET. A part of a compound leaf, or a small leaf formed on the petiole of a leaf branching out.

LEAGUE. A measure of length, principally used in reckoning distances at sea. The sea league is 3 nautical or geographical miles, or the 1-20th of a degree, and consequently about 3.45 English miles. The common land-league is a well-known itinerary measure on the continent of Europe, chiefly in France. The French, however, have two distinct leagues; the legal posting league, containing 2000 toises, and equal to 2.42 English miles, and a league of 25 to the degree, or equal to about 2.76 English miles.

The word is said to have been derived from the Celtic *leach*, stone; the distances having been marked by stones in the Roman provinces. See MILE.

LEOPARD'S BANE (*Doronicum*). An ornamental genus, and from the plants flowering early in spring, they are well deserving of cultivation; they grow in any garden soil, and may be increased with facility by dividing at the root.

The great leopard's bane (*D. pardalianchis*), is a perennial, native of Great Britain, growing in mountainous pastures or meadows. The root is creeping, and consists of several knobs connected by long fibres; woody at the crown. The stem is 2 or 3 feet high, hollow, round, leafy, and hairy; branched, and glutinous at the upper part. The leaves are rather soft and downy, heart-shaped, more or less regularly toothed, or wiry. The flowers, which appear in May, are solitary at the ends of the branches; 2 inches wide, of a uniform bright yellow; the

earliest overtopped by succeeding ones. The roots are aromatic, and used by sportsmen in Alpine countries against giddiness.

LEASE (from *locatio*, letting, or *dimissio*; from the French *laisser*, i. e. *dimittere*, to depart with). "A lease," says Woodfall, in his *Law of Landlord and Tenant*, "is a contract for the possession and profits of lands and tenements on the one side, and a recompense of rent or other income on the other; or it is a conveyance of lands and tenements to a person for life, or years, or at will, in consideration of a return of rent or other recompense. The party letting the land is called the lessor or landlord, and the party to whom the lease is made the lessee or tenant. The connection between landlord and tenant has gradually improved from that of master and slave into a state of almost total independence and mutual interest in the soil.

"The beneficial effects, both to the landlord and tenant, of leases of a sufficient duration to encourage men of capital and skill to properly cultivate the land need hardly be pointed out. And it will be very desirable to have as few restraining covenants introduced into these as possible. They merely retard and annoy the good farmer, and rarely improve the practice of the unskilful.

"In the northern part of England, custom and expediency have very generally fixed the duration of the lease at about 20 years. Experience will evince that the time is not always more than enough to allow the possessor of the land to conduct and mature a profitable system of management, and to pay to the owner an adequate rent. All the great operations of the husbandman have a prospective result as regards the profit to be derived. The capital expended in such cases is only to be drawn back by periodical returns after the lapse of time. In the providing of extraneous manures, in the adoption of rotations of crops, which, to be effectual to the purposes intended, must be extended through many seasons, in the draining of the land, and the like, time is necessary, both to effect the operations, and to recover with a future profit the capital employed. When, indeed, land is of very rich quality, and at once productive, without other outlay than the ordinary expenses of tillage, or when it has the means of fertilization near to it, and abundant, as in the vicinity of cities, the duration of the term may be comparatively short. But in other and dissimilar cases, this cannot be without a sacrifice of present income; and a landlord will scarcely fail to experience that if there be not a sufficient period of secure possession accorded to the occupier, the necessary expenditure on the cultivation of the ground will not be hazarded; but more than this, a person of good capital will, like every trader, regard as a benefit the power of carrying on his business undisturbed, and will set a pecuniary value on security and independence." (*Quart. Journ. of Agr.* vol. i. p. 795.) With regard to a lease in general, and its covenants, see a good paper (*Ibid.* vol. ii. p. 134). In speaking of rents, the author remarks, "As to the kind of rent to be paid, constant experience proves that the best and most satisfactory is a fixed rent in money.

To rents payable in grain, or in money regulated by the prices of grain, there is this obvious objection, that the tenant will generally be required to pay the highest rent when he is least able to do so, that is, when prices rise from a deficiency in the produce of the crop." And when speaking of the lease and its precautionary covenants, he observes, "the greatest error consists in vain precautions and attempts to provide against every possible contingency which, from the nature of the transaction, and the unforeseen events to which it may give rise, it is impossible to do. All that can be done is to make as precise as possible the conditions which experience shows to be necessary. The terms of the contract should be few and simple, and easily understood and complied with. Not only are hurtful covenants to be avoided, but such as are unnecessary, since to increase the number of them too much serves but to perplex the lessee, and give birth to future quarrels, and since all experience on the subject shows that the interests of either party may be sufficiently guarded without multiplying too much conditions, penalties, and restrictions."

LEASH. A term applied to game, &c., by sportsmen, and which implies three; as three hares, partridges, &c. It also signifies a line to hold a dog by.

LEATHER (Germ. *leder*; Dan. *læder*). The prepared skins of animals. The principal object of the art of converting skin into leather is to render it strong and tough, durable, and often water-proof, and to prevent its destruction by putrefaction. The skins are first cleansed of hair and cuticle, then impregnated either with vegetable tan and extract, as in the production of what is called *tanned* leather. In this process the tannic acid, which is the active principle of the astringent vegetables employed, combines with the gelatin of the skins, and forms an insoluble tannate of gelatin. It is this formation which renders the skins impermeable to water, and checks the tendency to decomposition which they, in common with all animal matter, possess. Instead of tan, some leather is prepared with alum and other salts, as for *tawed* leather. These processes are sometimes combined; and tanned leather often undergoes the further operation of *currying*, or impregnation with oil. As instances of these different results,—thick sole-leather is tanned; white kid for gloves is tawed; the upper-leather for boots and shoes is tanned and curried; and fine Turkey leather is tawed and afterwards slightly tanned. Morocco leather, as it is called, is chiefly prepared from sheep-skins. Shammoy leather is generally sheep or doe-skin, prepared by dressing, lining, &c., and dyed, if necessary, and then finished in oil. Russia leather acquires its peculiar odour from birch tan. There is an excellent abstract of the manufacture of different kinds of leather in *Ure's Dictionary of Arts, &c.*, which those who wish to pursue the subject further may consult. The leather manufacture of Great Britain is of very great importance, being inferior, in point of value and extent, only to those of cotton, wool, and iron.

LEATHER-WOOD (*Dirca palustris*). This

is a low shrub, and native of the United States, growing in moist, shady places, seldom rising more than four feet high, spreading into a head, with many small and very flexible branches. The flowers are produced at the extreme ends of the former years' shoots; they are of an herbaceous colour, and make a tolerable appearance. The flowers, which appear the latter end of March, before any perfect leaves, are of a yellow colour. The bark is uncommonly tough, yet the enclosed wood is very brittle. It was highly valued by the native Indians, and used in the place of cords. This plant, according to the information of Mr. W. Bartram, occupies an extensive range of territory, from Canada to Georgia. (*Willich's Dom. Ency.*)

LEAVEN (Lat. *levare*, to raise). A piece of sour dough, used to ferment and render light dough or paste. It is a very imperfect substitute for yeast; and as it communicates to the bread an astringent taste, which few persons relish, it ought to be used only where yeast cannot be procured. As, however, the latter ferment cannot always be obtained, especially during winter, I shall state the most simple methods of preparing, as well as of preserving it, under the article **YEAST**.

By the law of Moses, leaven was strictly forbidden during the passover; and the Jews, who were taught to regard it from the vigil of the feast as unclean, with religious scrupulosity purified their houses from the contaminating influence. See **BREAD**.

LEEK (*Allium porrum*). The leek is a hardy biennial; for, although it attains perfection in size and for culinary purposes the first year, it does not run to seed until the second, the perfecting of which it also often survives. The whole plant is eaten, being employed in soups, &c., and is by some persons boiled and eaten with meat. There are four varieties: the Mus-selburgh, and the large London leek, which are by far the best; the Scotch or flag, which is larger and hardier; and the Flanders. It is raised solely from seed, which must be sown first in the end of February, a small crop for transplanting in June and July, as well as in part to remain where sown; again for the main crop in the course of March or early in April; and, lastly, towards the close of April or beginning of May, for late transplanting. These sowings are in general performed broadcast, and raked in; though some gardeners employ drills, the plants to remain after thinning: the leek, however, is so much benefited by transplanting as obviously to point out the error of this practice. When the plants are three or four inches in height, in eight or ten weeks after sowing, they must be weeded, hoed, and thinned, where growing too close, to two or three inches apart; water also being given, in dry weather, will, with the above treatment, strengthen and forward them for transplanting in another month, or when six or eight inches high: They must be taken away regularly from the seed-bed, the ground being well watered previously, if not soft and easily yielding. When thinned out, they may be left to remain in the seed-bed six inches asunder, as they do not grow so large as the transplanted ones, which must be set by the dibble in rows ten

inches apart, and eight in the lines, being inserted nearly down to the leaves, that the neck, by being covered with the earth, may be blanched. Water in abundance must be given at the time of planting, and the long weak leaves shortened, but the roots left as uninjured as possible. The bed should be hoed over occasionally, as well to kill the weeds as to loosen the soil. By this treatment, and by cutting off the tops of the leaves about once a month, as new ones are produced, the neck swells to a much larger size. The several sowings above directed will yield a supply from August until the following May, when they advance to seed. A portion should be always taken up and laid in sand previous to the ground being locked up by continued frost, but they will not keep many days in this situation. To obtain seed, some of the finest roots of the previous year's growth, which have been left where raised, may be transplanted thence in February or the early part of March, eight inches asunder, in a row beneath a warm fence; and when seed-stems arise, they must be attached to stakes for support, or to the fencing: the closer and sooner they are drawn to this latter, the better will it enable the seed to ripen; for in cold summers, particularly in open exposures, it never comes to maturity, and by the first sharp autumnal frost it is entirely destroyed. Good varieties never flower before May or June, and ripen their seed in September. The heads should be cut when changed to a brownish colour, with a foot in length of the stalk left attached, for the convenience of tying in bundles, three or four together, to dry: when they are perfectly dry, they may be hung up and kept in the head until wanted, or immediately thrashed out and stored. As the husk is very tough, it is usual, when small quantities have to be operated upon, to rub them against a tile, which breaks it more easily than any other mode that can be adopted. (*G. W. Johnson's Kitchen Garden.*)

LEES. The dregs or feculencies of liquors, which, after being separated by fermentation, fall to the bottom of the vessels. All the various kinds of lees, such as those of wine, beer, ale, oil, &c., may be made use of as manures when they can be had in sufficient quantities.

LEGS. The extremities that form the support of animals. Of the four legs of a horse, the two before have several parts, each of which has a peculiar name: thus, by the name of fore-leg, we commonly understand that part of the fore-quarters that extends from the hough to the pastern-joint, and which is frequently called the shank. The part that corresponds with it in the hinder quarters is called the instep. In the language of the manege, a horse is said to want the fifth leg when he is tired, and, bearing upon the bridle, lies heavy upon the rider's hand.

LEGUMINOUS PLANTS (from *legumen*, pulse) are those which bear legumes or pods, such as beans, peas, tares, &c. The *Leguminosæ* are a very extensive natural order of plants, found in all parts of the world, forming large trees and huge twiners in the tropics; herbaceous plants or small bushes, rarely trees in colder countries. The order contains a very

great variety of useful and beautiful species, some of which, like clover, lucern, sainfoin, and vetches, are cultivated for cattle; others, as beans, peas, lentils, and various other kinds of pulse, form part of the food of man. Indigo, logwood, and many more, are well-known dyeing plants: several acacias produce gum; certain *Astragali* yield tragacanth; the tamarind and others bear pods whose interior is filled with an agreeable pulp; *Cassia acutifolia* and other species of cassia yield senna; *Glycyrrhiza*, the liquorice-root; *Ceratonia*, the wild locust fruits of Scripture: finally, many are valuable tonics, and some are dangerous narcotics, among which the common laburnum is to be named.

Leguminous crops, according to the strict agricultural acceptation, include beans, peas, and other pulse. But the class is made to embrace a much more extensive range of plants, namely, all such as are considered as ameliorating or enriching crops, such as clover, potatoes, turnips, carrots, beets, cabbages, &c. These latter are far less exhausting than the culmiferous or grain plants, as few of them mature their seeds, and all, on account of their broad leaves, draw more or less nourishment from the atmosphere. They also ameliorate the condition of the soil, by dividing and loosening it with their tap and bulbous roots. As they generally receive manure and drill culture, they are peculiarly adapted to enrich and prepare the soil for the culmiferous crops.

LEICESTER SHEEP. See SHEEP.

LENTICULAR. A botanical term, signifying lens or pea-shaped.

LENTIL (*Ervum Lens*, from *erw*, tilled land in Celtic; some of the species are a pest in cultivated ground, being useless and too prolific weeds). Pl. 7, s. An exotic plant of the vetch or tare kind, cultivated in some parts of England as fodder for cattle. The lentil is an annual, growing to the height of about eighteen inches, with stalks and leaves like those of tares, but smaller, and producing pale purple flowers, which are succeeded by small flat pods, containing two or three round, hard, smooth, and flat seeds. There are two sorts of lentil, the white and the yellow; but the latter affords the greater quantity of fodder. The seeds of this plant are generally sown in March or April, in the proportion of one and a half to two bushels per acre. Lentils also furnish good dry fodder for cattle, and particularly for cutting into chaff as trough-meal for sheep and horses.

LETTUCE (*Lactuca*, from *lac*, milk, on account of the milky juice which exudes from the plants when broken). There are in England three indigenous species of lettuce, all biennials.

1. Strong-scented lettuce (*L. virosa*), which grows about hedges, old walls, and the borders of fields on a chalky soil, not uncommon. The whole herb abounds with an acrid, fetid, milky juice, having the smell of opium, but only slightly narcotic, and little likely to produce the consequences attending the use of that drug. This juice springs out suddenly in large drops, on the slightest touch, from the calyx and tender leaves, when the plant is in flower, but not at other times; evincing a considerable degree

of irritability in the plant. The root is tap-shaped. Stem solitary, two or three feet high, round, smooth, sparingly leafy, scarcely branched, paniced at the top, a little prickly below. Leaves horizontal, nearly smooth, finely toothed, radical ones numerous, obovate, undivided, depressed. Flowers numerous, paniced, light-yellow.

2. Prickly lettuce (*L. scariola*). This species is found in waste ground, and dry, stony borders of fields. The whole herb is glaucous, milky, bitter, but less fetid than the preceding. Stem two or three feet high, leafy, paniced. Leaves numerous, vertical, not horizontal, variously pinnatifid and toothed; thin midrib furnished with a close row of prominent prickles, their base clasping the stem. Flowers small, pale lemon-coloured.

3. Least lettuce (*L. saligna*). This species grows in chalky waste ground, or about salt marshes. The whole plant is very slender. Stem about two feet high, wavy, pale-brown or whitish, somewhat branched, leafy throughout. Leaves glaucous, smooth except the midrib beneath, linear, hastate or pinnatifid, entire, sessile. Flowers in small alternate tufts composing long clusters, very small, pale-yellow, open in sunshine only, and soon fading. (*Smith's Eng. Flor.* vol. iii. p. 344.)

Of the well-known cultivated lettuce (*L. sativa*) there are many varieties, which are divided into families, the cos and the cabbage. The first are more grown in summer than winter; the second at all seasons, but more usually in winter, on account of their superior hardihood. The cos varieties are characterized by being of an upright growth, and, with the exception of the Brighton, require to have their leaves drawn together for blanching; the cabbage, as growing close to the ground, produces a blanched heart, in the manner of a cabbage, without any assistance. The cilicias are of a nature intermediate between the two. When young, the cabbage varieties are in general sweeter than those of the cos at the same age; but at full growth this is reversed: hence the latter are preferred for salads, and the former for soups.

The cabbage varieties succeed better in a hotbed than the cos.

The following varieties are recommended for cultivation in England; but as some of them have been found not to succeed well in this country, those enumerated in the article KITCHEN GARDEN had better be depended on for the main crop.

CABBAGE VARIETIES.

Drumheaded.
Brown Dutch.
Tennisball.
Hardy green, or Capuchin.
Prussian.
Prince's.
Common white.
Large white.
Imperial.
Grand admirable.
Large Roman.

COS VARIETIES.

Brighton.
Black-seeded green.
Early Egyptian.
Green.
White or Versailles.
Silver.
Spotted or leopard.
Green and brown Cilicia
Lop.

Lettuces thrive best in a light, rich soil, with a dry substratum. In a poor or tenacious one they never attain any considerable size, but run to seed prematurely. Like most other crops, that soil is to be preferred which is rich rather

from prior cultivation than the immediate application of manure. It is of advantage to trench it; and if manure is necessarily applied at the time of insertion, it should be in a state of forward decay. For the first and last crops of the year, a warm, sheltered situation is required; but for the midsummer ones, a border that is sheltered during the meridian, but far from being confined or under the shadow of trees, is to be preferred. Lettuce is propagated by seed: that for the first crop should be sown in a frame, on a warm border, or slender hot-bed, at the end of January or early in February; at the close of this last month a larger quantity may be sown in any open situation, and repeated once every three weeks in small proportions until the end of July, for summer and autumn use; to be continued, at similar intervals, until the close of September, for winter and early spring. They may be sown either broadcast or in rows, moderately thin, each variety separate, lightly covered, and care being taken that the bed is trampled upon as little as possible. It is usual, when the plants are about a month old, or two inches in height, to thin them to three or four inches apart, those removed being pricked out at similar distances. Those from the sowings in January and February, in a similar situation to that in which they were raised; and thence until August in any open situation. Those of the August sowing must be divided into two portions; the largest being selected and planted in an open compartment for late autumn use, and the smaller on a warm border for winter and early spring.

When planted out finally, they must be set in rows a foot apart each way, which is abundant for the largest variety, and not more than necessary for the smaller. At the time of every removal, whether of picking out or planting, water must be given moderately, and until the plants are rooted. It may be remarked, that transplanted lettuces never attain so fine a growth as those left where sown, nor become so soon fit for use; those which are planted out at once to remain, being better in these respects than those which are pricked out previous to final planting. The difference in their time of becoming fit for use, however, is of advantage, as by these means a more perfect succession is obtained. Those which are planted to withstand the winter are best planted on the summit or south side of ridges, as this is a great protection from excessive wet, from which they always suffer. In every stage of growth they must be kept free from weeds, well watered, and the earth around them frequently stirred for the extirpation of slugs and snails, which are particularly injurious, and are very prevalent in moist seasons.

When the cos varieties have attained an advanced growth, they require their leaves to be drawn together with a shred of matting, to render the interior blanched, care being taken that it is not performed so tight as to bruise them. Under every favourable circumstance for a vigorous growth, the plants, especially of the cos varieties, and during dry seasons, will yet run up to seed before the heart is perfectly blanched: to retard this, it is an effectual practice, at the time of tying them up, to cut out the centre of

each with a sharp knife. The plants raised from the September sowing may be divided as directed for those of August; but, in addition, some of the cos varieties may be planted on a warm border, to have the shelter of frames and hand-glasses.

To produce seed, some of the finest and most perfect plants of each variety that have survived the winter, or from the forwardest sowing of the year, should be selected. The seed from any that have run up prematurely cannot be depended upon. All other plants must be removed from their neighbourhood, themselves being left at least a foot apart; neither is it allowable for two varieties to flower near each other, as only mongrel varieties will be obtained. Each stem is advantageously attached to a stake, as a support in tempestuous weather. It is to be observed, that the branches must be gathered as the seed ripens upon them, and not left until the whole is ready, as some will ripen two or three weeks before others, and consequently the first and best seed will be shed and lost. It must be well dried before it is beaten out and stored. Lettuce seed is considered to be best the second year; but when three years old it refuses to vegetate.

The juice of the lettuce inspissated is termed *lactucarium*. It possesses slight narcotic properties, and is useful in coughs.

LETTUCE, LAMB'S. See CORN SALAD.

LEVELLING. In husbandry, implies rendering the ground even, and removing of impediments to the common operations of tillage. This is generally done by the plough, but sometimes machines are employed for the purpose.

LEVER. In mechanics, an inflexible rod or bar, movable upon a *fulcrum* or prop, and having forces applied to two or more points. The lever is one of the mechanical powers; and being the simplest of them all, was the first that was attempted to be explained.

Examples of the application of the lever are of constant occurrence in the mechanical arts. The crowbar, the handspike, nippers, pincers, &c., are levers of the first kind. The second kind includes the chipping knife, the common door, nutcrackers, the wheelbarrow, &c. To levers of the third kind belong the sheep-shears, the treddle of the turning-lathe, tongs, &c. The bones of animals are generally levers. The socket of the bone is the fulcrum; a strong muscle, attached to it near the socket, is the power; and the weight of the limb, with whatever resistance is opposed to its motion, is the weight. A very moderate contraction of the muscle thus gives considerable motion to the limb. (*Gregory's Mech.* vol. ii.)

LEVERET. A young hare, in the first year of its age.

LEY, LEA, or LAY. Land in the state of sward or grassy surface.

LIBER (Lat. *bark*). In botany, the interior lining of the bark of exogenous plants. It consists of woody tissue in great quantity, and very thick-sided, intermixed with cellular tissue. It appears to be formed annually, at the same time as the concentric zones of wood, and is intended by nature to convey downwards the secretions elaborated in the bark and leaves:

The liber is the principal seat of lactiferous vessels.

LIBRARIES, FARMERS'. Collections of books on agricultural and horticultural subjects are now becoming very general throughout the country, through the instrumentality of farmers' clubs. They cannot fail of being eminently useful to the cause of agriculture, by diffusing among the cultivators of the soil the latest discoveries and improvements in husbandry, as well as the different opinions and theories entertained on matters having reference to agriculture and its collateral sciences of chemistry, botany, natural history, geology, meteorology, and vegetable physiology, &c.

LICE ON ANIMALS. There is not an animal that does not, under suitable circumstances, nourish in its hair, wool, feathers, or its skin, some kind of louse; and sometimes more than one kind of these parasites lodge and prey on the same animal. In ordinary cases, they do not produce much mischief, but when they increase so much as to produce the disease called mange (*Pityriasis*), they become truly formidable. The cause of animals being troubled with lice, may usually be traced to a want of cleanliness. When the dust and sweat accumulated on the hair, and in contact with the skin of the ox or horse, are allowed to remain undisturbed by the comb or brush; when the stables are kept filthy, unventilated, and unwholesome; when animals, reduced in autumn by want of pasture, or by living in unhealthy ones, are suffered to take their chance for the winter without extra care or attention; or when a beast loaded with pediculi is turned into the yards or the stables of those exempt from these parasites, it may be expected that they will multiply and infest animals. When we see horses rubbing their tails, biting their manes, and showing other signs of uneasiness and irritation; when cattle are observed to be rubbing their heads against posts or fences, and the hair coming off from the head and neck; or when sheep tear out tufts of wool with their teeth, and bite these places till blood appears, we may expect that lice are present. On most animals, these parasites have some favourite place of resort; on horses, the mane and tail; on horned cattle, around the nose, base of the horns, and the neck; on sheep, they run over every part; and on swine, they do not seem to be confined to any particular location.

Pure air, room for exercise, plenty of food, and above all, cleanliness, are the first things to be attended to in the cure of this evil. Curying, brushing, and washing should be resorted to, as, except in bad cases, this treatment will be usually sufficient to free the animal from these insects, without recourse to other remedies. Where these fail, it will be necessary to have recourse to such external or internal applications as shall operate directly on the vermin.

One of the most common remedies is the mercurial ointment, commonly called *unguentum*; but this, though effectual, cannot be used without some danger, as numerous instances have occurred in which valuable animals have been destroyed by its too free use. Care should be taken to prevent the animal from

biting itself where the ointment is applied, until it has had time to take effect. A decoction of tobacco leaves, in a strong lye, forms a very good wash; but this, too, owing to the narcotic poison of the tobacco, has caused death. Various vegetable remedies have been resorted to, among which are the seeds of the larkspur (*Delphinium staphysagria*); and the leaves and flowers of the *ledum palustre*, or marsh, or Labrador tea. The roots of the black hellebore, or a decoction made from them, have been used with success; and it is said that the water in which the skins or parings of potatoes have been boiled will effectually destroy lice by a few washings. The internal use of sulphur is an excellent remedy, and if given to animals occasionally, is one of the best preventives.

It is more difficult to apply remedies for lice to sheep than to any other animals. The English shepherds make use of a salve compounded of white arsenic and corrosive sublimate, carefully parting the wool, and applying the ointment in small quantities directly to the skin, and rubbing it down with the finger. Tessier prefers tobacco smoke to this ointment, as attended with less danger in its use. The sheep is held in such a manner that tobacco smoke is forced from a bellows among the wool to the skin in all directions. After this fumigation, the sheep must be placed in the open air, that the vapor may have room to pass off without being inhaled by them. Perhaps the best remedy for lice in animals, where they have not become so numerous as to produce the disease *Pityriasis*, is to rub any oil, such as whale oil or melted lard, on such places as they most frequent, or on parts of the animal where they will be most likely to come in contact with it. All the pediculi breathe through what are termed spiracles or openings in their bodies, and the least particle of oil spread over their bodies, by causing suffocation, at once effects their destruction. This is also a perfectly harmless remedy. But prevention in this case is better than cure; and neatness, cleanliness, and good keeping, by insuring comfort and health, leaves no opportunity for the attacks of vermin. (*Cultivator.*)

LICE ON PLANTS. See APHIDIANS, AMERICAN BLIGHT, and INSECTS.

LICHENS. Plants of a very low organization, which grow on the bark of trees or rocks, when they form a kind of incrustation, or upon the ground, when they consist of irregular lobes, parallel with the earth's surface. Occasionally, in all situations, they are found in a branched state; but their subdivisions are generally irregular, and without order. Their fructification consists of hard nuclei, called *shields*, which break through the upper surface of the *thallus*, or main substance of the lichen, are of a peculiar odour and texture, and contain the reproductive particles. Lichens abound in the cold and temperate parts of the world. The greater part are of no known use; but some, as the reindeer-moss (*Cenomyce rangiferina*), the Iceland moss (*Cetraria Islandica*), and various species of *Gyrophora*, are capable of sustaining life, either in animals or man. The Iceland moss, when deprived of its bitterness by soaking in an alkali and then boiling, br-

comes, indeed, a diet recommended to invalids. Others are used as tonic medicines, as *Variolaria faginea* and *Parmelia parietina*. Their principal use is, however, that of furnishing the dyer with brilliant colours; orchard, cudbear, and perolle, with many more, are thus employed. (*Brande's Dict. of Science.*) See Moss.

LICKS. A term applied in the United States to places where salt springs escape from the earth and impregnate the soil, and sometimes give rise to an efflorescence of common salt. To such spots the deer, buffalo, and almost all graminivorous animals resort, for the purpose of licking the surface. See SALT.

LID. In botany, the calyx which falls off from the flower in a single piece.

LIFE EVERLASTING. See CUDWEED.

LIGHT, ITS INFLUENCE ON VEGETATION. That light has a considerable influence upon the growth of plants, is an observation that must have been very early made by mankind. The inferior green colour of plants growing in the shade, as in woods, or when covered with earth, or inverted vessels, would clearly indicate to the most careless observer, that light at least influenced the colour of vegetation: every gardener, in truth, takes advantage of this fact, when he is blanching his culinary vegetables. But it was not till after the days of Priestley, that the other chemical effects which light produces upon a growing plant were so much better understood.

It is probable that this influence commences at a very early period in the life of the plant, with even the germination of the seed. Ingenhousz, says Dr. Thomson, found that seed always germinate faster in the dark than in the light. (*Exper. sur la Veg.* 11.) And these experiments were repeated by Sennebier with equal success. (*Mém. Physico-Chem.* vol. iii. p. 41.) But the Abbé Bertholin, who distinguished himself so much by his labours to demonstrate the effect of electricity on vegetation, objected to the conclusions of these philosophers, and affirmed that the difference in the germination of seeds in the shade and in the light, was owing, not to the light itself, but to the difference in the moisture in the two situations, the moisture evaporating much faster from the seeds in the light than from those in the shade; and he affirmed that when precautions were taken to keep the seeds equally moist, then those in the sun germinated sooner than those in the shade. (*Jour. de Physique*, 1789.) But when Sennebier repeated his former experiments, and employed every possible precaution to insure equality of moisture in both situations, he constantly found the seeds in the shade germinated sooner than those in the light. We may conclude, therefore, that light is injurious to germination; and hence one reason for covering seeds with the soil in which they are grown. But from the more recent experiments of Saussure, there is reason to believe that light is only injurious to vegetation in consequence of the heat it produces; for where the direct rays of the sun were intercepted, though light was admitted, the germination of the seeds was not sensibly retarded. (*Rech. Chem. sur la Veg.* p. 23; *Thomson's Chem.* vol. iv. p. 307.)

And with regard to the after-growth of plants,

light exercises a very considerable influence. It is now clearly ascertained that plants vegetating in the light, absorb carbonic acid gas from the atmosphere, and emit oxygen gas; but when vegetating in the dark different effects are produced, for then carbonic acid gas is emitted, and oxygen gas absorbed. (See GASES.) This latter process is thus explained by Liebig:—"It is true that the decomposition of carbonic acid is arrested by the absence of light; but then, namely, at night, a true chemical process commences, in consequence of the action of the oxygen in the air upon the organic substance, composing the leaves, blossoms, and fruit. This process is not at all connected with the life of the vegetable organism, because it goes on in a dead plant exactly as in a living one. The substances composing the leaves of different plants being known, it is a matter of the greatest ease and certainty to calculate which of them during life should absorb most oxygen by chemical action where the influence of light is withdrawn. The leaves and green parts of all plants containing volatile oils, or volatile constituents in general, which change into resin by the absorption of oxygen, should absorb more than other parts which are free from such substances. Those leaves, also, which contain either the constituents of nutgalls, or compounds in which nitrogen is present, ought to absorb more oxygen than those which do not contain such matters. The correctness of these inferences has been distinctly proved by the observations of De Saussure; for whilst the tasteless leaves of the *Agave Americana* absorb only 0.3 of their volume of oxygen in the dark during 24 hours, the leaves of the *Pinus abies* which contain volatile and resinous oils absorb 10 times, those of the *Quercus robur* containing tannic acid 14 times, and the balmy leaves of the *Populus alba* 21 times that quantity. This chemical action is shown very plainly also in the leaves of the *Cotyledon calycinum*, the *Cacalia ficoides*, and others; for they are sour like sorrel in the morning, tasteless at noon, and bitter in the evening. The formation of acids is effected during the night by a true process of oxydation; these are deprived of their acid properties during the day and evening, and are changed, by separation of a part of their oxygen, into compounds containing oxygen and hydrogen, either in the same proportions as in water or even with an excess of hydrogen, which is the composition of all tasteless and bitter substances. When the green leaves of the poplar, the beech, the oak, or the holly, are dried under the air-pump, with exclusion of light, then moistened with water, and placed under a glass globe filled with oxygen, they are found to absorb that gas in proportion as they change in colour. The chemical nature of this process is thus completely established. The diminution of the gas which occurs can only be owing to the union of a large proportion of oxygen with those substances which are already in the state of oxides, or to the oxydation of the hydrogen in those vegetable compounds which contain it in excess. The fallen brown or yellow leaves of the oak contain no longer tannin, and those of the poplar no balsamic constituents. (*Org. Chem.* p. 28.)

The action of light upon the growing plant is in every point of view full of interest to the cultivator: "If all the branches of a tree, exclusive of one," said Mr. T. M. Knight (and he was one of the ablest of modern vegetable physiologists), "be much shaded by contiguous trees, or other objects, the branch which is exposed to the light attracts to itself a large portion of the ascending sap, which it employs in the formation of leaves and vigorous annual shoots, whilst the shaded branches become languid and unhealthy. The motion of the ascending current of sap appears, therefore, to be regulated by the ability to employ it in the trunk and branches of the tree; and this current passes up through the alburnum, from which substance the buds and leaves spring. But the sap which gives existence to, and feeds the root, descends through the bark, and if the operation of light give ability to the exposed branch to attract and employ the ascending or alburnous current of sap, it appears not improbable that the operation of proper food and moisture in the soil, upon the bark of the root, may give ability to that organ to attract and employ the descending or cortical current of sap." (*Selection of Papers*, p. 160.) "M. Decandolle, I believe, first observed that the succulent shoots of trees and herbaceous plants, which do not depend upon others for support, are bent towards the point from which they receive light, by the contraction of the cellular substance of their bark upon that side, and I believe his opinion to be perfectly well founded. The operation of light upon the tendrils and stems of the Ampelopsis and ivy appears to produce diametrically opposite effects, and to occasion an extension of the cellular bark wherever that is exposed to its influence; and this circumstance affords, I think, a satisfactory explanation why these plants appear to seek and approach contiguous opaque objects, just as they would do if they were conscious of their own feebleness, and of power in the objects to which they approach, to afford them support and protection. The tendril of the vine is internally similar to that of the ampelopsis, though its external form and mode of attaching itself, by twining round any slender body, are very different. Some young plants of this species which had been raised in pots in the preceding year, and had been headed down to a single bud, were placed in a forcing house, and the shoots from these were bound to slender bars of wood, and trained perpendicularly upwards. Their tendrils, like those of the ampelopsis, when first emitted, pointed upwards, but they gradually formed an increasing angle with the stems, and ultimately pointed perpendicularly downwards, no object having presented itself to which they could attach themselves. Other plants of the vine, under similar circumstances, were trained horizontally, when their tendrils gradually descended beneath their stems, with which they ultimately stood very nearly at right angles. A third set of plants were trained almost perpendicularly downwards, but with an inclination of a few degrees towards the north, and the tendrils of these permanently retained very nearly their first position relatively to their

stems; whence it appears that these organs, like the tendrils of the ampelopsis and the claws of the ivy, are to a great extent under the control of light. A few other plants of the same species were trained in each of the preceding methods, but proper objects were placed in different situations near them, with which their tendrils might come into contact, and I was by these means afforded an opportunity of observing with accuracy the difference between the motions of these and those of the ampelopsis under similar circumstances. The latter almost immediately receded from light, by whatever means that were made to operate upon them; and they did not subsequently show any disposition to approach the points from which they once receded. The tendrils of the vine, on the contrary, varied their positions in every period of the day, and afterwards returned again during the night to the situations they had occupied in the preceding morning, and they did not so immediately or so regularly bend towards the shade of contiguous objects. But as the tendrils of this plant, like those of the ampelopsis, spring alternately from each side of the stem, and as one point only in three is without a tendril, and as each tendril separates into two divisions, they do not often fail to come into contact within their reach, and the effects of contact upon the tendrils are almost immediately visible. It is made to bend towards the body it touches, and, if that body be slender, to attach itself firmly by twining round it, in obedience to certain causes. The tendril of the vine, in its internal organization, is apparently similar to the young succulent shoot and leaf-stalk of the same plant; and it is abundantly provided with vessels or passages for the sap; and I have proved that it is alike capable of feeding a succulent shoot, or a leaf when grafted upon it. It appears, therefore, I conceive, not improbable that a considerable quantity of the moving fluid of the plant passes through its tendrils, and that there is a close connection between its vascular structure and its motions." (*Ibid.* p. 166.)

"The stems of the potato," he adds in another place, "as of other plants, rise perpendicularly under the influence of their unerring guide, gravitation, so long as they continue to be concealed beneath the soil; but as soon as they rise above it they are, to a considerable extent, under the control of another agent, light. Each inclines in whatever direction it receives the greatest quantity of it, and consequently each avoids and appears to shun the shade of every contiguous plant; gravitation labouring to give a perpendicular, the other a horizontal direction to the leaves, and the comparative power of one agent increasing, as that of the other decreases." (*Ibid.* p. 300—306.)

The opinions of Liebig, as to the chemical changes produced in plants, by the action of light, and its withdrawal, seem confirmed, in some degree, by those of Davy. "In the changes that take place in the composition of the organized parts," said that excellent philosopher, "it is probable that saccharine compounds are principally formed during the absence of light; gum, woody fibre, oils, au!

resins, during its presence; and the evolution of carbonic acid gas, or its formation during the night, may be necessary to give greater solubility to certain compounds in the plant. (*Agric. Chem.* p. 223.) And after giving a variety of experiments to elucidate the action of vegetation on the atmosphere (see GASES, THEIR USES TO VEGETATION), he adds, "These facts confirm the popular opinion, and when the leaves of vegetables perform their healthy functions, they tend to purify the atmosphere in the common variations of weather, and changes from light to darkness. It may occur, however, as an objection to these views, that if the leaves of plants purify the atmosphere towards the end of autumn, and through the winter and early spring, the air in our climates must become impure, the oxygen in it diminish, and the carbonic acid gas increase, which is not the case; but there is a very satisfactory answer to this objection. The different parts of the atmosphere are constantly mixed together by winds which, when they are strong, move at the rate of from 60 to 100 miles in an hour. In our winter, the southwest gales convey air which has been purified by the vast forests and Savannas of South America, and which, passing over the ocean, arrives in an uncontaminated state. The storms and tempests which often occur at the beginning and towards the middle of our winter, and which generally blow from the same quarter of the globe, have a salutary influence. By constant agitation and motion, the equilibrium of the constituent parts of the atmosphere is preserved; it is fitted for the purposes of life: and those events which superstition formerly referred to the wrath of heaven, or the agency of evil spirits, and in which they saw only disorder and confusion, are demonstrated by science to be ministrations of Divine intelligence, and connected with the order and harmony of our system." (*Ibid.* p. 230.)

LIGHTNING. An electric phenomenon, produced by the passage of electricity between one cloud and another, or between a cloud and the earth. The identity of lightning with electricity, though it had been previously suspected, was first directly demonstrated by the celebrated Dr. Franklin, in the year 1749, by the experiment of drawing sparks by the electric kite. Since that time the science of electricity has been greatly advanced; nevertheless, the cause of some of the appearances connected with lightning is not well explained even at the present day.

There are three phenomena in particular for which theory fails satisfactorily to account. The first is the form of the flash, which is almost always zigzag, or in broken lines, making a greater or smaller angle with each other. The second is the frequent repetition of the flashes from the same cloud, which often follow one another in quick succession, contrary to what takes place in the case of electric conductors, which generally recover their natural state, or discharge the whole of their electricity at a single stroke. The third is the length of the flash, which sometimes appears to embrace a large extent of the sky. This phenomenon can be best observed from the tops of mountains,

reaching above the clouds from which the lightning proceeds; and observers in such cases agree in stating that they have seen flashes certainly extending several miles in length.

The zigzag form of the flashes is common to lightning and the electric spark: the same explanation should consequently apply to both; but this the theory has not yet been able to give.

The theory of the electric fluid, and the well-ascertained differences in the conducting power of different substances, suggested the idea of protecting buildings from the destructive effects of lightning by metallic rods. Such rods are usually made of iron about half an inch in diameter. The lower portion should descend into the ground some 3 or 4 feet, and in all cases penetrate to the moist earth. It should be made rather larger than the rest of the rod, and have a slant from the foundation, or outwardly. Some recommend that the lower end should be pointed in the same manner as the upper extremity. The top of the rod should have one or more sharp points. As iron is so liable to rust, by which the points become blunted, it is usual to have these either gilt or tipped with platinum, so as to be preserved from oxidation. The tops of the rods may be raised some 4, 6, or 8 feet above the chimneys or highest points of the buildings they are intended to protect. If the buildings be large, there should be more points than one elevated at the different parts. Indeed, some persons who have devoted attention to the subject, say that there should always be several projecting points raised to receive the lightning from different directions. Lightning rods cost but little, as the platinum points can be bought for \$1,25, and the conductors may be easily made by any blacksmith. They should have as few joints as possible, and be inspected from time to time to see whether any separation exists, and whether the joint remains in its place. Where, from rust or other causes, any interruption to the course of the electric fluid occurs, a lightning rod, instead of furnishing protection, is an additional source of danger.

LIGHTS, NORTHERN, or AURORA BOREALIS. A luminous meteor, generally appearing in the northern part of the sky, and presenting a light somewhat resembling the dawn or break of day. The appearances which it exhibits, and the forms it assumes, are so proverbially unsteady, that it is not possible to comprehend them under any general description. In the Shetland Isles, and other countries in high latitudes, the northern lights are the constant attendants of clear and frosty evenings in winter. They are most frequent in autumn. A very interesting account of this meteor, and of the works treating on this subject, will be found under the head "Aurora Borealis," in *Brande's Dict. of Science, &c.*

LIGNEOUS (Lat. *lignum*, wood). In entomology, a part so called when it is composed of a hard, inelastic substance like wood.

LIGNIN (Lat. *lignum*). The woody fibre. This most important proximate principle of vegetables exhibits itself in a variety of forms, constituting the different textures of hard and soft wood, and various fibrous products, such as hemp, flax, cotton, &c. When by fine me-

chemical division it is reduced to a pulpy state, it is formed into paper. When by different reagents all the soluble matters are extracted from wood, the insoluble residue is lignin; its ultimate components are carbon, oxygen, and hydrogen, the two latter elements being in the same relative proportions as in water; so that woody fibre may be considered as a compound of carbon and water, and, according to Dr. Prout's experiments, almost exactly in equal weights. Lignin is very unperishable, but under certain circumstances it is attacked by *dry rot*, arising out of the growth of a parasitic fungus, which causes its rapid decay. Damp timber, in situations where air has not free access, is particularly subject to its attacks; and when once it has made its appearance, the well-seasoned timber in its neighbourhood becomes liable to the same disease. The dry rot may be prevented by impregnating the timber with certain saline solutions, and of these, solution of corrosive sublimate has been found most effectual; this (the bi-chloride of mercury) combines chemically with the albumen of the wood, and the compound is very indestructible. (See *DRY ROT*.) Lignin has also a strong attraction for alumina, and hence linen, cotton, paper, and other forms of this fibre, may be aluminized by steeping them in hydrated alumina diffused through water, or more effectively by soaking them in certain aluminous solutions, drying them, and afterwards washing out the excess of the salt. It is in this way that cotton goods are impregnated with alumina for the purpose of dyeing and calico printing. Other metallic oxides exhibit similar attractive powers, especially the oxide of iron. The analogy that exists between the composition of sugar, gum, starch, and even vinegar and lignin, suggests the possibility of the conversion of those substances, by an exchange of their proximate elements, into each other; and it has accordingly been found that by carefully roasting pure and fine sawdust, it is rendered partially soluble in water, and that a part of it is converted into a nutritious substance, probably intermediate between sugar and starch, and which, when mixed with a little flour, yields a palatable bread, not very unlike that made by some of the inhabitants of the northern parts of Europe of the bark of trees. Mixed with sulphuric acid, lignin passes into gum, and from this sugar may be obtained, by boiling it for some hours in a very dilute sulphuric acid; this sugar, when purified, much resembles grape or honey sugar. By this process, rags may be converted into nearly their own weight of this peculiar saccharine matter.

The production of vinegar by the destructive distillation of wood, was originally suggested about the middle of the 17th century, by Glauber, a celebrated German chemist of that time; it has lately become a very important branch of manufacture in England. Upon the whole, there are very few natural products equally important with lignin in their applications to the useful and ornamental arts. See *PROLIGNOUS ACID*.

LILAC (*Syringa*, from *syrinx*, a pipe. The

branches are long and straight, and are filled with *medulla*; hence the old name of the lilac, pipe-tree. The English name of the genus is from lilac or lilag, the Persian word for the flower). The species of lilac are well known elegant shrubs.

The common lilac (*Syringa vulgaris*) is a shrub originally from Constantinople, growing to the height of 18 or 20 feet. The elegant lilac-coloured bunches of flowers are very sweet and graceful to the eye. There is also the white lilac, still more delicate-looking, and equally sweet-scented. The most beautiful variety of the common purple lilac is that known by the title of the Scotch lilac.

The Chinese lilac (*S. chinensis*) is a native of China, and less in size than the common lilac; it was first brought to this country in 1795. Blooms violet-coloured flowers in May.

The Persian lilac (*S. persica*) is a native of Persia, and seldom exceeds five or six feet in height, blowing light purplish pink flowers in May. The lilacs love a good garden soil, and may be propagated by layers, shoots, and suckers from the roots.

LILY (*Lilium*, derived from the Celtic word *li*, signifying whiteness; on account of the beautiful white flowers of the original species). This is a fine ornamental and well-known genus of exotic plants, almost all of which are remarkable for the delicacy and beauty of their flowers. Most of the species succeed in a rich, light soil, but the American species should be grown in peat. (*Paxton's Bot. Dict.*)

Miller, in his *Dictionary*, mentions 13 species, with their varieties: but there are now more than 34 known species, besides innumerable varieties: the finest for garden ornament are as follows:—

The superb martagon (*L. superbum*). A beautiful plant, blowing many bright orange flowers spotted with violet. It loves bog soil.

Purple martagon, which grows 3 or 4 feet high, blooming reddish or white flowers spotted with purple. It blows in July. It is sometimes called Turk's cap. It is a native of Germany.

Scarlet martagon (*L. chalcedonicum*). Native of the Levant, blowing a bright scarlet flower in June and July. It likes a good soil.

Turk's turban (*L. pomponium*), blows a pretty pendulous red flower in June, in the shape of a turban. In Kamschatka the bulb of this species is cultivated the same as the potato is in this country.

Orange or fire lily (*L. bulbiferum*). Large flower, of a deep orange colour, flowering in June and July. The Russians and Tungusians also eat the roots of this species, either boiled in milk or roasted. A German author informs us that these mealy roots might, in times of scarcity, be made into wholesome bread. The roots are cathartic, and the leaves cooling.

Tiger lily (*L. tigrinum*). A beautiful showy bulb, blowing an orange flower in June: it loves a sandy soil and open situation.

Philadelphian lily (*L. Philadelphicum*). Native of North America, blowing a deep orange spotted or scarlet flower in July. This very elegant plant may be known from the other

species by the claws of the petals. The colour of the flower is orange-red. Protect it in winter by spreading coal ashes over it.

The American or Canadian lily (*L. Canadense*), has flowers of a yellowish orange. It is a fine plant, growing 2 or 3 feet high, and found in abundance on the marshy shores of the Delaware below Philadelphia. It is perennial, and flowers in July.

The Superb American lily (*L. superbum*), is a magnificent plant, which, says Dr. Wm. P. C. Barton, may be ranked among the finest vegetable productions of the United States. It frequently attains the height of 6 or 7 feet, supporting a profusion of elegant deep scarlet flowers. It is found on the marshy shores of the Delaware, and in the bogs of New Jersey and other states. A perennial, flowering in July and August.

The common white lily (*L. candidum*), is too well known to need description. It is hardy, and produces a beautiful flower, the fragrant odour of which is so powerful as to induce fainting if numbers of them be kept over night in a close apartment. The bulb roasted is emollient and suppurative. All descriptions of lilies are propagated freely by offsets from the bulbs, which should be taken up when the stem decays, and parted and replanted early in October, 5 to 6 inches deep, in a light, dry soil. The bulbs of martagons must never be transplanted till after the stem is decayed, as they will not bear being disturbed. Many varieties of lilies are produced from seed, which is treated in the same way as tulip seed.

LILY-OF-THE-VALLEY (*Convallaria majalis*, from the Latin *convallis*, a valley). This very elegant sweet-scented indigenous perennial is not reckoned among the lily tribe. It grows in woods, heaths, and at the foot of hills, flourishing and shedding its fragrance in May and June. The roots are thread-shaped, creeping, much entangled. Leaves two, radical, elliptical, 3 or 4 inches long, acute, entire, many-ribbed, smooth-stalked. Flower-stalk solitary, simple, radical, naked, semi-cylindrical, bearing a simple curved cluster of several pendulous, cup-shaped, white flowers, with rather distant segments. Berry as large as a black currant, scarlet. There are varieties with double or with purple flowers, sometimes seen in gardens; but not easy of cultivation, and far less elegant than the wild kind, which is among the most favourite of our native flowers.

This vegetable is eaten by sheep and goats, but refused by cows, horses, and swine. The flowers when dried have a narcotic scent, and if reduced to powder excite sneezing; hence they are sometimes used as a sternutatory. A beautiful green colour may be prepared from the leaves, with the addition of lime. The lily-of-the-valley will grow in any moist, shady situation, and even under the drip of trees, where few other plants would succeed. It is multiplied by dividing the roots in autumn. See SOLOMON'S SEAL.

LILY, THE DAY (*Hemerocallis*, from *ἡμέρα*, a day, and *καλλος*, beauty; alluding to the beauty and duration of the flowers). This is an ornamental genus of exotic flowering plants of the

simplest culture, thriving well in any light loamy soil, and readily increased by divisions. The most common species are the yellow day-lily (*H. flava*), a native of Siberia, blowing yellow flowers in June, and the fulvous or copper-coloured day-lily (*H. fulva*), a native of the Levant, blowing fulvous flowers in July and August.

LILY, THE WHITE WATER. Candock, or water-socks. (*Nymphæa*, from *nymphæ*, a water-nymph; alluding to the habitation of the plants.) These are beautiful plants, well worthy of cultivating in every collection. The stove species should be grown in tubs of water, placed in a warm part of the house, with some rich loamy soil at the bottom. The hardy kinds may be grown in ponds, canals, &c. They are all increased either by seeds, dividing the roots, or separating the tubers. (Paxton.)

The great white water-lily (*N. alba*) is a beautiful perennial, native of Great Britain, perhaps the most magnificent of all its native flowers, growing in clear ponds and slow rivers. The root is tuberous, horizontal, sending down numerous long, stout radicles which are fibrous at the extremity; leaves floating, a span wide, oval, heart-shaped, with nearly parallel or close lobes at the base, entire, smooth. Every part of the herb is slightly vascular, perspiring rapidly, and, though so succulent, drying very soon. Flowers four or five inches wide, white, with yellow stamens and pistil; the upper surface of the calyx leaves white, often tinged with pale red, generally destitute of scent. The stems are superior to oak-galls for dyeing green. The roots are astringent, and a weak infusion is said to be useful in lepra. The roots are used in Ireland and Jura for dyeing a brown colour. The Egyptians eat the roots boiled, and convert the seeds into bread. The Swedes also have used this root in prevailing dearth, as a substitute for corn; though it requires to be previously divested of its bitter taste by frequent washings. According to Gleditsch, the roots of this species and of the yellow lily are equally useful in tanning and currying. This plant is eaten by hogs, but disliked by goats, and totally rejected by cows and horses.

The white water-lily looks very handsome in sheets of water, or ponds in ornamented grounds, blowing its large flowers in June and July. They have a faint, sweet scent, and expand in sunshine, in the middle of the day only, closing towards evening, when they recline on the surface of the water, or sink beneath it. The same circumstance is recorded of the Egyptian *N. lotus*, from the most remote antiquity. The stimulus of light, which indeed acts evidently on many other blossoms and leaves, expands and raises with peculiar force these splendid white flowers, that the pollen may reach the stigma uninjured; and when that stimulus ceases to act, they close again, drooping by their own weight to a certain depth. When the flower-seeds ripen in August, the plant sinks again to the bottom. In transplanting the water-lily, the pond must be entered, the stem of the plant felt for, and the roots dug up with a large ball of its mud left round them. place it in an old fish-basket, and remove it speedily, to sink it in the place intended for its

removal. As the basket rots, the plant becomes fixed in its new situation. Propagate by throwing the ripe seed-vessels into large ditches of standing water, when the young plants appear the following spring.

The *Great American Water-Lily*, one of the most splendid productions of floral nature, is comparatively a rare plant. It is found in a pond about a mile below the city of Philadelphia, and not far from Gloucester Point, a place much resorted to by naturalists and amateur florists during the season of flowering (August). Some have asserted a belief that the seeds were introduced from Europe; but the fact that a plant precisely similar is found in other parts of the country, and even in ponds along rivers west of the Mississippi (the Kansas and Osage, for example), proves the *Cyamus* or *Nelumbium* a native of North America as well as of India, where it is called the *Sacred Bean*, and consecrated to religious purposes. "There is not," says Professor W. P. C. Barton, "any plant in North America comparable to this for grandeur, simplicity, and beauty. Truly may it be styled, as I have elsewhere called it, the *Queen of American Flowers*. I regret to say that it is not as abundant in our vicinity as it was five years ago. This may be an accidental or temporary decrease, owing to a disturbance of the site where it grows. The leaves are perfectly round, and centrally peltate. They are from a foot to eighteen inches in diameter, of a rich velvety green above, and very pale underneath. They are supported by petioles from two to three and a half feet in length." The flowers are pale-yellow, globose, and about three or four inches in diameter, supported above the surface of the water by petioles or a scape, a yard in length, frequently *muricate* towards the upper part. From this circumstance, together with an accurate examination of a fine Chinese painting of the India species, which differed in nothing from the American plant, except in the rose-coloured flower, Dr. Barton considers the two species as identical.

The seeds are a kind of nut, very similar to the chinquepin, of a very pleasant flavour, and eagerly sought after by boys. The Indians in the Far-West resort to them as food.

Of the genus *Nymphaea*, the *Fragrant Water-Lily* is a species native to the United States, a very beautiful aquatic plant, with white flowers, which exhale a delicious fragrance. The leaves and flowers both float on the surface of the water. It is a perennial.

LILY, THE YELLOW WATER (*Nuphar*, from *naufar* or *nyloufar*, the Arabic name of *Nymphaea*). This, like the last described, is a genus of very beautiful plants, admirably adapted for growing in ponds, cisterns, or lakes; and they are increased by dividing the roots, or by seeds, which have only to be thrown into the water where they are intended to grow. (*Paxton*.)

In England, the only indigenous species are, 1. The common yellow water-lily, or water-can (*N. lutea*), which is met with very frequent in the wild state in rivers and pools. The whole plant is rather smaller than the white water-lily. Footstalks two-edged, flattened on the upper surface; leaves entirely smooth, and

even rounded at the end, and generally at the lobes, which meet and lap over each other. The flowers, which appear in July, are about two inches wide, cupped, all over of a golden yellow, with the scent of brandy or ratafia, whence they are called *brandy-bottles* in Norfolk. They perhaps communicate this flavour by infusion to the cooling liquors or sherbets, so much used in the Levant. The seed-vessel, a coated berry, when ripe, bursts irregularly, not dissolving away into a mass of pulp, like the *Nymphaea*. The roots, like those of the white water-lily, are astringent, and contain a quantity of fecula. If moistened with milk, they are said by Linnæus to destroy crickets and cockroaches. Hogs will eat this aquatic plant, but all the other species of live-stock reject it.

This aquatic plant is what is so familiarly known in the United States by the name of splatter-dock, a perennial, blooming its yellow globular flowers in July and August, filling ditches, and extending for miles along the shallow banks of rivers, below high water-mark.

2. The least yellow water-lily (*N. pumila*). This is much smaller than the preceding, and flourishes principally in the highland lakes of Scotland. The marsh-trefoil is often called the dwarf water-lily.

Of the genus *Nuphar*, another species (*Kalmiana*) found in the United States is the *Small Water-Lily*, with leaves floating like those of the common splatter-dock, but only about one-third the size; yellow flowers, also floating, and about half an inch in diameter.

LIME. The border of a flower; also the branch of a tree.

LIME (Germ. *leim*, glue). This very useful earth is the oxide of a metal called *calcium*. In England it is obtained by exposing chalk and other kinds of limestone, or carbonates of lime, to a red-heat,—an operation generally conducted in kilns constructed for the purpose: the carbonic acid is thus expelled, and lime, more or less pure, according to the original quality of the limestone, remains. In this state it is usually called *quick-lime*. The purest quick-lime is obtained from the calcination of white marble. When sprinkled with water it becomes very hot, and crumbles down into a dry powder, called *slaked lime*, or *hydrate of lime*, owing to the water becoming consolidated and an essential part of the lime. When exposed for some weeks to the air, it also falls into powder, in consequence of the absorption of moisture; but a portion of carbonic acid is also absorbed, and the lime partially converted into limestone. The uses of lime are very numerous. Its most important application is in the manufacture of mortar and other cements used in building. It is also very extensively used as a manure to fertilize land.

LIME as a manure. There is some reason to infer that lime has been used as a manure from a very-remote period. M. P. Cato, in the oldest agricultural treatise which has escaped to us, describes, in his sixteenth and thirty-eighth chapters, with much minuteness, the best means of preparing it. And although, in the early writers on rural affairs, we find but few notices of its use as a fertilizer, yet we may reasonably

conclude that its employment was nearly as extensive and as early as that of chalk or marl, which were in very primitive times largely and skilfully used for a similar purpose. Pliny attests the use of it by the Roman cultivators as a dressing for the soil in which fruit trees were planted.

Of all the earthy manures found in England, lime is certainly the most powerful and rapid in its effects on the soil; and if its use is not so extensive on the clays and peaty lands of many districts of the island as is desirable, this does not arise from the limited powers of this earth, but rather from a variety of other causes, such as its expense, the impurity of the lime employed, and an ignorance of its most economical mode of application.

The common varieties of lime used by the English farmers, are procured by calcining either chalk or limestone. Such lime is therefore rarely, if ever, chemically pure, for it almost always contains a portion of silica (flint), alumina (clay), and some red oxide of iron. These, however, are not often present in sufficient quantities to influence the fertilizing powers of the lime to any material extent, as will be readily seen by the analysis of the limestones and the chalk usually employed by the limeburners. Common limestone is composed of

Carbonate of lime	-	-	-	Parts.
Water	-	-	-	95.05
Silica	-	-	-	1.68
Alumina	-	-	-	1.12
Oxide of iron	-	-	-	1.00
				.75
				100.

The slate-spar limestone contains—

Lime	-	-	-	54.70
Carbonic acid	-	-	-	43.30
Silica	-	-	-	0.55
Oxide of iron	-	-	-	0.80
Loss	-	-	-	0.65
				100.

Common chalk is composed of—

Lime	-	-	-	56.5
Carbonic acid	-	-	-	43.0
Water	-	-	-	0.5
				100.

united with various small proportions of the other earths. There is also a very considerable proportion of lime made in the north of England from the magnesian limestone (called by the Yorkshire farmers "hot lime"), all of which differ considerably in composition; that from Sunderland contains, in 100 parts,

Carbonate of lime	-	-	Parts.
Carbonate of magnesia	-	-	56.80
Clay, water, &c.	-	-	40.84
Oxide of iron	-	-	2.00
			0.36
			100.

This "hot lime," which is well known by the farmers in the neighbourhood of Doncaster, and other parts of the north of England, can only be applied in limited quantities, for the calcined magnesia of the limestone remains for a considerable period in its pure caustic form, without absorbing carbonic acid gas

from the atmosphere, and in this state its effect is very pernicious to many kinds of plants. It is only when pure, however, that magnesia is prejudicial to vegetation: by exposure to the atmosphere, it gradually and slowly absorbs carbonic acid gas, becomes carbonate of magnesia, and in this state forms a part of many cultivated plants. Some of the most fertile soils of Britain, in fact, contain it in this form, in considerable quantities.

Limestone occurs of various colours and shades, as well as of different degrees of hardness. In weight the compact varieties are very much alike, being generally a little more than $2\frac{1}{2}$ times (2.7) heavier than water. Limestone may be distinguished from other varieties of rock, by dropping on it some strong acid, such as the acetic acid (vinegar), sulphuric (oil of vitriol), or muriatic (spirit of salt), upon the addition of either of which bubbles of gas are observed to escape when lime is present, but not otherwise.

The action of the fire upon the chalk and the limestones merely deprives them of their water and carbonic acid gas, or fixed air. The farmer must not fall into the very common error of supposing that any thing is added by the fire to the lime; on the contrary, it loses very materially in weight, by being deprived of its carbonic acid gas, burnt or quick-lime losing about 44 per cent. of its original weight, a loss, however, which it gradually recovers by exposure to the atmosphere, which always contains this elastic vapour.

One of the most remarkable properties of quick-lime, is its tendency to combine with water. If quick-lime be moistened with a certain quantity of water, it soon becomes heathed, throws off a portion of the water in the form of steam, and falls to a very fine, white powder, which is a hydrate of lime, always containing 24 per cent. water; if, however, more water be added, the same hydrate is formed, but the excess of water agglutinates the powder into lumps or masses which will eventually become hard, and resemble stone. Still more water immediately applied to quick-lime, dissolves it, and forms lime-water. If quick-lime be exposed to the air, it also falls to a coarser powder by absorbing 12 per cent. of water and 24 per cent. of carbonic acid from the air, constituting a mingled carbonate and hydrate of lime. The same change occurs gradually with that which has been slacked by water and is exposed to the air, the carbonic acid of the atmosphere-replacing the water of the hydrate. The carbonate of lime, such as exists in chalk, limestone, &c., is scarcely soluble in pure water, but if the latter contain carbonic acid, as rain water usually does when in contact with the soil, the limestone enters into solution. (*Booth's Geology of Delaware.*)

The lime which I have used, observes Mr. C. W. Johnson, has been principally made from chalk, at an expense of about five pence or six pence per bushel. That which I made from the magnesia limestone was from the neighbourhood of Sunderland. This requires less fuel to convert it into lime than the common limestone. For the ordinary kinds, about one bushel of coals is required for five or six

bushels of the limestone; and from my own experiments, I am inclined to agree in opinion with many of the farmers of the midland counties, that the lime procured from limestone is rather more powerful in its effects on clay soils than that made from chalk.

In either case the shape of the kiln, and the steady gradual application of the heat, are very material circumstances to be regarded by those who burn their own lime. The limestone and chalk should be placed in the kiln (which I think is best of an egg shape), in moderately-sized pieces, free from the powdered chalk or stone; and care must be taken to have the earth thoroughly burnt, of which perhaps the best indications are its lightness, and the alteration of the colour of the flame issuing from the top of the kiln, which, when the lime is sufficiently made, loses its red tinge. The price of the fuel, and readiness of access to the limestone or chalk, of necessity governs the price of the lime: in some districts of the north it is made by the farmers for not more than one penny to three halfpence per bushel.

The chemical uses of lime to vegetation may be conveniently divided into two heads; first, its direct action upon vegetation; and secondly, its chemical operation on the matters contained in all cultivateable soils.

In its direct action, as a food or constituent of plants, its uses are highly important; for hardly a single plant has yet been analyzed, in which the presence of lime has not been detected, in combination with an acid. It must be regarded indeed as an essential ingredient in almost all vegetable substances, as a direct food of plants.

It is found in the commonly cultivated crops of the farmer, however, in very varying proportions: thus the ashes of the oat-plant contain more than five per cent. of lime; in two pounds' weight of the seeds of wheat are commonly found about 12 grains of carbonate of lime; in the same quantity of rye, about 13·4 grains; in barley 24·8 grains; 33·75 grains in the oat, and 46·2 in the same weight of rye-straw. It abounds also with magnesia in the wood of trees: the ashes of that of the oak contain about 32 per cent. of the earthy carbonates; those from the poplar 27 per cent.; from the hazel 8; of the mulberry 56; and from the hornbeam 26 per cent. The proportion however of lime found in plants varies with the composition of the soil on which they are produced. Thus the ashes of the leaves of the fir (*Pinus abies*), growing upon a limestone hill, were found to contain 43·5 per cent. of the carbonates of lime and magnesia, but the ashes from the leaves of another fir growing upon a granite soil yielded only 29 per cent. of the same earthy salts. There are very few soils fit for cultivation from which this earth is entirely absent, and its addition is commonly found by the farmer to promote the fertility of most barren lands—the most sterile heaths, for these are the very lands whose soils contain hardly a trace of lime; in that of Bagshot, for instance, it exists in a very minute proportion. The attraction of lime for the aqueous particles of the atmosphere is considerable. In my own experiments 1000 parts of lime previous-

ly dried in a temperature of 212° gained by exposure for three hours to air saturated with moisture, at a temperature of 60°, 11 parts. Professor Schubler found that the same weight gained in 12 hours 26 parts, in 24 hours 31 parts, in 48 hours 35 parts, when it appeared to have become saturated with moisture, for in 72 hours it had not again increased in weight. Lime therefore is not without its uses even in this respect to vegetation. Lime and chalk differ in their action, and in their value as fertilizers in several respects; thus lime dissolves and renders soluble the organic matters of the soil, which chalk does not; its action, too, as a direct food of plants, is more rapid, from the superior readiness with which it mingles with the soil. And again, its carriage is considerably lighter, for in the process of lime-burning almost all the water and carbonic acid gas of the chalk are driven off. These amounted in some specimens of Kentish chalk, which I examined, to more than 58 per cent.; so that when the farmer carries 42 tons of recently well-burnt lime, he conveys as much real earth on to his land as is sometimes contained in 100 tons of chalk.

The chemical action of the lime on the soil is also very considerable; mixing with the heavy adhesive clays, it renders them more friable, less liable to be injuriously acted upon by the sun, and much more readily permeable by the gases and vapour of the atmosphere. It renders them, the cultivator tells you, "more easily workable." And, again, the action of lime upon the organic substances always more or less contained in the farmers' soils is very considerable; and this benefit is not merely confined to the vegetable remains in the land, but it extends with equal energy to the dead and the living animal matters, with which, in a countless variety of forms, the soil is tenanted. There are few substances, in fact, more destructive to grub-worms, animalculæ, &c., than lime; and where these are destroyed by the action of the lime, the soil is, as a natural consequence, enriched by their remains. On soils which abound in sulphate of iron, which is commonly the case with those containing an excess of peat, the action of lime is not only highly beneficial in decomposing or rendering soluble the mass of inert vegetable remains, but the lime decomposes the sulphate of iron, and, uniting with its sulphuric acid, forms the well-known fertilizer, the sulphate of lime or gypsum of commerce.

When quick-lime is applied to the soil, it gradually becomes converted, by exposure to the atmosphere, into carbonate of lime (chalk); its action as a solvent ceases, and its presence is now only useful as a direct food or constituent of the farmer's crops. This, however, affords an opportunity for the beneficial repetition of the dressing with lime, so far as its solvent powers are available. But then, as might, for the above reasons, have been anticipated, the farmer finds that the after-limings never do so much good as the first; and as by each successive application the lime reduces still more and more the quantity of organic matters in the soil, so it follows as a natural consequence that after each succeeding dress-

ing, the benefit produced becomes less and less, and finally the cultivator informs us that "the land is tired of lime." This result has been experienced to a very considerable extent in the north of England, where the cheapness of fuel and the abundance of the common limestone has, in too many instances, tempted the farmer to add to his land lime in excessive quantities. For such over-limed soils, the only remedy is the addition of organic matters. In such cases, peat will, in moderate quantities, be occasionally found an excellent dressing.

The quantity of lime used per acre of necessity varies with the soil, and the expense with which it is procured. The heavy clay and peat soils require the largest proportions; the light lands need a much smaller quantity to produce the maximum benefit. I have used it at the rate of 25 bushels per acre, mixed with earth, on light soils, and never more than 100 bushels per acre on clays. This is the proportion commonly used on the heavy soils of the midland counties, and the deep clays of the weald of Kent. In Scotland they apply sometimes as much as 360 bushels per acre, and in Ireland still larger quantities have been successfully employed; and on some of the peat mosses of the north of England, more than 1000 bushels have been used with good effect. The employment of such large proportions, however, can rarely be justified, even when the lime is obtainable at a very low rate.

I have used lime, and have been present at other liming operations for many years. I have chiefly employed it either as a top-dressing, or which, for light soils, I much prefer, mixed with ditch scrapings, old banks or pond mud, at the rate of one bushel of lime to a cubic yard of earth. And then, after thoroughly mixing them together, and allowing the mass to remain for a month or six weeks, I have always succeeded in forming a most enriching compost, which, on even the gravelly soils of Essex, applied at the rate of 20 to 25 cubic yards per acre, both for wheat, clover, and potatoes (to which crop, in general, lime is prejudicial), has produced the most powerful effects, certainly increasing by one-third the produce of the natural soil. It is only in the state of mixture with earth, or peat, or salt, that I have found lime profitably useful for light, gravelly soils. Yet I have varied the application in a variety of ways and proportions, but still, for the gravels or sands, the result was never entirely satisfactory. But I have witnessed, as a dressing for the black hungry gravels of Spring Park, near Croydon, lime and peat mixed together, at the rate of 1 part of lime and 3 parts of peat, with the most complete success. The peat is reduced to a finely-divided state, and rendered partially soluble by the action of the lime, and is a most powerful top-dressing for young clovers. This is explainable (amongst other reasons) by the fact that the peat employed being saturated with a solution of sulphate of iron, the lime converted it into sulphate of lime, which is a constituent or direct food of clover. Equally successful, on light soils, have been my trials of lime, when mixed with common salt; 2 parts of lime, mixed with 1 part of salt in a dry state, and

suffered to remain for three months previous to its being used in a dry place. By applying this mixture at the rate of from 40 to 50 bushels per acre, crops of turnips have been grown under my directions fully equal to any produced by 20 cubic yards per acre of farm-yard compost: and in 1840, the produce of ground thus dressed fully equalled that of some adjoining lands of the same field, which had been manured with the ordinary compost. And an excellent neighbouring farmer, Mr. Foster, of Great Totham, in July, 1840, made an experiment with turnips, entirely confirming those I had elsewhere instituted. He applied a mixture per acre of 30 bushels of lime with 15 bushels of salt, to 10 acres of a field containing 12 acres. The land previously had a crop of rye, which was fed off with sheep; and on the 2 acres to which the salt and lime were not applied, the sheep had oil cake given to them, and, moreover, the land was sub-soiled to a depth of 18 to 20 inches. The field previously had a good summer fallow. The lime and salt was spread broadcast after the last ploughing, and harrowed in before the seed. The turnips were of the variety called green rounds. The land slopes to the south, and its soil is a light, mouldy turnip soil. In examining them in company with Mr. Foster, in the last week in August, he expressed himself abundantly satisfied with the result. The crop of turnips was equally good all over the field; if there was a shade of difference, it was in favour of the sub-soiled and cake-fed land; but the advantage, if any, was exceedingly inconsiderable.

In the use of this mixture, I have found the moisture of the atmosphere highly advantageous in increasing the operation of the lime and salt; an observation, too, which is not confined to the dry, gravelly soils on which my experiments were carried on. Thus, in 1839, on an exhausted, rather heavy turnip loam, 80 bushels per acre of a mixture of salt 1 part, and lime 2 parts, made three months previously, were spread in July, and sown with the white round turnips. The turnip plants came up equally well all over the field; but on the portions where the salt and lime were omitted, they speedily perished; but in every part dressed with the lime and salt, the crop was excellent.

In the dry season of 1840, however, another portion of the same field being treated in a similar manner, the effect produced by the lime and salt was not nearly so decisive; the plants were weak, the crop inferior.

I have found the lime and salt equally beneficial as a dressing for wheat and barley; but a description of those experiments will more properly be found under the head **SALT** and **LIME**; for when the application is made to the land, the lime and salt have, in fact, entered into new combinations; the compound applied is no longer a dressing with lime and salt, but with a mixture chiefly composed of chloride of calcium and carbonate of soda, with a portion of undecomposed lime and common salt. I have several times mixed lime, in cases where I suspected the presence of grub and the seeds of weeds, with farm-yard compost,

but never successfully. Convinced of the ill effects of the lime being thus mixed, I have long since abandoned the practice. There is, in fact, no beneficial object to be attained by this mode. The natural well-regulated fermentation of the dung effects all that the lime can do, and in a better manner; for the lime dissolves, and, to a considerable extent, decomposes the finer and richer portions of the compost; and it certainly renders the straw and other coarser portions of the manure drier and more difficult to dissolve in the soil. The practice, therefore, seems worse than useless.

In the application of lime to heavy clay land, I have always found that it was best, used either in its simple uncombined state, or after an ultimate mixture of sandy or light calcareous earths, or peat, or salt. But by no means of applying it (and I have varied my experiments in a variety of ways with considerable industry) on the land, could I ever produce superior effects than by applying the lime in its uncombined state, as well burnt and finely divided as possible; and this I have generally done as a top-dressing (merely harrowing it in with the seed), from considering that by the soluble property of lime (1 lb. of lime dissolving in 480 lbs. of water), the rain always conveys it deeper into the soil.

And yet, from an experiment recently made at my suggestion by my next neighbour, Mr. Foster, a very excellent farmer of Great Totham, in Essex, I am inclined to believe that the lime will produce effects nearly equally important when it is ploughed into the soil. This trial was made in December, 1839, on a field of 5 acres, whose soil is a cold, stiff, deep, hungry loam, that had previously borne a very poor crop of turnips, which were fed off with sheep. This field has a declination towards the southwest, and has always produced crops of a very inferior description. In the middle of December, after spreading 80 bushels per acre of lime (made from chalk) from the cart's tail, by the shovel, it was immediately ploughed in and drilled with the common red wheat. The effect was excellent, every one of the neighbours agreeing that the land never produced such a crop before. And that this was owing to the lime, was evident from the inferior produce on the spots where the lime had not been spread.

The exact quantity, however, per acre, Mr. Foster is unable to state, owing to his being prevented in the hurry of harvest from keeping it separate: he estimates it, however, at about $4\frac{1}{2}$ quarters per acre, and he is clearly of opinion that this large produce (for his land) arose not so much from the thickness of the crop, as from the largeness of the ears.

In the boggy, unreclaimed lands of Spring Park, the effect produced by the direct use of lime, at the rate of 200 bushels per acre, is excellent. The cost is there 4 pence per bushel, and it is that made from chalk. But on the light, hungry, black gravels of that farm, as well in fact as upon the clays of that district (and the same remarks apply in general to almost all light soils and situations), the lime is never productive of such powerful effects as when mixed with the earthy matters from

ditches, ponds, old banks, or headlands. But here let me earnestly impress upon the farmer the necessity and the great advantage of paying much more than common attention to the mixing of the lime with the earth.

The lime should not only be of the best and *recently* burnt description, but should be mixed as thoroughly and as finely as possible with the earth. By this means the heat generated in the mass by the slaking of the lime is considerable, and is productive of several advantages: it kills more completely insects of all kinds—seeds of weeds, and the more stubborn roots of weeds. And the mixed earths are rendered considerably more friable, and capable of a much more even and economical distribution on the farmer's crops, than by the ordinary careless way of mixing them. On peat soils, and on those abounding in the tough inert remains of the heath plants, lime is best applied in its purest state, unmixed with any other substances to weaken its effect. Its action on such soils is not difficult of explanation. It dissolves and renders soluble the organic matters of the soil, and it decomposes the sulphate of iron (or green vitriol) which it often contains. In such lands, too, we rarely find any lime: it furnishes, therefore, to them a portion of an earth whose presence is absolutely essential to the profitable growth of all the most valuable vegetables. How excellent such an addition is to these soils, even when applied only at the rate of 4 bushels per acre, has been proved by some extensive experiments of the Scotch planter, the growth of whose young woods has been very materially and rapidly promoted by merely placing a handful of lime under each plant. Now we have already seen how copiously this earth is found in the ashes, not only of the fir, but in those of all other timber trees. So unvaried, indeed, is the presence of the salts of lime in vegetables, that they have been supposed to produce a similar supporting effect to that the same salts of lime yield in the bones of animals. And it is certainly worthy of remark that the phosphate and carbonate of lime, of which the bones of all animals are chiefly composed, are precisely the salts of lime the most universally present in vegetables.

Lime must, therefore, be classed amongst those manures which commonly serve to promote the *permanent* fertility of the land, for unless it is washed by the moisture of the atmosphere, or the flood waters, it can only be removed from the soil by becoming the food for the cultivator's crops. In poor, peaty soils, no other manure can be compared to it, either for powerful effect, or for rapidity of action; and its usefulness is nearly as great on the stiffest clay land. Whenever, therefore, the *permanent* improvement of such soils shall be considered with that general and that patient attention which the importance of the object demands, at that period the fertilizing powers of lime will be still more generally appreciated, and its services be far more extended than at present.

The quantity of lime applied per acre of necessity varies with the description of the soil; that which contains most organic matter will,

of necessity, bear a larger proportion than that which is more free from vegetable or animal remains. The quantity usually applied is much too large, and the dressing too often repeated without proper consideration; and it is not until the land becomes absolutely overcharged with lime, that the farmer begins to have a suspicion that his land is *tired* of it. In Ireland it is sometimes applied to old pasture leys intended for potatoes, at the rate of 400 bushels per acre; and on some of the moors in Derbyshire, 1500 bushels per acre have been found not too large a quantity. In Scotland the quantity usually applied for light land is about 160 bushels per acre; for stiff clay soils from 240 to 360 bushels. On the stiff clays of the Weald of Kent, the quantity usually employed is about 100 bushels per acre, and that is often repeated every 5 years, on the fallow before wheat.

Lime may be as readily produced by burning limestone with peat as with coals; the heat produced is amply sufficient, and the heat more easily managed.

According to the views of Professor Daubny and M. Prideaux, lime operates beneficially on some soils, by promoting the disengagement of potash and other substances, where these exist in the mineral materials, thus converting dormant *earthy* or saline constituents into agents active in the promotion of vegetable growth. The soil of a field exhausted by long-continued cropping, was found to yield double the quantity of potash, after being dressed with lime. The action, therefore, of lime upon the *earthy* matters of many soils, is exceedingly beneficial. The frequent application of lime, however, tends to exhaust such soils, by the rapid reduction of the proportion of their potash, which is not only furnished more copiously as a constituent to the growing crops, but by dissolution in the water becomes drained from the land.

Although beneficial, from these chemical effects exerted over the soil in setting free and rendering active some of its most fertilizing agents, it is generally admitted that the greatest benefit derived from the use of lime, is from its action upon the vegetable and animal matters with which it is brought into contact, when introduced into the soil. In numerous trials made by Professor J. F. W. Johnston, lime appeared to produce very slight benefits upon lands, in which organic (animal and vegetable) matter was deficient.

An ordinary liming will rarely amount to 1 per cent. of the entire weight of the soil. It requires about 400 bushels, or 12 or 15 tons of burned lime, per acre, to add 1 per cent. of lime to a soil 12 inches deep, or 2 per cent. when the depth is only 6 inches. The good effects of lime are most decided, when used as a top dressing and kept near the surface. A much smaller quantity will answer, when applied immediately upon being slaked with water, as in this state lime is quite soluble, but very slowly so, after it has been exposed to the atmosphere and become like chalk. See CHALK. When after slaking it has become too wet, so as to be cemented into lumps, these decompose so slowly, that they may be almost regarded as a dead mass.

The amount of lime taken from the soil by

crops, is far greater than is generally understood. Prof. J. F. W. Johnston states the weight of lime thus carried off in 25 bushels of wheat at 9 lbs.; 50 bushels of oats 9 lbs.; 38 of barley at 15 lbs.; 2 tons of rye-grass 33 lbs.; 2 tons red-clover 126 lbs.; 25 tons of turnips 140 lbs.; 9 tons of potatoes 270 lbs. This includes the lime in all its forms, and especially the all important phosphate in the grain. To this great source of exhaustion of the soil, must be added the lime which combines with several acid matters, forming compounds more or less soluble in water, in which state it is drained from the land, or sunk into the earth beyond the reach of plants.

Although light soils are most readily exhausted of lime, they possess the great advantage over heavy clays, of allowing the carbonic acid in rain water more ready access to the roots of plants, and atmospheric air more ready entrance to all decomposing manures, such as bones, fish, rape-cake, &c. This may afford an explanation of the cause why lime, as well as other fertilizers, frequently fail to show prominent benefits on certain lands. In order to act most favourably, they need the presence of carbonic acid and atmospheric air.

There is perhaps no other country so richly endowed with this earth as England, for, to say nothing of its great strata of chalk, how endless are the masses and varieties of limestones. Let us not therefore neglect, but extend, by every means in our power, the use of the treasures we possess; for by so doing we may not only increase the fertility of lands already (like the more tenacious clays for instance) in some degree productive of food, but we can bring into cultivation, by the judicious employment of this powerful earth, the most sterile peats, the trembling bogs, the most worthless heaths: the inferior plants, such as the acid sorrel, are banished by its influence, and the soil which once only held the stagnant water impregnated with unwholesome vegetable and mineral matters, is now made to produce the most useful of the cultivator's crops; and the improvement, too, is of even national importance, for such lands not only furnish additional employment to the labourer, but they now purify an atmosphere which their exhalations in an unimproved state once corrupted.

"Much has been written and said relative to the preservative and destructive effects of lime on organic manures, from which we learn that it operates both ways, according to its chemical state. If employed as quick-lime, and placed in contact with organic matter, its alkaline properties would lead us to infer a decomposing influence, which is confirmed by experience; but the effect is of short duration, and is succeeded by the reverse operation, that of preserving such matter from farther decomposition. The truth is, if we could insure a continuance of its caustic state, we might be equally sure of its constant decomposing power, but by this action it generates carbonic acid from the organic matter uniting with it and forming a neutral carbonate, which either acts like other salts in preventing decomposition by its *presence* or *catalytic* influence, or

being formed and hardened in the interior of the organized material, protects it from farther decay. For this reason it may be used to prevent excessive fermentation in the dung-hill; and to the same properties we may in part ascribe its utility in the soil, viz., that of permitting the slow and gradual decay of organic matter in quantities suited to the demands of vegetation. It has been supposed that the chief value of lime as a manure lay in its caustic or destructive effects, but that this position is untenable is proved by the successful application of marls, and even powdered limestone, which are robbed of their caustic qualities. Sir H. Davy and others who have written on the subject of agriculture, refer the utility of lime to its causticity, and state that 'chalk, marl, or carbonate of lime will only improve the texture of the soil or its relation to absorption; it acts merely as one of the earthy ingredients.' This view is unquestionably incorrect, for it has been known to produce astonishing effects on peaty soils, when applied in the form of carbonate and not caustic lime, and powdered limestone as well as marl have been successfully used on ordinary soils. Besides, if 'the formation of soluble matter from insoluble organic materials' be the chief effect of lime, this effect should take place immediately, while the lime is in its caustic state; but it appears that it soon becomes carbonated in the soil, or by exposure to the air, and yet its useful effects are more perceptible a considerable time after its application, and may be perceived for many years. Whence it appears that its action on organic matters in the soil is continued (probably not increased) in the soil after carbonation.

"Much of the vagueness in descriptions relative to the use of lime has arisen from an imperfect knowledge of the organic constituents of soils, which have lately been partially developed. Authors have divided the organic matter into soluble and insoluble, by the former of which we understand the humic, crenic, and apocrenic acids, and by the latter, humin, humus-coal, and vegetable fibre; and they state that lime is injurious where there is much soluble matter in the soil, as it forms insoluble combinations. The truth is, the humate of lime is partially soluble, the crenate somewhat so, and the bi-crenate very soluble. Now, by admitting these acids as active ingredients in soils, we are at no loss to account for the utility of carbonate of lime, for the weak affinity of the carbonic acid is overcome by their superior attraction, and more soluble salts are formed which may then be received into the rootlets of plants. There can be no doubt, however, that caustic lime is of greater benefit where a soil contains humin and vegetable fibre, as it promotes their incipient decomposition. The utility of lime, therefore, is threefold: first, that of decomposing organic matter, and rendering it a suitable nourishment for plants; secondly, that of combining with organic matter and rendering it capable of being received into the vessels of vegetable organization for promoting vegetation; and, lastly, that of lengthening the time of decomposition of organic matter, which, therefore, yields nu-

trition in proportion to the demands of a plant in the progress of its growth.

"It has been supposed by many to be necessary that lime should be caustic, as it is only then soluble, but it should not be forgotten that the carbonate is also soluble in water containing carbonic acid; and farther, it is not necessary that either the carbonate or quick-lime alone should be dissolved in order to explain its influence in vegetation, for moisture, the medium of chemical action, is always present in the soil, and assists in its soluble combination with the organic acids. There is, however, another action of lime with reference to the soil itself, which is of importance, viz., that it renders clayey lands looser, and sandy soils more tenacious. The latter of these contrary effects is of a chemical character, and there is little doubt that lime acts like mortar by combining the particles of sand together. The former is partly mechanical, the mingling of less cohesive earthy matter with the clay, and partly chemical, in which the lime dissolved by rains is washed into the crevices and cracks of the clay, where, becoming carbonated, it prevents their farther adhesion. To effect these results most powerfully, it is evident that the lime should be employed in a caustic or water-slaked state. According to these views, therefore, it is a matter of less moment on what kind of land lime should be spread, as it tends to ameliorate its condition or texture, and is the medium of conveyance of nutrition to vegetable life.

"Nearly all the limestone employed in Delaware for spreading on the soil is magnesian, and it is therefore worth investigating how far the magnesia may be injurious. One of the first limestones employed for this purpose in Pennsylvania, from which lime derived much of its reputation as a manure in this section of country, and which has not lost its character to the present time, is nearly of the same composition with Jeanes' stone; a very fair proof that such a content of magnesia is not injurious under certain circumstances. Sir H. Davy's view of the subject appears to be correct, that magnesia in a caustic state is injurious, but that when carbonated it is beneficial. It was stated that it remains caustic for a long time exposed to the air, and particularly when mingled with lime; therefore, in employing a magnesian limestone, if there is little vegetable matter in the soil it will be apt to injure the crops; but this effect may be obviated by mingling it with fermenting manure, which will rapidly carbonate it. There is another view of the subject which has never been broached, viz., the influence of the organic acids in the soil. If much humic acid be present, it will form humate of magnesia, soluble in 160 parts of water, while humate of lime requires 2000, so that it will be taken up in greater quantity than lime. But by referring to the quantity required by plants as shown by an analysis of their ashes, we find that oak requires about 5½ times as much lime as magnesia, and that ashes of straw yield nearly 12 per cent. of carbonate and phosphate of lime, and no magnesia, from which it would seem that the latter is injurious to plants from its

excess where humic acid is abundant. But if the soil contain much humin, and other insoluble organic matter, its action in a caustic state would be beneficial like that of lime. We have, therefore, in Delaware abundant means of rendering magnesian lime useful, by employing it in conjunction with peaty matter, the black soil of marshes, creeks, &c." (*Booth's Geology of Delaware.*)

All the grain crops, as well as those of grass, are greatly benefited by judicious applications of lime in some of its various forms. Oats take up a larger proportion than almost any other grain, and hence are observed to be specially benefited by lime. Rye and Indian corn are also greatly benefited by lime, and with regard to wheat, the following strong testimony is from Dr. Jackson, the able American chemist and geologist. "I find," he says, "by chemical examination of several soils, that a very minute quantity of carbonate of lime, viz. from one to two per cent., is amply sufficient to render them capable of bearing heavy crops of good wheat. I am also satisfied that a soil is incapable of producing wheat of good quality if it does not contain carbonate of lime, for this substance is an essential ingredient of this grain."

It has been computed that every person who consumes 1 lb. of wheat bread daily, will, in the course of one year, take into his system 3 lbs. 6 oz. 3 drs. and 44 grs. of phosphate of lime. "This circumstance is supposed to explain the reason why this kind of bread is so superior to that made of other grain, as phosphate of lime forms a principal element of human bodies. It is found in milk, where nature seems to indicate that it is contained for the nourishment of the young animal, from the remarkable fact that, when they are able to take other food, the milk loses its proportion of this substance. Although phosphate of lime is contained in considerable quantities in the adult secretions, it is not known in those of the young, being all taken up for the purposes of nutriment. The shells of eggs are formed of this substance, and Dr. Paris has ascertained the singular fact that, if the legs of a hen be broken, she will lay her eggs without shells until these are repaired, for which the lime is required. Hens will also lay their eggs without shells if there is a deficiency of lime in the yard in which they roam. It is a remarkable circumstance, that although the grain contains the phosphate, the straw contains the carbonate of lime. Carbon is, next to water, the principal support of vegetation." (*Cultivator.*)

Lime-Kilns and Burning.—A lime-kiln is a furnace or rough structure erected for the purpose of converting limestone into the lime of commerce, by keeping it for some time in a white heat.

The forms of lime-kilns vary; but the best is that of the frustrum of a cone, which permits the ignited mass in the upper part to settle down freely as the lower portion is drawn out. In some places the kilns are sunk in the earth, in the form of inverted cones, and lined with brick. It is calculated that such kilns will burn 150 bushels of lime in 24 hours. When chalk is used, and it is dry, 5 bushels may be burnt with one bushel of coals; but the damp-

ness of the chalk lessens considerably the power of the fuel. Peat is sometimes used instead of coals, and some burners prefer it to coal. Whatever the fuel may be, that is the best which prevents the lime from running together in masses. The best test of the lime being sufficiently calcined is its slaking, and falling into complete powder when water is poured on it.

Some excellent practical remarks upon lime burning, by Sir G. C. Stewart Monteath, were published some time since. He observes:—"Having been engaged in burning lime for the supply of an extensive district of country for agricultural improvements, and being distant from coal 16 miles, it was desirable to find out the best constructed kiln for burning lime with the smallest quantity of coal, and having been aware, from experiment, that the kilns generally employed in Great Britain for burning lime are of a construction too narrow at bottom and too wide at top, many kilns of this construction being not more than 3 or 4 feet wide at bottom, and 18 feet wide at the height of 21 feet, were found to waste the fuel during the process of calcining the lime, or, in other words, did not produce more than two measures of burnt lime shells for one measure of coal; but it is to be understood that, in whatever construction of kiln lime is burnt, the fuel required to burn limestone must vary according to the softness, or hardness, or density of the stone, and the quality or strength of the coal used. The same measure of coal in Scotland called chews, when employed, will burn a greater quantity of lime in a given time than the same quantity or weight of small coal, the chews or small pieces of coal admitting the air to circulate more freely through the kiln. Though this fact should be well known to lime burners, yet they frequently employ small coal in burning lime, from its being procured at a less price, though really at a greater expense, as it requires a much larger quantity to produce the same effect, and a longer time to admit of equal quantities of lime being drawn out of the same kiln in a given time.

"For a sale of lime for agricultural purposes in a limited district, I have found kilns of small dimensions to be most profitable; the construction of a kiln I have employed for many years was of an oval shape, 5 feet wide at bottom, widening gradually to 6 feet at the height of 18 feet, and continuing at that width to 28 feet high from the bottom. A kiln of this construction has been found to burn lime in much less time, and with a smaller proportion of fuel, than kilns of larger dimensions narrow at bottom and wide at top, as heat is well known to ascend more rapidly in a perpendicular than in a sloping direction, from which arises the superiority of a narrow kiln, with sides nearly perpendicular, compared with one with sides that slope rapidly.

"These narrow kilns will admit of being drawn out of them every day, if fully employed, more than two-thirds, or nearly three-fourths, of what they contain, of well-burnt lime; and afford fully three of lime shells for one measure of coal, when large circular kilns will not give out more than one-half of their contents every

day, and require nearly one of coal for every two measures of lime burnt. In a country sale of lime, the quantity sold every day is liable to great fluctuations: two or three cart-loads will sometimes only be required from an establishment which, the day before, supplied forty; and as lime is known to be a commodity, when exposed to the action of air, which becomes more bulky and heavy, and in that state does not admit of being carried to a distance without additional labour, it has been an object of importance with me to find out a construction of a kiln which will allow of lime being kept for several days without slaking, and at the same time to prevent the fire escaping at the top of the kiln, if the kiln stands 24 hours without being employed, especially during the autumn and winter, when the air is cold and the nights long. I now employ kilns of an egg shape, and also oval; the oval-shaped kilns are divided by arches across the kiln, descending 4 feet from the top; the object of the arches across the kiln is to prevent the sides of the kiln falling in or contracting, and also to enable you to form circular openings for feeding in the stone and coal at the mouth of the kiln; upon this plan, a kiln of any length might be constructed with numerous round mouths. In the model of the kiln sent to the Highland Society, Booker's conical cover may be seen revolving upon an iron ring placed upon the circular mouth, and having placed a lid to the cover, I am enabled to prevent the escape of heat at the top, and by cast-iron doors at the bottom the air is prevented passing through the kiln; so that, by these precautions, the lime burner can regulate the heat, and prevent its escape for several days, when the fire would be extinguished at this season in the course of 24 hours. This is an object of great importance, as it enables the lime to be burnt as well, and with as small a quantity of fuel in the winter as the summer season, and to supply the farmer with as well burned lime, and at any time of the year, which cannot be done in the common construction of kilns, open both at top and bottom, for the reasons I have before stated. From the great expense attending the driving of fuel from a distance of 25 miles from my own coal-pits, I have adopted the practice of coking the coal, which is a saving of eight-twentieths of the weight; and I find that an equal measure of coal and coke furnish the same quantity of heat in burning lime, which is somewhat paradoxical, but not the less true. The coal is found to have little effect upon the stone till it is deprived of its bitumen, or is coked in the kiln; for, during the time the smoke is emitted from the top of a lime kiln, little or no heat is evolved. A kiln in which coke is the fuel employed, will yield near a third more lime shells in a given time than when coal is the fuel; so that coke may be used occasionally when a greater quantity of lime is required in a certain time than usual, as it is well known to lime burners that the process of burning is done most economically when the kiln is in full action, so as almost constantly to have a column of fire from the bottom to the top of the kiln, with as short intervals as possible in working the kiln.

"In working a kiln with narrow circular

mouths, the stone and coal should be carefully measured, so that the workmen can proportion the fuel employed to the quantity of stones, and it is obvious that the quantity of coal to be used must depend upon its relative quality and the hardness of the stone to be burnt. If this measure was adapted to kilns of any construction, the lime snells would be found better burnt.

"Circular kilns are constructed with similar eyes or openings at the bottom, and not more than 8 feet wide at 18 feet from the base, and contracted to 4 or 5 feet wide at top. In lighting the kiln at the commencement of burning, some care should be taken not to allow the fire to remain below the upper grate. There are two iron grates at the bottom of the kiln: the upper grate consists of iron bars 8 or 10 inches distant from each other across the kiln, between which the pieces of burnt lime fall down upon a lower grate with iron bars one inch from each other, which allows the lime ashes to fall through them into an ash pit; these lime ashes are found very useful as a top-dressing for grass ground, and are a clear gain to the proprietor of lime-kilns for public sale. As a burner of lime for agriculture in an extensive district of country to the extent of 150,000 imperial bushels annually, the value of the lime ashes which fall through the lower grate amounts to more than 150*l.* annually; the lower grate is 3 feet above the ground, and the upper grate is the same distance from the lower one. The kilns I employ at Closeburn are upwards of 30 feet high, and nearly perpendicular, which is the cause of the great heat in this construction of kiln, and which is found to burn lime more equally than circular kilns of large dimensions. (*Trans. High. Soc.* vol. ii. p. 127.)

The limestone quarries of Scotland are described by Mr. Carmichael (*Ibid.* vol. v. p. 57): he observes, when speaking of the uses of this valuable earth, "how sterile must have been the soil, how cheerless the dwellings, and how scanty the resources of Britain before lime came into general use." And on the method of calcining limestone in some of the limestone quarries in Scotland there is a paper. (*Ibid.* p. 441.)

Limestone Gravel.—There are some traces of this manure in the Isle of Anglesea; but in general, it is seen in quantities only in Ireland, where it is very common. It is in appearance only common gravel, of a blue colour, mixed with stones as large as a man's fist, and also with loam or clay: it has a strong effervescence with acids, and, when used, is attended with the usual effects of marl or lime. For bogs, it exceeds every other manure, as its weight assists in the improvement of that loose and spongy soil. Upon strong clays, the use of it is unrivalled, for it has all the effect of a dressing of lime, and gives friability yet more than chalk does. It destroys moss infallibly. Upon whatever soil it is used, it is found very durable, lasting, in many instances, in great heart, from twenty to forty years. In limestone counties, all blue gravels should be examined; for it is an invaluable treasure, wherever found.

LIME or LYME GRASS. See ELYMUS.

LIME PLANT. A name applied in the Northern and Eastern States to the indigenous plant called in the Middle States May Apple (*Podophyllum peltatum*).

LIMESTONE. A generic term for those varieties of carbonate of lime which are neither crystallized nor earthy; the former being *calcareous spar*, the latter *chalk*; when burned, they yield *quick-lime*. See GEOLOGY, CHALK, LIME.

LIME TREES (*Tilia*). These are for the most part ornamental, lofty-growing trees, well suited for avenues and parks. They thrive in any soil, and are increased by layers or seeds; if by layers, the tree must be cut down close to the ground, and from its roots a great number of shoots are produced in the following year: these will be strong enough to lay down the succeeding autumn. Trees raised from seed are far preferable to those raised from layers. The Russian bass-mats are made from the inner bark of the lime tree, while the wood, from its being light and white, is much used by the carver and musical instrument maker.

The charcoal is used in the manufacture of gunpowder, and is considered as scarcely inferior for that purpose to the charcoal produced from the alder and willow. If we possess no evidence sufficiently conclusive to prove that the lime tree in any of its forms is truly indigenous in Britain, we have at least enough to show that it has long been naturalized, and that its introduction must have taken place at a very distant period; for, upon referring to the earlier works, such as Turner, Gerard, &c., we find it (in the form of *T. E. microphylla*) spoken of as a well-known, and in their estimation, apparently, as a native tree. By many botanists (says Mr. Selby), several species of lime are enumerated as inhabitants of Europe; and Sir J. E. Smith makes three distinct species of those cultivated and grown in Britain; viz., *T. Europæa*, *T. grandifolia*, and *T. parvifolia*, the two latter answering to the *T. platyphylla* and *T. microphylla* of other authors. We are, however, continues Mr. Selby, inclined to adopt the views and follow the opinion of the author of the *Arboretum Britannicum*, and to consider these not as specifically distinct from *T. Europæa*, in its usual form, but as marked varieties, or, as Mr. Loudon designates them, *races*, originally produced from the seed of one, and which have been kept distinct, and perpetuated by means of layers, grafting, and other artificial modes of propagation; a view we think strongly corroborated by the fact that the seeds of the different kinds, or supposed species, do not always produce plants exactly similar to the trees from which they are gathered, but run into varieties, the seed of *T. E. platyphylla* often producing plants similar in every respect to those of *T. Europæa* (the common lime), and so with the other kinds.

The lime tree appears to have been held in repute in ancient as well as in modern times; for we learn from Theophrastus that it was known to the Greeks; and Pliny speaks of it as a tree held in high esteem by the Romans, not only for the ornament and shade it afforded, but for the qualities of its wood, and the various purposes to which it was adapted. Nearly two hundred years have elapsed since it was plant-

ed along the streets of continental as well as English towns, where their width would admit of it, as affording a pleasant shade and protection during the summer heats, and it was extensively used in that style of gardening called architectural, as it bore cutting with the knife or shears with patience and comparative impunity. Examples of this style still exist in some parts of England, and are frequent upon the Continent, in France and Holland, where pyramids, arches, and colonnades are formed of this tree, and sometimes these produce an imposing effect. As an ornamental tree in picturesque gardening, the lime is well worth cultivating, as it ranks in the first class in point of magnitude, frequently attaining a height of eighty or ninety feet, and a trunk corresponding in circumference to such an altitude. The lime holds an important place in the *Materia Medica* of France and other continental countries; but its medicinal powers are very feeble.

Loudon, in his *Encyclopædia of Plants*, enumerates eight species or varieties of the linden or lime tree (*Tiliaceæ*). 1. *Tilia rubra*, the red or common linden. 2. *T. intermedia*, or intermediate. 3. *T. parvifolia*, or small-leaved. 4. *Platyphylla*, or broad-leaved. All these are found indigenous in the woods of Britain. 5. *T. Americana*, American lime or linden. (See BASS-WOOD.) 6. *T. pubescens*, downy and thin-leaved lime tree. 7. *T. heterophylla*, or various-leaved lime tree. The three last-named species are indigenous to North America. 8. *T. alba vel argentia*, the white or silver linden, which is stated to be a native of Hungary.

Michaux has described the three American species of lime tree, one of which has been already referred to under its common name of Bass-wood. The American white lime is doubtless a distinct species from the *Tilia alba* of Hungary.

"I have not," says Michaux, "met with the white lime tree east of the river Delaware, but it is abundant in Pennsylvania, Maryland, Delaware, and the Western States. It does not grow, like the preceding species, in elevated places, nor amidst other trees in the forests, and is rarely seen except on the banks of rivers. I have particularly observed it on those of the Susquehanna, the Ohio, and the streams which empty into them.

"The height of the white lime tree rarely exceeds forty feet, and its diameter twelve or eighteen inches. Its young branches are covered with a smooth, silver-gray bark, by which it is recognised in the winter. The leaves are very large, denticulated, obliquely heart-shaped and pointed, of a dark-green on the upper surface, and white beneath, with small reddish tufts on the angles of the principal nerves. This whitish tint is most striking on solitary trees exposed to the sun.

"The flowers come out in June, and, as well as the floral leaf, are larger than those of any other lime tree with which I am acquainted. The petals are larger and whiter, and are impregnated with an agreeable odour. The seeds are round, or rather oval, and downy.

"The wood of this tree is white and tender, and I believe it is never employed in the arts.

"This and the folk-song species have re-

ceived no popular specific names, but are both called lime tree and bass-wood: that of white lime, which I have given to this species on account of the colour of its foliage, is peculiarly appropriate.

"The Downy Lime Tree belongs to the southern parts of the United States. It grows on the borders of rivers and large marshes, where the soil is cool and fertile, but not exposed to inundation. It is little multiplied, and consequently is not taken notice of by the inhabitants; for this reason, and because it is the only species of its kind in the maritime parts of the Carolinas and of Georgia, it has received no specific denomination, and is called simply lime tree; to which I have added the epithet *downy*, derived from a character of its foliage not observed in the preceding species.

"This tree is forty or fifty feet in height, with a proportional diameter. In its general appearance it resembles the American lime tree, which grows farther north, more than the white lime tree, which belongs to the Middle and Western States. Its leaves differ widely in size, according to the exposure in which they have grown: in dry and open places they are only two inches in diameter, and are twice as large in cool and shaded situations. They are rounded, pointed at the summit, very obliquely truncated at the base, edged with fewer and more remote teeth than those of the other lime trees, and very downy beneath. The flowers, also, are more numerous, and form larger bunches, and the seeds are round and downy.

"The wood is very similar to that of the other species, and I do not know that it is ever employed."

In some parts of Europe, the honey gathered by bees from a species or variety of the linden is in great request for its superior qualities, and real or supposed healing virtues. It would be highly desirable to have a tree introduced into the United States which offers such a great resource to the bee culturists. See HONEY.

Insect enemies.—The European species of lime or linden, which has been extensively introduced into the United States as an ornamental tree, has suffered greatly of late years from the attacks of several destructive insects. Some of these are in the form of long, dark-coloured worms or caterpillars, with strong webs, which eat off the foliage; others bore into the wood of the body and branches, chiefly in the crotches, and so destroy the strength of the limb, or the body itself, that one or both yield readily to the wind, or gradually decay and die. There are also the leaf-beetles, the most elegant of the family of *Chrysomelians*, which inhabit the leaves, not only of the linden, but of the elm, the broods being found in April, May, and June, and even a second brood in September and October. The trees are often seriously injured by these flies or beetles and their larvæ. After a very minute description of this beautiful leaf-beetle, with its dark-green body, silvery-white wing-covers, ornamented with green spots, and rose-coloured wings, Dr. Harris remarks that he thinks the grubs go into the ground to turn to pupæ. When they become so numerous as seriously to injure the lime and elm trees, Dr.

Harris recommends the employment of decoctions of tobacco or of walnut leaves, thrown on the trees by means of a garden or fire engine; a method which has been tried with good effect for the destruction of the larvæ of *Galeruca californiensis*, which appear occasionally in swarms, and entirely strip the leaves from the elm trees in midsummer. Dr. Harris describes a species of lime-looper which proceeds from an umber-moth greatly resembling that known in Europe, and called by naturalists *Hybernia defoliaria*. The American insect, however, differs so much in the larva state from the European, as to entitle it to be classed as a distinct species; and accordingly Dr. Harris has called it *Hybernia tiliaria*, the lime tree winter-moth, from *Tilia*, the scientific name of its favourite tree. The fore-wings of the male moth are rusty buff or nankin-yellow, sprinkled with very fine brownish dots, and banded with two transverse, wavy, brown lines, the band nearest the shoulders being often indistinct. In the space between the bands, and near to the thick edge of the wing, there is generally a brown dot. The hind-wings are much paler than the others, and have a small brownish dot in the middle. The colour of the body is the same as that of the fore-wings; and the legs are ringed with buff and brown. The wings expand one inch and three-quarters. The body of the female is grayish or yellowish-white; it is sprinkled on the sides with black dots, and there are two square black spots on the top of each ring, except the last, which has only one spot. The front of the head is black; and the antennæ and the legs are ringed with black and white. The tail is tipped with a tapering, jointed egg-tube, that can be drawn in and out, like the joints of a telescope. Exclusive of this tube, the female measures about half an inch in length. The eggs are beautiful objects when seen under a microscope. They are of an oval shape and pale-yellow colour, and are covered with little raised lines, like net-work, or like the cells of a honey-comb.

As these span-worms appear at the same time as canker-worms, resemble them in their habits, and often live on the same trees, they can be kept in check by such means as are found useful when employed against canker-worms. See SPAN-WORM.

LINDEN TREE. See LIME TREE.

LINEN (Germ. *lienwand*). A species of cloth woven with the fibres of the flax plant. The linen manufacture has been prosecuted in England for a very long period; but though its progress has been considerable, particularly of late years, it has not been so great as might have been anticipated. It is only within the last fifty years that any machinery has been used in the production of linen cloth; the first mills for the spinning of flax having been constructed at Darlington, about forty-eight years ago. The principal seat of the manufacture is, in England, Leeds and its immediate vicinity, and in Lancashire, Dorset, Durham, and Salop; in Scotland, Dundee, which, indeed, may be regarded as the chief seat of the British manufacture; and in Ireland, the province of Ulster. The entire value of the linen manufacture of Great Britain and Ireland is estu

mated at 8,000,000*l.*, and the total number of persons employed in it, about 185,000.

LING (*Calluna vulgaris*). A species of heath. To avoid the inconvenience of giving a new generic appellation to the hundreds of plants familiar to everybody as *Ericæ* or heaths, Mr. Salesbury has judiciously called our common ling *Calluna*, from *καλλιωνο*; which is doubly suitable, whether with Mr. Salisbury and Dr. Hull we take it to express a *cleansing* property, brooms being made of ling, or whether we adopt the more common sense of the word, to *ornament* or *adorn*, which is very applicable to the flowers. This shrub grows almost everywhere, on dry moors, heaths, and open, barren wastes, as well as in woods where the soil is sandy or turfy. The stems are bushy, repeatedly and irregularly branched. Leaves deep green, minute, sessile, acute, keeled, somewhat arrow-shaped, closely imbricated on the young branches, making a quadrangular figure, like a close-beaten chain; they are generally smooth, but in one variety are densely hoary all over. The flowers are stalked, drooping, in longish unilateral clusters, soon overtopped by leafy shoots. The inner calyx, which is the most conspicuous part of the flower, is of a shining permanent rose colour. The flowers appear in June and July. Grouse and other birds, as well as some quadrupeds, eat the seeds and young shoots. There is a white-flowered variety, and a very beautiful double red one, cultivated in gardens, whose flowers, from a copious multiplication of the corolla, resemble little roses. See **HEATH**.

LINIMENT (Lat. *lino*, I anoint). In farriery, a semi-fluid ointment, or a soapy application to rub upon painful joints. The term is also applied to spirituous and other stimulating applications for external use. Liniments are intended either to lubricate or to stimulate; but in either case they can only be regarded as topical applications, their influence not extending beyond the part to which they are applied. In some instances they are anodyne; and contain solutions of opium in oil.

LINSEED or **FLAXSEED** (Lat. *lini semen*; Germ. *Leinsaat*). The seed of the flax plant. See **FLAX**. This seed is small, oval, oblong, flattened laterally, acute at the extremities, glossy, brown; but internally white. It is inodorous, and tastes mucilaginous and oily. The husk or testa yields much mucilage to water, and the kernel a large proportion of oil to pressure. Besides upwards of 11 per cent. of oil, linseed contains wax, an acrid soft resin, extractive, a yellow colouring matter, starch, gum, tannic acid, albumen, gluten, emulsive, and some salts. When the seeds are burnt, the ashes contain oxide of copper. The infusion of linseed in boiling water yields a demulcent mucilage, which is much used as a domestic medicine in coughs, and in cases of acrimony in the urinary discharge. The linseed should not be boiled in the water, as that extracts the oil as well as the mucilage, and renders the decoction nauseating.

Linseed is much used in the economy of the farm, for feeding cattle and other purposes. A bushel of linseed averages in weight about 51 pounds; this weight, when crushed, produces

about a quarter of its weight of linseed oil, and the remainder is cake. The great bulk of this seed is obtained from the Baltic and the Black Sea, and recently considerable quantities have been received from Egypt and Hindostan: of this last, the general character is, that although the seed is good, the impurities with which it is mixed are very considerable, such as the seeds of rape, &c.; for which reason the oil obtained from it does not possess the drying qualities of that expressed from the unmixed linseed, and the dealers in consequence will not give so much for it. This arises not from any intentional adulteration, but from the bad farming and want of cleanliness of the orientalists.

Linseed oil contains a very considerable quantity of mucilage, which it almost entirely deposits by time; and hence, old linseed oil is more valued by the painter, but for the grazier, perhaps, its nutritive powers decrease by time. It is said by some persons, that it is to the presence of this mucilage that we must attribute the fattening quality of linseed oil when mixed with other substances, for linseed oil by itself is almost as powerful a purgative as castor oil, for which purpose indeed it is very commonly employed by the farmer; but on the other hand, we must remember, that in small doses, even castor oil is very fattening. Linseed is in fact commonly given to some birds, parrots for instance, for this purpose. Its purgative properties are very inferior to those of castor oil.

LINSEED CAKE. Linseed cake is a well-known and valuable article for the food of live stock, almost equally good for cattle, sheep, and horses. It is the residuum, or refuse, left after the oil is expressed from linseed. 1000 parts of it, according to Davy, contain about 151 parts of nutritive matter. Its price has induced many attempts to economize its application. It has been often given as recommended by Mr. Hillyard, mixed with other substances, whose value he thus estimates:—

“The weekly cost of feeding each beast, including the expense of getting up, carting, and cutting the turnips and hay, and attendance, will be—

10½ bushels of turnips	-	-	s.	d.
1½ cwt. of hay	-	-	2	9
			5	3
			8s.	
Turnips	-	-	2	9
1½ cwt. of cut and uncut hay	-	-	3	9
¾ bushel of meal	-	-	3	0
1 pint of linseed oil	-	-	0	6
			10s.	
½ bushel of linseed	-	-	3	6
3 gallons of meal	-	-	1	6
Cut and uncut hay	-	-	3	9
Turnips	-	-	2	9
			11s. 6d.	
21 oil cakes, at 3½d.	-	-	6	0
3 gallons of meal	-	-	1	6
Cut and uncut hay	-	-	3	9
Turnips	-	-	2	9
			14s.	

“No food,” says Mr. Hillyard, “can be given to stall-feeding beasts that will fatten them so soon or so well as linseed oil-cake. It certainly is expensive feed, but not so expensive as it appears to be, taking into consideration that it fattens quicker. Beasts that have been fed with it, do not, after a long drift to market, lose their firmness of handling, as those do, fed

without either cake or linseed, and whose dung is not of equal value. Some winters I have fed with linseed instead of cake, and found it answer very well, although it added to the trouble of feeding. My mode of preparing it has been to break it in a little hand-mill, and steep it in cold water in seven tubs of a size sufficient for one day's feed; in this way it will have been steeped seven days before it is mixed with cut hay and barley, or (which is better) bean meal. If steeped in hot water, two days will do; if steeped longer than three, it is apt to get a little sour, which, in my opinion, is not quite so well for the beasts. Boiling it is troublesome, but it thus becomes more of a jelly, and mixes better with the cut hay and meal, and it prevents the numerous seeds of weeds, found in foreign linseed, from vegetating. One stone of linseed, in a mixture of other food, will do as much towards feeding as two stone of cake, which is merely the husk of the seed after the oil has been pressed out. Linseed, without being mixed with meal, is of too relaxing a nature.

"Finding at Christmas, 1838, that I could not get English oil-cake at home at less than about 12*l.* 10*s.* per ton, I determined to feed the 35 beasts then in my stalls, in the following way, and I never had beasts that became better meat; but as the process of preparing the food is very troublesome, I should not recommend this way of feeding without the owner of the beasts will daily see that all is done right:—

	s.	d.
Three feeds daily, of half a bushel of cut hay, which is 5 lbs. each, and 4 lbs. uncut at night; 1 cwt. and not quite a quarter	3	6
Boiled linseed, 2 lbs. daily, 56 <i>s.</i> per quarter; weight, 50 lbs. per bushel	2	0
Boiled potatoes, 2 lbs. daily, 1½ gallons	1	6
Molasses (which is feeding, but may be left out when the beasts have taken to the linseed, as it is only given to make the mixture palatable), about a ½ lb. daily	0	9
Turnips, or mangel wurzel	2	6
Barley and bean meal, mixed, 3½ gallons	1	9
	12	0

"If this mixed food could be pressed together to form a cake, it would be a feeding one, and the cost 11*d.* per stone. As a proof that this mixture is both palatable and nutritive to beasts, they will not eat, excepting in the night, where they have none of it, any of the sweetest hay that can be put before them." (*Prac. Farm*, p. 89.)

Many farmers use ground linseed mixed with bran and chaff for their stock, deeming it a more economical plan than the employment of linseed cake. Others use the linseed unground. The saving by this mode, however, is doubtful, for it is by no means certain that the oil possesses any very material fattening properties; and if it does not, then the cake is decidedly the cheapest. For at the present prices (1841), 51 lbs. of linseed are worth 7*s.* 6*d.*, while 51 lbs. of cake, at 11*l.* per ton, are only worth about 5*s.*; and admitting that the oil does contain some fattening properties, yet it must be remembered that the value of the oil obtained from a bushel of linseed is worth, for other purposes, about 4*s.* But, on the other hand, I am aware that a very intelligent farmer near Rumford, Mr S Poole, who, in 1840, fed

his bullocks with a mixture of linseed oil and cut chaff, and also other bullocks with linseed cake and hay, considered the oil to be the cheapest of the two, and in all respects equally fattening, but then it is certain that this mode requires more attention in the mixture of the oil and chaff than the other plan. He commenced with about a quarter of a pint per day, and gradually increased it to a pint.

The reported results of experiments in feeding cattle with linseed do not always agree. In a standard work we find the following passage: "Two Scots were fed on English linseed cakes; two Devons on unboiled linseed; two others on boiled linseed; and another pair of Devons on foreign; all of them having as much hay and chaff as they could eat. It was a losing concern in every case. The value of the manure was not equal to the difference of the cost and the selling prices; and, strange as it may appear, the greatest loss was sustained, when the beasts were fed on oil-cake; the next when foreign cake was used; the next when boiled linseed was used; and the least of all when the simple unboiled linseed was given.

LINSEED JELLY is easily made by adding to 6 quarts of water 1 quart of linseed, boiling it for 10 minutes. This, mixed with other substances, is sometimes given to live-stock as food, and, mixed with milk, is very nutritive for calves.

LINSEED OIL is an excellent purgative for sheep, from 2 to 3 ounces; for horses, in doses of from 16 to 24 ounces; for cattle, from 16 to 20 ounces. The quality of linseed oil may be determined in the following manner: Fill a phial with it, and hold it up to the light; if bad it will appear opaque, turbid, and thick; its taste is acid and bitter upon the tongue, and it smells rancid; and strong oil, from fine full-grown ripe seed, when viewed in a phial, will appear limpid, pale, and brilliant; it is mellow, and sweet to the taste, has very little smell, is specifically lighter than impure oil, and when clarified dries quickly and finely. (*Quart. Journ. of Agr.* vol. v. p. 467.)

LIP. In botany, the lower petal of any irregular flower.

LIQUID MANURE. Liquid manure is not a mode of fertilizing the land altogether of modern origin, for a fermented mixture of water and night-soil has, from a very early period, been employed by the Chinese farmers; those of Italy certainly practised irrigation in the days of Virgil (*Georgics*, b. i. v. 106—109), and Cato adds that they employed a mixture of grape-stones and water to fertilize their olive trees (b. xxxvii.). Columella praises very highly the use of putrid stale urine for vines and apple trees (b. ii. c. 15), commending also the lees of oil for the same purpose. More modern agricultural writers have united in praising various liquid preparations; thus Evelyn (whose ingredients most of the authors recommend), in his *Treatise on Earth*, p. 123-160, gives several recipes, some of which have served as the basis for recent modes of preparing liquid manure, such as the dung of cattle, urine, salt and lime, and nitre. Of these artificial mixtures, salt 1 part, and lime 2 parts, mixed together and allowed to remain in a heap for 2 or 3 months (Mr. Bennett turns

over 3 or 4 times in this period), is fully equal, if not superior, to any thus recommended, most of which I have tried. When mixed with water and spread over land intended for wheat, at the rate of from 25 to 35 bushels of the salt and lime to 10 or 15 tons of water per acre (and it answers very nearly as well when carried on the land dry), excellent results are produced. The wheat which I have thus grown on clover leys has been superior in height, and strength of straw, to any I have seen produced under different modes of treatment, and the seed very bright and heavy.

All substances, whether organic, earthy, or saline, which are employed to fertilize the soil, or become the food of plants, can only be rendered thus serviceable to vegetation when they are presented to the roots of plants in solution, or in a fluid state; and although this may appear at first rather a sweeping position, yet such is the real fact, the compost of the farm-yard, the crushed bones of the turnip cultivator, the oil and bones of fish, the gypsum of the grazier, the earths, lime, magnesia, and even silica, and all the saline manures, are dissolved by some process or other before they can be absorbed by vegetables. Every attempt which has been hitherto made to make plants imbibe the most minutely divided powders which chemistry can produce, has been entirely fruitless. Davy ineffectually tried the finest impalpable powder of charcoal, and with much perseverance I have fruitlessly employed the earths, saline substances, and organic matters, for the same purpose.

This absolute necessity for every substance which is the food of plants being of a soluble nature did not escape the sagacity of the early Greek and Egyptian philosophers; it is true they carried their conclusions with regard to subjects of natural philosophy too far, as in this instance, when they asserted that water is the only food of plants; yet they must have patiently noticed many facts in vegetable economy, unaided as they were by the light of modern vegetable chemistry, before they could have arrived at a conclusion so nearly approaching the truth. The idea was probably of Egyptian origin, for the cultivators of that country could not fail to notice the magic fertilizing powers of the waters of the Nile, whose annual overflow is perhaps the most extensive natural irrigation taken advantage of by the cultivators of the earth.

The same wild dream of water being the sole food of vegetables was again revived, so lately as 1610, by M. Van Helmont, a celebrated Dutch chemist, who made some very plausible, deceptive experiments on a willow tree, which he watered only with rain water; researches, however, whose inaccuracy (owing principally to rain water, as usually collected, not being quite pure) was shown in 1691 by Mr. Woodward. Although, therefore, it is now well ascertained that water is not the only food of plants, yet it certainly contributes universally and largely to their support; and, as it has been well observed by Davy, no manure can be taken up by the roots of plants unless water is present; and water, or its elements, exists in all the products of vegetation. (*Lecture 15.*)

It must not, however, be concluded that these carefully considered conclusions, from the results of often-repeated laborious experiments, are erroneous, because transparent water, *apparently* pure, as in water-glasses, or in irrigation, promotes the growth of bulbs, grass, &c., since the very purest spring water, even rain water, contains foreign substances, as I have clearly ascertained by experiment; and when only chemically pure water is employed to water plants, they cannot be made to flourish. I have fruitlessly varied the attempt in several ways. All the experiments of Dr. Thomson were equally unsuccessful, the plants vegetating only for a certain time, and never perfecting their seeds. Similar experiments were made by Hassenfratz and Saussure, and others, with the same unfavourable result. Duhamel found that an oak which he had raised from an acorn in common water, made less and less progress every year. The florist is well aware that bulbous roots, such as hyacinths, tulips, &c., which are made to grow in water, unless they are planted in the earth every other year, at first refuse to flower, and finally even to vegetate. Moreover, it has been unanswerably shown by many very accurate experiments (*Rech. sur la Vég.* p. 51), at the varied repetition of which I have personally assisted, that the quantity of nourishment or solid matters absorbed by the roots of plants is always in proportion to the impurity of the water with which they are nourished; thus some beans were made to vegetate under three different circumstances; the first were grown in distilled water; the second were placed in sand and watered with rain water; the third were sown in garden mould. The plants thus produced, when accurately analysed, were found to yield the following proportions of ashes:—

1. Those fed by distilled water	-	-	3.9
2. Those fed by rain water	-	-	7.5
3. Those grown in soil	-	-	12.0

And again, all attempts to make plants flourish in the pure earths have failed utterly when they have been watered with pure water; yet a totally different result I have invariably experienced when I have employed an impure solution or liquid manure. My trials have been entirely supported by those of M. Giobert, who, having formed of the four earths, silica, alumina, lime, and magnesia, a soil in the most fertile proportion, in vain essayed to make the plants flourish in it when watered with pure water only; but every difficulty was removed when he moistened it with the water from a dunghill, for they then grew most luxuriantly; and M. Lampadius still further demonstrated the powers of such a foul liquid manure, for he formed plots composed of only a *single earth*, pure lime, pure alumina, pure silica, and planted in each different vegetables, watering them with the liquid drainings from a dunghill, and he found that they all flourished equally well. The soluble matters of a soil ever constitute, in fact, its most fertilizing portion; and if by any artificial means the richest mould is deprived of these, as by repeated washings in cold or boiling water, the residuum, or remaining solid matter, is rendered nearly sterile: this fact, first accurately demon-

strated by M. Saussure (*Rech.* 150), I have since confirmed, by a variety of experiments of my own.

The soluble matters or liquid manures consumed by plants are sometimes imbibed by their roots unaltered; in other cases they are decomposed during their absorption. The earths, gypsum, and other salts, are instances of the first class; oil, and other purely animal matters, of the last. Davy found that some plants of mint, which he forced to vegetate in sugar and water, apparently absorbed the sugar unaltered, for they yielded a considerably larger proportion of a sweetish vegetable extract than those of the same weight which he had grown in common water; and it is an ascertained fact, that the roots of plants will absorb or reject the various earthy substances of a soil, or even when placed in a saline solution, in a very remarkable manner: thus, when equal parts of gum and sugar were dissolved together in water, and some perfect plants of *Polygonum Persicaria* placed with their roots in the solution, it was found that they absorbed 36 parts of the sugar, but only 26 of the gum; and when in precisely the same proportions and manner Glauber salt, common salt, and acetate of lime were used, then it was found that the roots of the *Persicaria* separated these salts from the solution with much ease, absorbing 6 parts of the Glauber salt, 10 parts of the common salt, but not a trace of the acetate of lime. (*Thomson*, vol. iv. p. 321.)

These facts will not be uninteresting to the irrigators or occupiers of the English water-meadows, since they may, in some degree, serve to account for the beneficial action of water on such lands—a question not nearly so well understood as it ought to be, and on which widely differing opinions are commonly held by practical farmers. It is a theme intimately connected with the subject of this article, for irrigation is, in truth, a mode of applying the weakest of liquid manures, on a very bold scale, to grass-lands. See IRRIGATION.

The employment of artificially-prepared liquid manure (though little known at present in England) is very extensive on the Continent: the Swiss farmers call it *gulle*; in France it is denominated *lizier*; and by the Germans, *mist-wasser*. They prepare it throughout many of the German states, and in the Netherlands, by sweeping the excrements of their stall-fed cattle into under-ground reservoirs, mixing it with four or five times its bulk of water, according to the richness of the dung: five reservoirs are generally employed, of such a size that they each take a week to fill; and thus each has four weeks allowed to ferment before the mass, which in this time becomes of an uniform consistence, is removed, by means of a portable pump, in water carts, or large open vessels. A similar plan is adopted in the north of Italy, and from time out of mind has been practised by the Chinese. In that empire, however, the cultivators chiefly employ night soil, which is made into cakes for this purpose with lime or clay, in all their large cities, to prepare their liquid manure.

It is from long experience an admitted fact among the German farmers, that there are no

manures so powerful in their operation as those which are liquids, such as human urine or bullocks' blood; so that no English farmer need fear deception as to their asserted value. This very fact was submitted some years since to the consideration of Professor Hembstadt, of Berlin, by the Saxon and Prussian authorities, who were anxious to apply the contents of the city drains towards fertilizing the barren lands in the neighbourhood of Dresden and Berlin. This talented agriculturist undertook, in consequence, a series of valuable experiments, which, varied in every possible way, were carried on for a considerable period; the result of them, so highly advantageous to the prosperity of Germany, Hembstadt then published. They were repeated with unvaried success by Professor Schübler, and the results may be stated in the following order:—

If the soil, without any manure, yield a produce of three times the quantity of seed originally sown, then the same quantity of land will produce—

- 5 times the quantity of seed sown, when dressed with old herbage, grass, leaves, &c.
- 7 times, when dressed with cow dung.
- 9 times, with pigeons' dung.
- 10 times, with horse dung.
- 12 times, with *human urine*.
- 12 times, with *sheep's dung*.
- 14 times, with human manure or *bullocks' blood*.

Thus it will be seen that, of seven usually employed fertilizers, the liquid manures, urine and blood, were found to be decidedly the most powerful.

Both with regard to the quantity of liquid manure applied per acre, and the mode of spreading it, much must depend upon the circumstances under which the cultivator is placed, and the richness of the liquid he employs. If the impurities dissolved, or mechanically suspended in the water, are equal to 1 part in 10, then 20 to 30 tons per acre of the liquid manure I have found amply sufficient, under ordinary circumstances, to produce the most excellent results; if the fluid mass is purer, then more must be applied. For gardens, and small plots of ground in general, the liquid may be readily and evenly distributed over the beds by means of a watering-pot or garden-engine; for fields it must be carried in water-carts, and distributed either by being let into a transverse trough, pierced with holes in the manner of those employed for street waterings, or the Flemish plan may be adopted (especially when the manure is of too considerable thickness to flow readily through holes), of taking it into the fields in the water-carts, open at the top (furnished with slight movable covers), and then distributing it out of the cart very evenly by means of a scoop; and I have invariably perceived the advantage of ploughing the liquid into the soil *as soon after it was spread on the land as possible*. The cultivator will find great advantage if he uses the garden engine, watering-pot, or cart, from straining the liquid manure before he pumps it out of the reservoir, either through straw, coarse sand, or a basket; the pieces of straw, and other coarsely-divided matters thus separated by the strainer, he will discover add very

slightly to the fertilizing powers of the liquid, and yet they all materially hinder the even distribution of the manure.

The expense, per acre, of such an application of liquid manure, I thus estimate, supposing the cow-herd to be employed:—

	£ s. d.
Three tons of cow or other fresh dung - - -	0 18 0
Labour in mixing and occasionally stirring it with from 20 to 25 tons of water - - -	0 2 0
Carting, and spreading it on the field - - -	0 8 0
	£1 8 0

If it shall occur to the farmer that the quantity of solid manure thus added to the soil will not, in reality, much exceed two tons per acre, and that this is, in appearance, a very small allowance, I would remind him that the quantity thus conveyed consists of the soluble or richest portion of the manure, and is, in fact, the extract without any of the straw, or other inert residuum usually carried on to the soil; besides, it is a very erroneous, though common conclusion, that to produce fertility a manure must be used in large quantities. I have observed in this paper that a flooding with river water, so productive of heavy crops of grass in the water meadows, does not carry on to the land more than 2 tons per acre of animal and vegetable substances; and in the successful experiments of the late Lord Somerville, at Fairmile, with whale blubber, not more than a ton and a half per acre were applied. The Essex farmers find three-quarters of a ton of sprats amply sufficient; and 2 cwt. per acre of gypsum is the ordinary successful allowance for grass land. The exact evenness, therefore, with which a manure is spread over the land is a highly important consideration as regards the economy of manures. There is no commonly cultivated plant which more delights in liquid manure than the potato. It naturally luxuriates near to wet ditches: on plots which have received the drainage of a dunghill it grows with the greatest rapidity. I have invariably found that, to any liquid mixture intended as a manure for potatoes, the addition of 5 or 6 bushels of salt per acre is productive of great good, both as regards the quantity and quality of the potatoes.

On clover leys intended for wheat, the liquid should be turned into the soil as early as possible after it is spread; and if this operation is performed in moist, cloudy weather, a very material advantage will be perceptible in the succeeding crop. The warmth of the sun is certainly prejudicial to the thinly-spread liquid manure, composed of finely-divided animal and vegetable substances.

Of the tanks for receiving or preparing the liquid manure, I may remark that I have always found them best made of flints or bricks set in good mortar or Parker's cement; they may be bedded in clay, but I would not recommend the use of clay for the brickwork, since worms are sure eventually to penetrate through it; and I advise the shape to be something like a decanter, larger at the top than at the bottom, in the manner introduced at Eastbourne and in Cornwall, chiefly by the advice of Mr. Davies Gilbert.

Mr. Milburn has given the annexed estimate for cutting, walling, plastering, and covering a tank of the following dimensions:—Length within, 13 feet 6 inches; width, 6 feet 6 inches; depth, 6 feet, equal to 19½ cubic yards.

	£ s. d.
Cutting at 3d. per cubic yard - - - - -	0 7 7
Walling, including bricks and mortar - - -	6 8 0
Plastering and cement - - - - -	0 16 0
Covering and flags - - - - -	2 15 0
(<i>Trans. High. Soc.</i> vol. ix. p. 280.)	10 6 6

This would be a tank sufficiently capacious for a farm of 150 to 200 acres.

To the presence of a large proportion of urine, the richest of liquid fertilizers, must be chiefly attributed the luxuriant effects produced by the liquid manure, as prepared on the Continent, and from the use of the sewerage matters of large towns, as so strikingly proved in the case of the Craigtintny water-meadows, near Edinburgh, where the drainage is employed in the state in which it issues from the sewers, and from its use several crops of the most luxuriant grass are annually obtained. "All urine," said a late distinguished chemical philosopher, "contains the essential elements of vegetables in a state of solution." By a careful analysis, human urine in its fresh state was found, by Berzelius, to contain the following substances:—

	Paris.
Water - - - - -	93.300
Urea (the peculiar animal matter of urine) - - -	3.010
Sulphate of potassa - - - - -	0.371
Sulphate of soda - - - - -	0.316
Phosphate of soda - - - - -	0.294
Common salt - - - - -	0.445
Phosphate of ammonia - - - - -	0.165
Muriate of ammonia - - - - -	0.150
Lactate or acetate of ammonia - - - - -	
Lactic or acetic acid - - - - -	
Animal matter, soluble in alcohol - - - - -	1.714
Inseparable urea - - - - -	
Earthy phosphate (earth of bones) with fluat of lime - - - - -	0.100
Uric acid - - - - -	0.100
Mucus of the bladder - - - - -	0.032
Silica (earth of flint) - - - - -	0.003
	100.

Thus it will be seen that there is hardly a single ingredient found in urine which is not either a direct food for vegetation, or furnishes by its decomposition a supply in another form; for in it are thus detected the ammoniacal salts of the dunghill, the phosphate of lime of bones, as well as of many cultivated vegetables, and abundance of easily decomposed animal matters.

The urine of the horse is nearly as rich in animo-vegetable matters; its composition, according to the experiments of Fourcroy and Vauquelin, are as follows:—

	Paris.
Water and mucus - - - - -	94.0
Urea - - - - -	0.7
Carbonate of lime (chalk) - - - - -	1.1
Carbonate of soda - - - - -	0.9
Benzoate of soda - - - - -	2.4
Muriate of potassa - - - - -	0.9
	100.

The following are the constituents in that of the cow, as found by Professor Brande:—

	Parts.
Water - - - - -	65.0
Urea - - - - -	4.0
Phosphate of lime - - - - -	3.0
Muriates of potassa and ammonia - - - - -	15.0
Sulphate of potassa - - - - -	6.0
Carbonates of potassa and ammonia - - - - -	4.0
Loss - - - - -	3.0
	100.

It would appear, from some experiments of Dr. Belcher, that the ammoniacal salts of urine have a forcing or stimulating power, which considerably hastens the vegetation of plants. His experiments were made with the common garden cress; and, in his trials, some plants nourished with a solution of phosphate of ammonia were 15 days more advanced than plants growing under similar circumstances, but watered with plain water. In some experiments of Mr. Gregory, who watered half a grass field at Leyton with urine, the portion thus treated yielded nearly double the quantity of hay produced by the other unmanured portion; and the use of the urine of the cow, so extensively employed for grass lands, and in the garden and orchard, by Mr. Harley, in the neighbourhood of Glasgow, was attended with results equally satisfactory, producing, when diluted with water or soap-suds, very superior crops of grass on land of a very inferior description. I shall conclude with a few observations on the loss which the cultivated lands of England incessantly sustain from the neglect of the liquid manure of the sewers of her cities and large towns,—a question to which I have before alluded in this paper, and which is not nearly so well understood as is desirable. Thus, by carefully conducted experiments, and very accurate gaugings, it has been found that the chief London sewers convey daily into the Thames about 115,000 tons of mixed drainage, consisting, on an average computation, of 1 part of solid and 25 parts absolutely fluid matters; but if we only allow 1 part in 30 of this immense mass to be composed of solid substances, then we have the large quantity of more than 3800 tons of solid manure daily poured into the river from London alone, consisting principally of excrements, soot, and the débris of the London streets, which is chiefly carbonate of lime: thus, allowing 20 tons of this manure as a dressing for an acre of ground, there is evidently a quantity of solid manure annually poured into the river equal to fertilizing more than 50,000 acres of the poorest cultivated land! The quantity of food thus lost to the country by this heedless waste of manure is enormous; for, only allowing one crop of wheat to be raised on these 50,000 acres, that would be equal to the maintenance (calculating upon an average produce of three quarters of wheat per acre) of 150,000 persons. London, too, is only one huge instance of this thoughtless waste of the agricultural riches of the soil of England; from every other English city, every town, every hamlet, is hourly passing into the sea a proportionate waste of liquid manure; and I have only spoken of the solid or mechanically suspended matters of the sewerage; the absolutely fluid portion is still rich in urine, ammoniacal salts, soda, &c., when all the mechanically suspended matters have been

separated from the other portions. According to very careful experiments, this fluid part often contains 16 per cent. of animal matters, salts, &c., intimately or chemically combined with the water.

No farmer, after such an analysis of the sewerage of a large city, can feel surprised at the important results from the use of that sewer water, as long practised in the vicinity of Edinburgh. After learning the composition of such a foul mass—its endless mixture of organic matters—its soot—its carbonate of lime—and, above all, its urine, the forcing nature of the ammoniacal salts which that fluid contains, added to the presence of the other matters which are the food of plants, and the constant supply of such irrigation water in all seasons—he will readily give credence to the talented editor of the *Quarterly Journal of Agriculture*, when he asserts that, by such treatment of the Edinburgh meadows with the sewerage irrigation, they have been increased in value several pounds per acre yearly.

I have often employed, with decided effect, in my own garden, for vines, peach, and standard apple trees, liquid manure, prepared either by mixing one part by weight of cow dung with four parts of water, or the collected drainage of the stable and cow-house. Of these the vine is by far the most benefited by the application; but to whatever fruit-tree the gardener has occasion to apply manure, there is no form so manageable and so grateful to the plant as the liquid. It has been found advantageous to plants cultivated in stoves to apply even a liquid manure, composed of six quarts of soot to a hogshead of water; and although this is a very unchemical mixture, yet it has been found by Mr. Robertson to be peculiarly grateful and nourishing to pines, causing them to assume an unusually deep healthy green; and for stoved mulberry, vine, peach, and other plants, the late Mr. Knight, of Downton, employed a liquid manure, composed of one part of the dung of domestic poultry, and 4 to 10 parts of water, with the most excellent result—the trees maintaining, at the end of two years, “the most healthy and luxuriant appearance imaginable.” (*Trans. Hort. Soc.* vol. ii. p. 127.)

In whatever way we view the question of liquid manure, an abundant field of research presents itself on every side: it is evidently an investigation likely to amply repay the cultivator for the labour he may be induced to bestow upon it. By such manures, nourishment for vegetation is more equally diffused through the soil, and becomes more speedily serviceable to the crop, than by any other mode of cultivation. I have endeavoured, also, in this article, to convince the farmer of what I have long remarked in my own practice—that a much smaller quantity of manure, if uniformly mixed with land, is sufficient for all the purposes of fertilization than is commonly believed. Such investigations must be of the highest interest to the farmer and to the public in general, for they relate to the increased produce of the land of England; and not only does a fortunate experiment carry with it its own reward, but even an unsuccessful one is not without its advantages,—it serves, at least, as

a beacon to other cultivators, and affords that satisfaction which ever accompanies the acquirement of knowledge. (*Journ. Roy. Ag. Soc.* vol. i. p. 147.)

LIQUORICE (*Glycyrrhiza*, from *glnkus*, sweet, and *rhiza*, a root; the sweetness of the root of liquorice is well known). A deep, light, sandy loam suits all the species of this genus, and they are readily increased by slips from the roots with eyes, and planting them in spring.

Common liquorice (*G. glabra*) is a native of the south of Europe; but it is also cultivated in England for medicinal use. It is a leguminous plant, with unequally pinnated leaves, composed of ovate, retuse leaflets; the flowers are in racemose spikes, shorter than the leaves. The legumes are smooth, and six-seeded. The root, when fit for use, is long, about the thickness of the finger, grayish without, and yellow within. The sweet, subacid, mucilaginous juice contained in the root is much esteemed as a pectoral demulcent. Liquorice requires three years to perfect its growth, when the roots are taken up about the end of November with the spade; they are then washed, the fibres trimmed off, and the smaller roots which are termed "offal," are separated from the larger. The small roots are dried and ground into powder; but the larger, which form the principal article of profit, are packed up and sold to the druggists. A fair crop will yield from 18 to 20 cwt., at an average price of about 45s. per cwt.; but the expense of digging up and preparing it for market is not short of 10*l.* per acre; which, great as it may appear, is by no means extravagant, if we consider the depth to which the roots run, and the care which is necessary to avoid breaking or leaving any of them in the ground. (*Paxton's Bot. Dict.*; *Brit. Husb.* vol. ii. p. 330.)

LIQUORICE, WILD. A species of the genus *Galium* (*Circæans*) found in the United States, frequent in rich woodlands, &c. Its root is perennial, and the stems grow 12 to 18 inches high, often branched near the base. The flowers are purplish-white, and appear in June and July. The leaves have a sweet taste, resembling liquorice. See **MILK-VERCH**.

LITTER. The straw, fern, or other dry substances which are placed under horses and cattle in the stables, cow-houses, farm-yards, &c., for the purpose of keeping the animals clean and warm, and providing a supply of manure. In this last view, all sorts of dry materials should be carefully collected and stacked up for winter use.

LIVERWORT (*Anemone hepatica*, *Hepatica Americana*, or *Three-lobed Liverwort*) is very common in the open woodlands of the United States, where it flowers in Pennsylvania in May, and matures its seed in May and June. This plant has acquired much notoriety, of late years, as a remedy in pulmonary consumption; but its virtues have doubtless been greatly exaggerated. Dr. Darlington thinks it the only species in the United States. (*Flora Cestricea*.) See **HEPATICÆ**.

LIVE-STOCK. See **HORSES, CATTLE, SHEEP, &c.** In Great Britain, the live-stock forms the chief wealth of a farm. The term implies cattle; but poultry, too, is strictly live-stock; and

in some countries, fish, game, bees, &c., are of that importance that they are considered to be live-stock. In several districts of England, rabbits are so, and that to a very essential extent. In some parts of southern Europe, even the silk-worm is live-stock.

Through the combined exertions of many distinguished writers, and the practical knowledge of modern breeders, a very material alteration for the better in the breeds of live-stock has taken place, and is still progressing; and there is little reason to doubt but that still greater improvements are yet to be effected. To such researches too much attention can hardly be paid; for on the well or ill stocking of the land will mainly depend the cultivator's success. To this end, however, much must rest on the circumstances in which he is placed. See **AGRICULTURE IN THE UNITED STATES**.

LIVE OAK (*Quercus virens*). See **OAK**.

LOAD. A term used in the United States rather vaguely, and meaning different amounts or measures in different places. The general meaning of a load of manure, according to Buel, is what can be drawn by two horses, or two oxen, to the field where it is to be applied. At Boston and other large towns in the Eastern, as well as other States, the term load is applied commonly to express as much as can be drawn by four and even six cattle upon a hard road, or about 96 cubic feet. A load of earth, clay, or marl, is generally estimated at a cubic yard, or 27 cubic feet.

LOAM. By this term is generally understood dark-coloured, rich mould, principally composed of dissimilar particles of earth and decomposed vegetable matter, moderately cohesive, and therefore neither retentive of moisture, like clay, nor too ready to part with it, like sandy soil. According as the different ingredients predominate, loamy soils are of different qualities—friable and mellow, middling, or heavy loams. (*Pract. Husb.* p. 284.) Loam is supposed to consist chiefly of woody fibre in a state of decay, which, as it progresses, acquires a black-brown colour, and is then mould or loam. It is a continued source of carbonic acid, as almost every particle of it is enveloped by an atmosphere of that gas, which is absorbed by the roots of plants, and replaced by atmospheric air, to be again converted into carbonic acid. Upon this transformation the influence of loam on vegetation is readily understood: it does not itself nourish plants, but it presents to them "a slow and lasting source of carbonic acid, which is absorbed by the roots." (*Liebig, Organic Chemistry in its Application to Agriculture*, p. 48—61.) See **HUMUS**.

LOBELIA (*Lobelia*, in honour of Matthew Lobel, author of various botanical works. He was a native of Lisle; became physician and botanist to James I., and died in London in 1616). This is an extremely interesting genus of plants, on account of the beauty of the blossoms, and the medicinal properties of some of the species. The green-house, and stove, shrubby, and herbaceous kinds, grow well in a mixture of peat and sand; the shrubby kinds are readily increased by cuttings in the same kind of soil, and the herbaceous species by dividing and by seeds. The hardy herbaceous

kinds do well in a light, rich earth, or peat soil; but in winter most of them require the protection of a frame. The green-house annuals and biennials must be sown in pots, and treated as other green-house annuals and biennials. The seeds of the hardy kinds have only to be sown in the open border. *L. longiflora* is one of the most venomous of plants. Barton says the Spanish Americans call it *Rebenta cavallos*, because it proves fatal to horses that eat it, swelling them till they burst. Taken internally, it acts as a violent cathartic, the effects of which no remedy can assuage, and which terminate in death. Another American species, namely, *L. inflata*, commonly called Indian Tobacco, is a powerful antispasmodic and emetic, and is much employed to allay the paroxysm of spasmodic asthma. There are two indigenous species: 1. The water lobelia (*L. Dartmannia*), which grows in the lakes of Wales, Scotland, Ireland, and the north of England. The root consists of many long, simple, whitish fibres. Herb smooth, immersed in water like the *Hottonia*. Leaves numerous, two inches long, linear, entire, with two longitudinal cells. The stem is nearly naked, terminating in a simple cluster of light-blue, drooping, alternate flowers, raised several inches above the water, which appear in July and August.

2. Acrid lobelia (*L. urens*). This grows wild on bushy heaths in Devonshire. The root is fibrous; stem a foot or more in height, nearly upright; lower leaves ovate, slightly toothed; upper lanceolate, serrated; the flowers are in erect clusters, terminal, of a purplish-blue colour, appearing in August and September. The whole herb is milky, fetid, and very acrid.

LOBLOLLY BAY (*Gordonia lasyanthus*). This American tree is comprehended within the same limits with the long-leaved pine, being confined to the maritime parts of the Southern States, to the two Floridas, and to Lower Louisiana. It is very abundant in the branch swamps, and exists in greater proportion than the red bay, swamp bay, and black gum, with which it is usually associated. In the pine barrens, tracts of 50 or 100 acres are met with at intervals, which, being lower than the adjacent ground, are kept constantly moist by the waters collected in them after the great rains. These spots are entirely covered with the loblolly bay, and are called bay swamps. Although the layer of vegetable mould is only 3 or 4 inches thick, and reposes upon a bed of barren sand, the vegetation of these trees is surprisingly luxuriant.

The loblolly bay grows to the height of 50 or 60 feet, with a diameter of 18 or 20 inches. For 25 to 30 feet its trunk is perfectly straight. The small divergency of its branches near the trunk gives it a regularly pyramidal form; but as they ascend they spread more loosely, like those of other trees of the forest.

The leaves are evergreen, from 3 to 6 inches long, alternate, oval-acuminate, slightly toothed, and smooth and shining on the upper surface. The flowers are more than an inch broad, white and sweet-scented; they begin to appear about the middle of July, and bloom in succession during 2 or 3 months. This tree possesses

the agreeable singularity of bearing flowers when it is only 3 or 4 feet high

The fruit is an oval capsule, divided into 5 compartments, each of which contains small, black, winged seeds. These seeds appear to germinate successfully only in places covered with *sphagnum*, a species of moss which copiously imbibes water, and in which are found thousands of the young plants, which are plucked up with ease.

The bark of the loblolly bay is very smooth while the tree is less than 6 inches in diameter; on old trees it is thick and deeply furrowed. In trunks which exceed 15 inches in diameter, four-fifths of the wood is heart. The wood is of a rosy hue, and of a fine, silky texture: it appears to be very proper for the inside of furniture, though the cypress is generally preferred. It is extremely light: when seasoned it is very brittle, and it rapidly decays unless it is kept perfectly dry: hence it is entirely neglected in use, and is not employed even for fuel.

The value of the loblolly bark in tanning compensates in some measure for the uselessness of its wood: it is employed for this purpose throughout the maritime parts of the Southern States and of the Floridas. For, although this branch of industry is by no means as extensively practised in this part of the country as in the Northern States, and though these regions afford many species of oak, yet the species whose bark is proper for tanning are not sufficiently multiplied to supply the consumption. As much of the bark of the Spanish oak as can be obtained, of which the price is one-half greater, is mixed with that of the loblolly bay. This tree has the advantage of maintaining very long the circulation of its sap, so that the bark may be taken off during three or four months.

The luxuriance of its vegetation, the beauty of its flowers, and the richness of its evergreen foliage place the loblolly bay among the magnolias; and, with the other species, it contributes to the ornament of the forests in the southern parts of the United States. It is less sensible to cold than the big laurel. (*Michaux.*)

LOBLOLLY PINE (*Pinus taeda*). See **FIRS**.

LOCKED-JAW. See **TETANUS**.

LOCKING OF WHEELS. The means of fastening them so as to prevent their running too swiftly upon the horses, when coming down steep hills. This is effected in various ways; as by chains, sledges, friction-bars, &c. See **WHEEL**, and **WAGON**.

LOCULAR. A term in botany. A fruit is called unilocular if it contains but one cell, bilocular if it contains two cells, and so on. In many instances, one or more of the cells are abortive, and become obliterated as the fruit ripens.

LOCUST. A name given by the English to the large grasshoppers, but which, in the United States, and indeed almost universally, is applied to the group of insects which naturalists have termed *Cicadians*, and which are also called harvest-flies.

These insects are readily distinguished by their broad heads, the large and very convex eyes on each side, and the three eyelets on the

crown: by the transparent and veined wing-covers and wings; and by the elevation on the back part of the thorax in the form of the letter X. The males have a peculiar organization, which enables them to emit an excessively loud buzzing kind of sound, which, in some species, may be heard at the distance of a mile; and the females are furnished with a curiously contrived piercer, for perforating the limbs of trees, in which they place their eggs. The musical instruments of the male consist of a pair of kettle-drums, one on each side of the body, and these, in the *seventeen-year Cicada* (or locust, as it is generally but improperly called in America), are plainly to be seen just behind the wings. These drums are formed of convex pieces of parchment, covered with numerous fine plaits, and, in the species above named, are lodged in cavities on the sides of the body behind the thorax. They are not played upon with sticks, but by muscles or cords fastened to the inside of the drums. When these muscles contract and relax, which they do with great rapidity, the drum-heads are alternately tightened and loosened, recovering their natural convexity by their own elasticity. The effect of this rapid alternate tension and relaxation is the production of a rattling sound, like that caused by a succession of quick pressures upon a slightly convex and elastic piece of tin plate. Certain cavities within the body of the insect, which may be seen on raising two large valves beneath the belly, and which are separated from each other by thin partitions having the transparency and brilliancy of mica, or of thin and highly polished glass, tend to increase the vibrations of the sounds, and add greatly to their intensity. In most of our species of *Cicada*, the drums are not visible on the outside of the body, but are covered by convex triangular pieces on each side of the first ring behind the thorax, which must be cut away in order to expose them. On raising the large valves of the belly, however, there is seen, close to each side of the body, a little opening, like a pocket, in which the drum is lodged, and from which the sound issues when the insect opens the valves. The hinder extremity of the body of the female is conical, and the under-side has a longitudinal channel for the reception of the piercer, which is furthermore protected by four short grooved pieces fixed in the sides of the channel. The piercer itself consists of three parts in close contact with each other; namely, two outer ones grooved on the inside and enlarged at the tips, which externally are beset with small teeth like a saw, and a central, spear-pointed borer, which plays between the other two. Thus this instrument has the power and does the work both of an awl and of a double-edged saw, or rather of two key-hole saws cutting opposite to each other. No species of *Cicada* possesses the power of leaping. The legs are rather short, and the anterior thighs are armed beneath with two stout spines.

The duration of life in winged insects is comparatively very short, seldom exceeding two or three weeks in extent, and in many is limited to the same number of days or hours. To increase and multiply is their principal business in this period of their existence, if not

the only one; and the natural term of their life ends when this is accomplished. In their previous states, however, they often pass a much longer time, the length of which depends, in great measure, upon the nature and abundance of their food. Thus maggots, which subsist upon decaying animal or vegetable matter, come more quickly to their growth than caterpillars and other insects which devour living plants: the former are appointed to remove an offensive nuisance, and to do their work quickly; the latter have a longer time assigned to them, corresponding in some degree to the progress or continuance of vegetation. The facilities afforded for obtaining food influence the duration of life; hence those grubs that live in the solid trunks of perennial trees, which they are obliged to perforate in order to obtain nourishment, are longer lived than those that devour the tender parts of leaves and fruits, which, though they last only for a season, require no laborious efforts to be prepared for food. The harvest-flies continue only a few weeks after their final transformation, and their only nourishment consists of vegetable juices, which they obtain by piercing the bark and leaves of plants with their beaks; and during this period they lay their eggs, and then perish. They are, however, amply compensated for the shortness of their life in the winged state by the length of their previous existence, during which they are wingless and grub-like in form, and live under ground, where they obtain their food only by much labour in perforating the soil among the roots of plants, the juices of which they imbibe by suction. To meet the difficulties of their situation and the precarious supply of their food, for which they have to grope in the dark in their subterranean retreats, a remarkable longevity is assigned to them; and one species has obtained the name of *Cicada septendecim*, on account of its life being protracted to the period of seventeen years.

This insect has been observed in the south-eastern parts of Massachusetts, but does not seem to have extended to other parts of the state. The earliest account that we have of it is contained in Morton's *Memorial*, wherein it is stated that "there was a numerous company of flies, which were like for bigness unto wasps or bumblebees," which appeared in Plymouth in the spring of 1633. "They came out of little holes in the ground, and did eat up the green things, and made such a constant yelling noise as made the woods ring of them, and ready to deafen the hearers." Judge Davis, in the Appendix to his edition of Secretary Morton's *Memorial*, states that these insects appeared in Plymouth, Sandwich, and Falmouth in the year 1804; but, if the exact period of seventeen years was observed, they should have returned in 1803. Circumstances may occasionally accelerate or retard their progress to maturity, but the usual interval is certainly seventeen years, according to the observations and testimony of many persons of undoubted veracity. Their occurrence in large swarms at long intervals, like that of the migratory locusts of the East, probably suggested the name of locusts, which has commonly been applied to them in this country. It appears

that these insects come forth at different places in different years.

Dog-day Harvest-fly.—Another species of harvest-fly, though it does not make its appearance in such formidable numbers as the seventeen-years locust, is much more frequently met with. Dr. Harris calls it the dog-day harvest-fly (*Cicada canicularis*), from its invariably coming about the beginning of dog-days. "During many years in succession," says Dr. Harris, "with only one or two exceptions, I have heard this insect on the 25th day of July, for the first time in the season, drumming in the trees, on some part of the day between the hours of ten in the morning and two in the afternoon."

Dr. Harris describes about twenty other species of the locust family found in Massachusetts, and concludes the subject in the following words:

"After so much space has been devoted to an account of the ravages of grasshoppers and locusts, and to the descriptions of the insects themselves, perhaps it may be expected that the means of checking and destroying them should be fully explained. The naturalist, however, seldom has it in his power to put in practice the various remedies which his knowledge or experience may suggest. His proper province consists in examining the living objects about him with regard to their structure, their scientific arrangement, and their economy or history. In doing this, he opens to others the way to a successful course of experiments, the trial of which he is generally obliged to leave to those who are more favourably situated for their performance.

In the south of France the people make a business, at certain seasons of the year, of collecting locusts and their eggs, the latter being turned out of the ground in little masses, cemented and covered with a sort of gum, in which they are enveloped by the insects. Rewards are offered and paid for their collection, half a franc being given for a kilogramme (about 2 lbs. 3½ oz. avoirdupois) of the insects, and a quarter of a franc for the same weight of their eggs. At this rate 20,000 francs were paid in Marseilles, and 25,000 in Arles, in the year 1613; in 1824, 5,542; and in 1825, 6,200 francs were paid in Marseilles. It is stated that an active boy can collect from 6 to 7 kilogrammes (or from 13 lbs. 3 oz. 13·22 dr. to 15 lbs. 7 oz. 2·09 dr.) of eggs in one day. The locusts are taken by means of a piece of stout cloth, carried by four persons, two of whom draw it rapidly along, so that the edge may sweep over the surface of the soil, and the two others hold up the cloth behind at an angle of 45 degrees. This contrivance seems to operate somewhat like a horse-rake, in gathering the insects into winrows or heaps, from which they are speedily transferred to large sacks. A somewhat similar plan has been successfully tried in this country, as appears by an account extracted from the *Portsmouth Journal*, and published in the *New England Farmer*, vol. v. p. 5. It is there stated that, in July, 1826, Mr. Arnold Thompson, of Epsom, New Hampshire, caught in one evening, between the hours of 8 and 12, in his own and his neighbour's grain-

fields, 5 bushels and 3 pecks of grasshoppers, or, more properly, locusts. 'His mode of catching them was by attaching two sheets together, and fastening them to a pole, which was used as the front part of the drag. The pole extended beyond the width of the sheets, so as to admit persons at both sides to draw it forward. At the sides of the drag, braces extended from the pole to raise the back part considerably from the ground, so that the grasshoppers could not escape. After running the drag about a dozen rods with rapidity, the braces were taken out, and the sheets doubled over; the grasshoppers were then swept from each end towards the centre of the sheet, where was left an opening to the mouth of a bag which held about half a bushel; when deposited and tied up, the drag was again opened and ready to proceed. When this bag was filled so as to become burdensome (their weight is about the same as that of the same measure of corn), the bag was opened into a larger one, and the grasshoppers received into a new deposit. The drag can be used only in the evening, when the grasshoppers are perched on the top of the grain. His manner of destroying them was by dipping the large bags into a kettle of boiling water. When boiled, they had a reddish appearance, and made a fine feast for the farmer's hogs.' When these insects are very prevalent on our salt marshes, it will be advisable to mow the grass early, so as to secure a crop before it has suffered much loss. The time for doing this will be determined by data furnished in the foregoing pages, where it will be seen that the most destructive species come to maturity during the latter part of July. If, then, the marshes are mowed about the first of July, the locusts, being at that time small and not provided with wings, will be unable to migrate, and will consequently perish on the ground for the want of food, while a tolerable crop of hay will be secured, and the marshes will suffer less from the insects during the following summer. This, like all other preventive measures, must be generally adopted, in order to prove effectual; for it will avail a farmer but little to take preventive measures on his own land, if his neighbours, who are equally exposed and interested, neglect to do the same. Among the natural means which seem to be appointed to keep these insects in check, violent winds and storms may be mentioned, which sometimes sweep them off in great swarms, and cast them into the sea. Vast numbers are drowned by the high tides that frequently inundate our marshes. They are subject to be attacked by certain thread-like brown or blackish worms (*Filaria*), resembling in appearance those called horse-hair eels (*Gordius*). I have taken three or four of these animals out of the body of a single locust. They are also much infested by little red mites, belonging apparently to the genus *Ocypete*: these so much weaken the insects by sucking the juices from their bodies, as to hasten their death. Ten or a dozen of these mites will frequently be found pertinaciously adhering to the body of a locust, beneath its wing-covers and wings. A kind of sand-wasp preys upon grasshoppers, and provisions her nest with them. Many birds devour them, par-

ticularly our domestic fowls, which eat great numbers of grasshoppers, locusts, and even crickets. Young turkeys, if allowed to go at large during the summer, derive nearly the whole of their subsistence from these insects." (*Harris's Treatise on Insects.*)

In England, Locust is the common name of a species of insects forming a group or sub-genus of the *gryllus* of Linnæus. They have coloured elytra, and large wings, disposed, when at rest, in straight, fan-like folds, as in other orthoptera, and frequently exhibiting bright blue, green, or red colours. The thorax is capacious, to afford room for the powerful muscles of the wings, and is marked in many species with one or more crests, or wart-like prominences. The locusts fly by starts, but frequently rise to a considerable height. Certain species, called "migratory locusts," unite in incalculable numbers, and emigrate, resembling, in their passage through the air, a dense cloud: wherever they alight, all signs of vegetation quickly disappear, and cultivated grounds are left a desert. One species (*Acridium migratorium*, Latr.), occasionally commits devastations in the south of Europe and Poland; and stragglers have sometimes reached England, a circumstance which happened in 1748: but they soon perished. To our ideas of the association of insects, the swarms of locusts which have occasionally appeared in oriental countries seem almost incredible. Major Moor states that a flight which ravaged the Mahratta country, and which he saw at Poonah, extended in a dense column 500 miles, and hid the sun like an eclipse. On that occasion, the natives fried and ate them. The devastation which they make is forcibly described by the prophet Joel: "The land is as the garden of Eden before them, and behind them a desolate wilderness."

LOCUST-BORER. See BORERS.

LOCUST, HONEY or SWEET. See HONEY LOCUST.

LOCUST TREE (*Hymenæa*, from Hymen, the god of marriage; in reference to the two leaflets). The species of locust tree are highly ornamental; they delight to grow in loam and peat, and cuttings will root in sand under a glass in heat. The young plants should be planted out in the autumn of the second year, cutting them down within three inches of the ground. They must be preserved from the attacks of hares and rabbits, which are very destructive to them. See ACACIA.

LOCUST TREE CATERPILLARS. These are produced from the eggs of a butterfly belonging to a tribe which, from their habit of flying but a short distance at a time with a jerking motion, have acquired the name of skippers (*Hesperiadæ* or *Hesperians*). They frequent grassy places, low bushes, and thickets. When they alight, they usually keep the hind-wings spread out horizontally, and the fore-wings partially closed, but not entirely so, as in other butterflies.

The *Tityrus skipper* (*Eudamus tityrus*), and its offspring, are thus described by Dr. Harris. "Wings brown; first pair with a transverse, semi-transparent band across the middle, and a few spots towards the tip, of a honey-yellow colour; hind-wings with a short rounded tail

on the hind angles, and a broad silvery band across the middle of the under-side. Expands from 2 to 2½ inches.

"This large and beautiful insect makes its appearance, from the middle of June till after the beginning of July, upon sweet-scented flowers, which it visits during the middle of the day. Its flight is vigorous and rapid, and its strength is so great that it cannot be captured without danger of its being greatly defeated in its struggles to escape. The females lay their eggs, singly, on the leaves of the common locust tree (*Robinia pseudacacia*), and on those of the viscid locust (*Robinia viscosa*), which is much cultivated here as an ornamental tree. The caterpillars are hatched in July, and when quite small conceal themselves under a fold of the edge of a leaf, which is bent over their bodies and secured by means of silken threads. When they become larger, they attach two or more leaves together, so as to form a kind of cocoon or leafy case to shelter them from the weather, and to screen them from the prying eyes of birds. The full-grown caterpillar which attains to the length of about two inches, is of a pale green colour, transversely streaked with darker green, with a red neck, a very large head roughened with minute tubercles, slightly indented or furrowed above, and of a dull red colour, with a large yellow spot on each side of the mouth. Although there may be, and often are, many of these caterpillars on the same tree and branch, yet they all live separately within their own cases. One end of the leafy case is left open, and from this the insect comes forth to feed. They eat only, or mostly, in the night, and keep themselves closely concealed by day. These caterpillars are very cleanly in their habits, and make no dirt in their habitations, but throw it out with a sudden jerk, so that it shall fall at a considerable distance. They frequently transform to chrysalids within the same leaves which have served them for a habitation, but more often quit the trees and construct in some secure place a cocoon of leaves or fragments of stubble, the interior of which is lined with a loose web of silk. They remain in their cocoons without further change throughout the winter, and are transformed to butterflies in the following summer. The viscid locust tree is sometimes almost completely stripped of its leaves by these insects, or presents only here and there the brown and withered remains of foliage, which has served as a temporary shelter to the caterpillars. For the modes adopted to destroy these, see CATERPILLARS.

LOLIUM. See RYE-GRASS.

LONDON PRIDE. See SAXIFRAGE.

LONDON ROCKET. See HEDGE-MUSTARD.

LONG-HORNED CATTLE. A breed of neat cattle now nearly extinct, chiefly distinguished by the length of the horn, the thickness and firm texture of the hide, the length and closeness of the hair, the large size of the hoof, and the coarse, leathery thickness of the neck. See CATTLE.

LOOPERS. See SPAN-WORMS

LOOSENESS. See DIARRHŒA, and DISEASES OF CATTLE AND SHEEP.

LOOSESTRIFE (*Lysimachia*, from *luisis*, dissolution, and *mache*, strife). A very pretty genus of plants, with mostly yellow flowers. All the species are of the easiest culture, and may be propagated by divisions, except *L. dubia* and *L. Limum-stellatum*, which must be increased by seeds.

Great yellow loosestrife (*L. vulgaris*), grows in watery, shady places, particularly the reedy margins of rivers. The root is creeping; stems 3 or 4 feet high.

Wood loosestrife, or yellow pimpernel (*L. nemorum*). This species, which is one of the elegant though not uncommon English plants, inhabits woods and shady, rather watery places. The stems are creeping at the base, decumbent, often pendant from banks and rocks.

Creeping loosestrife. Money-wort or herb twopence (*L. nummularia*). This is a handsome free-flowering plant, which, from its trailing habit, is well fitted for decorating rock-work. It grows wild in wet meadows, boggy pastures, and the borders of rivulets. The herbage is smooth, of a pale green; stems quite prostrate, creeping, a foot or two in length; leaves somewhat heart-shaped; flowers solitary, pale lemon-coloured, rather larger than the last species; stamens glandular. It flowers from June to August, and affords a wholesome food for cattle, especially sheep. On account of its sub-acid and mildly astringent properties, it is considered as one of the most efficacious vulnerary herbs. Bechstein asserts that the leaves and flowers of this plant, steeped in oil, furnish an excellent remedy for destroying the worms and insects infesting the floors of granaries.

LOPPED MILK. Provincially, milk that has stood till it has become sour and curdled.

LOPPING. The operation of cutting off the lateral or other branches of trees. See **PRUNING** and **PLANTATIONS**.

LOTUS. See **BIRDS' FOOT TREFOIL**.

LOUSINESS. In farriery, an affection of the skin, arising, in cattle or other animals, from the irritation of lice or other animalculæ, which may be distinguished by the naked eye. Most animals, and even insects, are subject to this annoyance. Lousiness in live-stock is produced by neglect and low keep. The best remedy is more attention to cleanliness, with better food. The lice may be killed by a dressing applied with a brush to the chief affected parts, composed of four ounces of black sulphur, mixed with a pint of train oil, or a small portion of weak mercurial ointment.

LOUSE-WORT. See **RATTLE**.

LOVAGE (*Ligusticum*, so named because some of the species grow in Liguria). A genus of hardy, herbaceous, and biennial, aromatic plants, which, as flowers, are not worth cultivating. They will grow in any soil, and are increased by seeds.

The Scottish lovage or sea parsley (*L. Scoticum*), grows on rocks, cliffs, and the sea-coasts of Scotland and the north of England, on a stem a foot high; root tap-shaped, warm and pungent; leaves stalked, twice ternate; foot-stalks bordered with a purplish compressed membrane at the base; umbels smooth, not very large, bearing white flowers, with a red-

dish tinge: these appear in July. This herb is eaten by the natives of Scotland and its isles, either crude as a salad, or boiled as greens. The flavour is highly acrid, and, though aromatic, stomachic, and perhaps not unwholesome, yet very nauseous to those who are unaccustomed to such food. It is relished by horses, sheep, and goats, but refused by cows. The stem yields English opoponax. The roots are reputed to be carminative, and an infusion of the leaves affords a good physic for calves.

Cornish lovage (*L. cornubiense*). This is a less common species, found sometimes in bushy fields in Cornwall. The root is spindle-shaped, contracted at the crown, descending to a great depth; when wounded, discharging a yellow, resinous juice. The stem is two or three feet high, solitary, erect, branched, striated, purple at the base. Leaves deep green; the radicles once, twice, or thrice pinnate, rough-edged, cut; stem-leaves ternate, lanceolate, entire. Ribs of the seeds bluntish.

LOVE-APPLE. See **TOMATO**.

LOVE-GRASS (*Eragrostis*, from *eros*, love, and *agrostis*, grass; in allusion to the beautiful dancing spikelets, whence also the English name). It is a pretty species of foreign grass, growing in gardens about a foot high in any common soil.

LOVE-LIES-BLEEDING. The common name of a species of amaranth (*A. caudatus*).

LOY. A very long, narrow spade, peculiar to the province of Connaught and some parts of Munster, and only suited to stony land, where a wider edge could not so easily penetrate. (*M. Doyle's Pract. Husb.*)

LUCAMA. A species of fruit growing in Chili, in size and flavour resembling a peach. (*Ed. Encyc.*)

LUCERN, or PURPLE MEDICK GRASS (*Medicago sativa*, Pl. 8, h). An artificial grass, called by the French *grand trefle*, which affords perhaps a larger produce of fodder than any other species of artificial grass. Although found growing wild in hedges, pastures, and the borders of fields in dry, calcareous soils, yet it can scarcely be considered a native of England. The stems are erect or somewhat reclining, about two feet high. Leaflets oblong, inclining to wedge-shaped; more or less acute, sharply serrated towards the end, clothed with close, silky hairs on both sides. The flowers are in clusters, many, bluish purple, with a small bristle-like bracte under each partial stalk. The legumes are spiral, with rarely more than two or three turns; they are silky when young.

This valuable grass is best cultivated on a good, dry, warm, barley soil; it is not adapted for heavy or wet soils. Being a deep-rooted plant, it requires a soil in which its roots can penetrate to a considerable depth. It should be sown on land perfectly clean, in the months of March or April, with (or best without) a crop of grain. It is only adapted to the southern parts of England, since extreme cold destroys it. It is best sown alone in drills, at a distance of 12 to 15 inches; the quantity of seed is from 10 to 16 lbs. per acre. Any vacancies in the drills may in the autumn or following spring be made good by transplanting

By careful weeding and hoeing, and frequent top-dressings (for which purpose gypsum, calcareous matters, ashes, &c., are excellent), the profitable duration of this crop may be extended eight or ten years, giving during that period, on an average, three or four cuttings per annum: the first of which, in favourable seasons, will be as early as the middle of April. It should always be cut before the appearance of the blossom. It may be made into hay, although much better adapted for soiling. An acre will, upon an average, produce fodder for two horses, from the first cutting to October. It is admirably adapted for milch cows, and is, indeed, relished by all live-stock.

"Lucern," as observed by Mr. Loudon (*Encyclo. of Gard.*) "is highly extolled by Roman writers; it is also of great antiquity in Spain, Italy, and the south of France; is much grown in Persia and Peru, and mown in both countries all the year round. It is mentioned by Hartlip, Blythe, and other early writers, and was tried by Lisle; but it excited little attention till after the publication of Harte's *Essays* in 1757 (? 1764). Mr. Towers, speaking of lucern, calls it 'the plant of plants.' 'I have grown lucern (he adds) during four or five years, and previously I had witnessed its great success and extensive culture in the Isle of Thanet.'"

In cutting for a cow, it will always be advisable to take the plant when it is tender and juicy; and such it will be when about a foot high. I have thus cut my plot over six times after the first year; but they who leave the plants to grow two feet high, will find the stems rigid, fibrous, and less juicy; and that what they gain in bulk will be lost in time and quality. Lucern is known to produce much milk, perhaps more than any other of the artificial grasses (*Leguminosæ*); but some complain that it communicates an austere or bitter flavour. I doubt the fact, but would always recommend that it be not given quite fresh to a cow, particularly at an early period after calving.

If the required quantity be cut over night, it will be fit for the stall by ten o'clock of the following morning, and again the afternoon meal should be exposed to the sun for 2 or 3 hours before it is used. "As to the trouble in managing an established crop, it is really nothing. Though I allow it is good to hoe twice during the summer, as the plot is cut piece by piece, yet one general fork-digging at that period of early spring when the plants exhibit the first symptom of growth, so as to remove every weed, and loosen the surface of the soil, will be amply sufficient to secure the safety and full development of the herb. Upon the whole, lucern is a plant of the utmost value; for if the seed be good, the ground rich and in heart, and rendered deep in the first instance by a thorough trenching, the young plants start into lively growth, attain strength in the shortest possible time, and yield a bulk of luxuriant herbage that cannot be surpassed. If the plant require four years to attain its maximum of power, it is still a giant even from its infancy, advancing from strength to strength. A well prepared field, if kept clean by the forking, will remain productive for more than ten years;

but as a change of crop always promotes abundance, it would be advisable to prepare a successional plot every six years." (*Quart. Journ. of Agr.* vol. ix. p. 96.)

About 80 pounds weight per day of 24 hours is sufficient for the largest cow, and half this, with corn, for a horse. No stock should at any time be permitted to graze upon it.

There are several varieties of lucern, with violet, yellow, and variegated flowers, which are supposed to be only a variation of the same plant, arising accidentally from the seed. However, neither the yellow nor the variegated is ever so strong as the purple flowered, and cannot, of course, be so profitable to the cultivator. Lucern may be estimated as the choicest of all fodder, because it lasts many years; will bear cutting down four, five, or six times a year; enriches the land on which it grows; will fatten cattle, and often proves a remedy for the diseased.

Those who wish to acquire more minute information relative to the management of lucern, may consult the Rev. Walter Harte's learned *Essays on Husbandry*; Rocque's *Practical Treatise on Cultivating Lucern Grass*; and *British Husbandry*, vol. ii. p. 307.

Lucern is sometimes called *French clover*, and has been introduced into the United States as a new plant under the name of *Brazilian clover*, called in South America *Alfalfa*, the Spanish name for lucern. It is a kind of grass which in some situations has been cultivated with great success in the United States. It is not, strictly speaking, a *clover*, though in some respects similar. It is a perennial, and in favourable soils the roots are said to live and flourish a great many years. Its advantages consist in affording a greater amount of foliage for any kind of stock than any other plant, with the same labour and expense. "Several years since, while residing in the State of Maine, we made several experiments with lucern, which, although some of them terminated unfavourably, satisfied us that the most favourable soil for it is a deep, sandy loam; and as the alluvial soils on this river are generally of this character, we last spring resolved on giving it a fair trial here. We procured from Boston a small quantity of seed, which was sown on the river 'bottom' the last week in May. As the soil had been badly managed for several years previous, we had feared that the great growth of weeds would check and smother the lucerne, and to guard against this, and get a chance to extirpate the weeds, we sowed the seed in drills. This was done very expeditiously and exactly with one of Ruggles, Nourse, and Mason's seed sowers.

"In the latter part of the month of July, the lucern had reached the height of 18 inches on an average, and had considerably blossomed. We cut it and fed it green, partly to hogs and partly to milch cows,—both ate it voraciously. In just four weeks from the time it was cut, it had again grown to nearly the same height as before, and was cut a second time,—and on the first of November it was cut a third time,—the crop being heavier than either of the preceding. A piece of common red clover (very flourishing) immediately adjoining, the soil

precisely similar, did not yield nearly *half* as much, in proportion, as the lucern.

"We have no doubt that it may be cut five times another year, and will yield at the rate of a ton and a half of *hay* to the acre at each cutting." (*Zanesville Gazette*.)

Upon analysis, the stems, &c., of lucern are found to contain gypsum, and this furnishes a satisfactory explanation of the fact, that plaster of Paris applied to the crop generally causes it to grow luxuriantly. Live-stock prefer plastered lucern to any other herbage.

LUG. A long measure of land, the same with a pole or perch, 16½ feet. In Gloucestershire it however signifies a land measure of 6 yards, or a rod, pole, or perch of 6 yards. It is a measure by which ditching and other similar operations are performed there. This term is likewise applied to the stick by which the work is measured. It is sometimes called *log*.

LUNGWORT (*Pulmonaria*; it derives both its common and generic names from its supposed medical properties in diseases of the lungs). The species of this genus are very pretty flowering plants, well adapted for ornamenting the front of shrubberies. They thrive in any common soil, and are readily increased by divisions.

LUPINE (*Lupinus*, from *lupus*, a wolf; in allusion to its exhausting or devouring the soil). The species of this genus are among the most beautiful of border flowers. They will flourish in almost any soil, but a rich loam suits them best. They perfect their seeds very freely, from which young plants are easily obtained. In agriculture, the lupine is cultivated principally for being turned in as a manure. (See **GREEN MANURES**.) This plant requires but little trouble or labour in its cultivation, as it will thrive in any soil except the bad chalks, and such as are very wet. It will even grow well on poor, hungry, worn-out land, especially if it be dry and sandy. When sown in February or March, after a single very shallow ploughing, and slightly harrowed in, it will blossom two or three times between May and August, and prove an excellent enricher of the ground when ploughed in just after its second blooming. The best time for mowing this sort of crop is after a shower of rain, as the seeds drop easily out of their pods when they are gathered too dry. They must, however, be laid up very dry, or worms soon breed in them. They are inferior to many other plants for the above use.

LUPINE, WILD. Mr. Nuttall has enumerated seven species of the lupine genus found in different parts of the United States and territories. Dr. Darlington has described common wild lupine, an ornamental plant, found in the woodlands and hills of the Middle States. The root is perennial and creeping; stem 9 to 18 inches high, herbaceous, erect, or decumbent, somewhat branching, striated, angular, and pubescent. Flower purplish-blue, with violet shades. Legume or pod about an inch and a half long and one-third of an inch wide, somewhat flattened, hairy, and of a dark tawny colour. Seed obovoid, slightly compressed, smooth, speckled or variegated with whitish and dark brown.

LURCHER. A sort of hunting dog, much like a mongrel greyhound, with pricked ears, a shaggy coat, and generally of a yellowish-white colour. It is a very swift runner, so that, if it gets between the burrows and the rabbits, it seldom misses taking them; and this is its common practice in hunting.

LURID. In botany, signifies a colour between a purple, yellow, and gray.

LYME-GRASS. See **ELYMUS**.

LYCHNIS (from *lychnos*, a lamp; on account of the brilliancy of the flowers of most of the species). This is an extremely beautiful genus of plants, well meriting extensive cultivation for the brilliancy of their flowers. A red variety is often cultivated in a double state, and called bachelor's buttons; a name, however, which is more frequently given to a species of *ranunculus*.

LYNCHET. A country term applied to the stripes or grassy partitions in arable fields in England, but mostly to such as are in the state of commonage.

LYNCH-PIN, or LINCH-PIN. The small pin, in carts or other carriages, that is put through the ends of the axle-trees, to confine the wheels on them.

LYRATE. In botany, leaves are called lyrate which are shaped in the form of a lyre

M.

MACERATION. The act of softening any substance by steeping it in cold water or other liquid.

MACHINE (Gr.). In a general sense this word signifies any thing which serves to increase or regulate the effect of a given force. Machines are either *simple* or *compound*. The simple machines are usually reckoned six in number; namely, the lever, the wheel and axle, the pulley, the wedge, the screw, and the funicular or rope machine. Compound machines are formed by combining two or more simple machines.

In husbandry, the term is applied to various implements, such as the **DRILL**, **THRASHING**, and **WINNOWER MACHINES**, the **STEAM ENGINE**, &c. See these respective terms.

MADDER (*Rubia*, from *ruber*, red, in allusion to the colour of the roots). This is a genus of interesting plants; any common garden soil suits them, and they are easily increased by seeds or divisions of the roots. The root of *R. tinctorum* is one of the most valuable dyes with which we are acquainted, and is a very important article of commerce. The plant is herbaceous, several stems rising from the same root; tetragonal, with hooked prickles at the angles. The leaves are four or six in a whorl, lanceolate, with the midrib on the under disk, and the margins aculeated. The flowers are small, yellow, supported on axillary trichotomous peduncles.

The dried root of the madder is long, cylindrical, the thickness of a goose quill, branched and covered with a reddish cuticle, which, as well as the bark, is easily separated; the odour is feeble, and the taste bitter and astringent. It is imported entire from Smyrna and the Levant, but in coarse powder from Holland and France.

The cultivation of madder has been attempted in England, and it is still carried on to a limited extent in some districts, but without any very great success or beneficial results, owing to the low price at which it can be procured from the Dutch growers and from Turkey.

Dyers' madder is an agricultural product which has been very successfully and profitably cultivated in the United States. The root of the plant is composed of many long, thick, succulent fibres, almost as large as a man's little finger; these are joined at the top in a head, like the root of asparagus, and strike very deep into the ground, being sometimes more than three feet in length. From the upper part or head of the root come out many side-roots, which extend just under the surface of the ground to a great distance, whereby it propagates very fast; for these send up a great number of shoots, which, if carefully taken off in the spring, soon after they are above ground, become so many plants. The root is perennial, although the stalk dies down every winter.

The soils most suited to the cultivation of madder are deep, fertile, sandy loams, not retentive of moisture, and having a considerable portion of vegetable matter in their composition. It may also be grown on the more light descriptions of soil, of sufficient depth, and in a proper state of fertility. The preparation of the soil may either consist in trench ploughings, lengthwise and across, with pronged stirrings, so as to bring it to a fine tilth; or, what will often be found preferable, by one trenching, two feet deep, by manual labour. The sets or plants are best obtained from the runners, or surface-roots of the old plants. These being taken up, are to be cut into lengths of from six to twelve inches, according to the scarcity or abundance of runners. Sets of one inch will grow if they have an eye or bud, and some fibres; but their progress will be injuriously slow for want of maternal nourishment. Sets may also be procured by sowing the seeds in fine, light earth, a year before they are wanted, and then transplanting them; or sets of an inch may be planted one year in a garden, and then removed to the field plantation. The season of planting is commonly May or June, and the manner is generally in rows nine or ten inches asunder, and five or six inches apart in the rows. Some plant promiscuously in beds with intervals between, out of which earth is thrown in the lazy-bed manner of growing potatoes; but this is unnecessary, as it is not the surface, but the descending roots which are used by the dyer. The operation of planting is generally performed by the dibber, but some ley-plant them by the aid of the plough. By this mode the ground is ploughed over with a shallow furrow, and in the course of the operation the sets are deposited in each furrow, leaning on and pressed against the furrow-slice. This, however, is a bad mode, as there is no opportunity of firming the plants at the roots, and as some of the sets are apt to be buried, and others not sufficiently covered. The after-culture consists in hoeing and weeding with stirring by pronged hoes, either of the horse or hand kind. Some earth up, but this is unnecessary, and even injurious, as tearing the surface-roots. The madder crop

is taken at the end of the third autumn after planting, and generally in the month of October. By far the best mode is that of trenching over the ground, which not only clears it effectually, but fits it at once for another crop. Where madder, however, has been grown on land prepared by the plough, that implement may be used in removing it. Previously to trenching, the haulm may be cleared off with an old scythe, and carted to the farmery to be used as litter to spread in the straw-yards. Drying the roots is the next process, and, in very fine seasons, may sometimes be effected on the soil, by simply spreading the plants as they are taken up; but in most seasons they require to be dried on a kiln, like that used for malt or hops. They are dried till they become brittle, and then packed up in bags for sale to the dyer. The produce from the root of this plant is different according to the difference of the soil, but mostly from ten to fifteen or twenty cwt., where they are suitable to its cultivation. In judging of the quality of madder-roots, the best is that which, on being broken in two, has a brightish-red or purplish appearance, without any yellow cast being exhibited. The use of madder-roots is chiefly in dyeing and calico-printing. The haulm which accumulates on the surface of the field, in the course of three years, may be carted to the farm-yard, and fermented along with horse-dung. It has the singular property of dyeing the horns of the animals who eat it of a red colour. Madder-seed in abundance may be collected from the plants in the September of the second and third years, but it is never so propagated. Madder is sometimes blighted, but in general it has few diseases. (*Loudon's Ency. Agr.*)

In the Netherlands, where every agricultural process is conducted with such skill and success, madder sometimes forms a crop. It is always put upon land of the best quality, and with plenty of manure. At the end of April or May, accordingly as the young plants are large enough to be transplanted, the land must be ploughed in beds of two feet and two feet and a half wide; the beds are then to be harrowed and raked, and the young suckers of the roots or plants are to be put down in rows, at intervals of a foot or a foot and a half, and six or eight inches distant in the row. During the entire summer the land should be frequently stirred, and kept free from weeds. In the month of November, when the leaves are faded, the plants are covered with two inches of earth by a plough, having the point of the coulter a little raised or rounded, so as not to injure the young plants. In the following spring, when the young shoots are four or five inches long, they are gathered or torn off, and planted in new beds, in the same manner as has been pointed out above; and then, in the month of September or October, after the faded leaves have been removed, the old roots are taken up. The madder thus taken up should be deposited under cover, to protect it from the rain; and, after ten or twelve days, placed in an oven moderately heated. When dried sufficiently, it is gently beaten with a flail, to get rid of any clay that may adhere to the plants; and, by means of a small windmill, is ground and sifted,

to separate it from any remaining earth or dirt. It is then replaced in the oven for a short time, and when taken out is spread upon a hair-cloth to cool; after which it is ground and cleaned once more. It is then carried to a bruising-mill, and reduced to a fine powder, after which it is packed in casks or barrels for market.

Several interesting communications upon the subject of the culture of madder in the Northern and Eastern States, may be found in the agricultural periodicals. (See *American Farmer*, *New England Farmer*, *Cultivator*, &c.)

Mr. Russel Bronson, of Birmingham, Huron county, Ohio, a successful cultivator of madder, has published a communication upon this subject, which contains the following information:

A location facing the south or south-east is to be preferred. A sandy loam not over stiff and heavy, or light and sandy, or a good brown, deep, rich upland loam, free from fowl grass, weeds, stones, or stumps of trees. Where a crop of potatoes, peas, corn, or wheat has been cultivated the past season, plough deep twice, once in September and once in October, and if rather stiff let it lie after the plough until spring. When the spring opens, and the ground has become dry and warm (say in Tennessee, 1st of April, Ohio, 15th, and New York, 25th to 1st of May—I speak of the spring of 1836), plough again deep, the deeper the better, then harrow well and strike it into ridges with a one-horse plough, 3 feet wide and 4 feet vacant, or making a ridge once in 7 feet, raising it, if on rather moist ground, 8 or 10 inches, and dry land 6 or eight from the natural level; then with a light harrow, level and shape the ridges like a well-formed bed of beets, &c.

We will suppose you intend to plant one acre of ground, and that you have purchased 8 bushels of tap roots in the fall and buried them like potatoes on your premises—count the ridges on your acre, and take out of the ground 1 bushel of roots and plant it on one-eighth of your ridges; you will then be able to ascertain how to proportion your roots for the remainder. The following is the *manner of planting, cultivating, &c.*, when the quantities of ground do not exceed 3 or 4 acres. One person on each side of the ridge to make the holes (plant 4 inches below the surface of the bed, or thereabouts, when covered) one on each side to drop the roots, and 1 on each side to cover, pressing the hill in the manner of planting corn; or, 3 persons may be placed on one side, as the case may be, whether you have 1 or more acres to plant. Let the owner be the dropper of roots, and his most thorough assistants behind him. Make the holes from 12 to 18 inches apart, and about 6 inches from the edge of the ridge. As the plants are supposed to have been purchased in the fall, the roots may have thrown out sprouts, and possibly have leaved. In this case, in dropping and covering, you will leave the most prominent sprout or sprouts a little out of the ground, as where a plant has leafed, it ought not to be smothered.

When the plant gets up 3 or 4 inches, weed with the hoe, and plough with 1 horse, between the ridges or beds, but not on them; this will take place 2 or 3 weeks after planting. When up 12 or 15 inches, many of the tops will

fall; assist them with 10 foot poles crossing the bed, covering them with a shovel or garden rake, throwing the soil from between the ridges. After loosening with the one-horse plough, you will with a shovel scatter the earth between the stalks rather than throw it into heaps; of course we wish to keep the stalks separate, as they are to form new and important roots in the centre of the beds. About the 20th of June, you may plough between the beds, and scatter more earth on the fresh tops (all but the ends), and when you get through, you may plant potatoes between the beds if you please. I do not recommend it, if you have plenty of land, although I raised 1070 bushels of pink eyes on 8 acres the first year, and 60 bushels of corn. If your land is perfectly clear of weeds, you are through with your labour on the madder crop for this year, except in latitudes where there is not much snow, and considerable frost; in this case cover in October 2 inches or thereabout. Second year, same operations in weeding, but no crop between; cover once in June. Third year, weed only. Fourth year, weed in the spring, if a weedy piece of ground.

Begin to plough out the roots in Tennessee, [3 years old] 1st September. Ohio, [4 years] same time. New York, 15th or 20th, after cutting off the tops with a sharp hoe. In ploughing out the roots use a heavy span of horses, and a large plough. We ought to choose a soil neither too wet nor too dry, too stiff or light. Shake the dirt from the roots, and rinse or wash, as the soil may be stiff or light; dry in a common hop kiln; grind them in a mill similar to Wilson's Patent Coffee Mill; this mill weighs from 1 to 2 pounds. The madder mill may be from 60 to 80 pounds weight. Grind coarse, and fan in a fanning mill; then grind again for market. The profit of this crop is immense; the exhaustion of soil trifling, and glutting the market out of the question.

Madder is used in whole, or part, for the following colours on wool, both in England, France, and America, viz. blue, black, red, buff, olive-brown, olive, navy blue, and many others; finally it produces one of the most beautiful, durable, and healthy colours that is at this time dyed; as for calico printers, it enters greatly into their dyes. (*Am. Farmer's Instructor*.)

As the tops of the plants spread very much, some advise placing them in hills somewhat like Indian corn, 4 and even 6 feet apart each way, and 2 plants in each hill.

Rules have been laid down by Miller, *On the Culture and Manufacture of Madder*, for managing the land, separating and planting the shoots, gathering and drying the roots, and for pounding, casking, and preparing them for sale, according to the most approved English practice. The reader who wishes to attempt the cultivation of madder, will also find some useful hints in the *Penny Cyclopædia*, vol. xiv. p. 260, and *Brit. Husbandry*, vol. ii. p. 332; *Beckmann's Hist. of Invent.* vol. iii.; and *The Complete Farmer*, vol. ii. The haulm of madder, though sometimes employed in the feeding of cattle, is not very generally used for that purpose, for it tinges red the milk, the urine, the sweat, and even the bones of the animals fed

upon it. The average annual imports into England are about 180,000 cwt. of madder-root and ground madder. The duty chargeable on consumption is 2s. per cwt. on the prepared madder, and 6d. per cwt. on the roots. Madder was formerly used as a medicine in jaundice: but it possesses no properties which entitle it to be regarded as a remedy in any disease.

MADDER, THE FIELD. See **SHERARDIA**.

MADDER, WILD (*Rubia peregrina*.) This is an indigenous species which is found growing in thickets and on stony or sandy ground in the west of Britain. The root is creeping, fleshy, and tender, of a tawny red, useful in dyeing, but it is very inferior to the cultivated madder. The stem is branched, spreading, square, perennial, partly shrubby, its angles rough with hooked prickles, as are the edges and midrib of the broad, shining, dark, evergreen, elliptical leaves, which are four or more in a whorl. The flowers, which appear from July to August, are yellowish green, five-cleft, in forked terminal panicles. The berries are juicy, in pairs, black and shining.

The plant known in the United States by the name of wild madder, is the *Galium tinctorium* of botanists, or Dyers' Goose-grass. It is a perennial, found in moist woodlands and low grounds, flowering in July and August. The stems rise 12 to 18 inches high, generally erect, and branched. The flowers are white. Pursh says, the North American Indians use this plant for dyeing their porcupine quills, leather, feathers, and other ornaments, of a beautiful red colour.

MADI. A plant, said to be a new genus, growing in Chili. Its seeds furnish an oil which has been preferred to any of the French olive oils. (*Ed. Encyc.*)

MAGGOT. See **FLY IN SHEEP**.

MAGNESIA (Fr. *Magnésie*; It. *Magnesia*). One of the primitive earths having a metallic basis. It is an oxide of magnesium. It is sometimes found native, nearly in a state of purity; but is generally prepared by calcining the common carbonate of magnesia. It is inodorous and insipid, in the form of a very light, white, soft powder, having a specific gravity of 2.3. It turns to green the more delicate vegetable blues, and requires for its solution 2000 parts of water at 60°. It is found combined with carbonic and other acids in plants.

It is a useful purgative in an acid state of the stomach; and taken daily, with short intervals intervening, it is a useful preventive of red gravel or lithic acid deposits in the kidneys.

As all kinds of grain are found to contain a certain proportion of phosphate of magnesia, the presence of this substance cannot be supposed to be merely accidental. Hence the inference that magnesia must be serviceable as a fertilizer. It enters largely into the composition of limestone, of which it constitutes sometimes almost one half. The magnesian lime has been long applied with the greatest advantage in Pennsylvania and elsewhere. In other places the admixture of magnesia with lime has been considered as producing sterility rather than benefit. See **EARTHS, LIME**.

When magnesian lime has been applied to ground in undue quantity, so as to have produced unfavourable effects upon vegetation, it

has been found that after two years its hurtful influence has become exhausted. Great quantities of it are annually taken from Sunderland to Scotland by the Fifeshire farmers, and applied by them as a manure, with the greatest benefits, even in preference to other kinds of lime. The same preference is shown by many Pennsylvania farmers, for magnesian lime. Experience has shown that it has been unfairly denounced by Sir H. Davy and Mr. Tennent, as a sterilizer.

MAGNOLIA (named by Plumier after *Pierre Magnol*, prefect of the botanic garden at Montpellier, and author of several works on plants; he died in 1715). This is a genus of very elegant and showy plants when in flower, and well worthy of extensive cultivation. The hardy kinds, being remarkably handsome shrubs, should be planted in conspicuous situations where they will flower profusely when they attain a good size. *M. glauca*, and some others, grow best in a peat soil in a moist situation. They are generally increased by layers put down in spring or autumn, or by seeds; when the layers are first taken off, they should be potted in a mixture of loam and peat, and placed in a close frame till they have taken fresh root. None of the leaves should be taken off or shortened, nor any shoots be cut off, as they will not succeed so well; for the more branches and leaves are on the sooner they will strike fresh root. The Chinese kinds are often inarched or budded on *M. obovata*, one of the readiest growing kinds, which takes readily. The seeds of the North American species are received annually from that country. They should be sown as soon as possible after their arrival, in pots of light rich earth, covering them half an inch deep; these may be placed either in a hotbed or a warm sheltered situation, or they may be sown in the open ground, and when the plants are of sufficient size, they should be planted out singly into pots, and sheltered till they have taken fresh root; they should also be protected from the frost by a frame for two or three successive winters, giving them the benefit of the open air in mild weather.

The Genus *Magnolia* contains about fifteen species, almost exactly divided between China and the United States. There is also one species in tropical America. The trees are distinguished by a bark more or less camphorated and aromatic; the leaves are alternate, entire, and large, partly ovate, and in some species auriculate at the base. The flowers are large, fragrant, white, yellowish, or brown; the seeds scarlet or fulvous.

The following summary of the American species is from *Nuttall's Genera of North American Plants*.

1. *M. grandiflora*. The most magnificent tree of the southern states, the trunk often presenting a living column of 80 or 90 feet elevation, almost unobstructed by branches, and terminated by a spreading top of the deepest perennial verdure. 2. *Glauca*. 3. *Macrophylla*. This small pyramidal tree produces the largest leaves and flowers of any other North American plant. The limits of this interesting species appear to be extremely local. I first

observed it in Tennessee near the banks of Cumberland river, but of very small size. In the Southern States it is not at present known to the most assiduous collectors in any other spot than a single narrow tract of about 2 miles in length, 12 miles southeast of Lincolnton (Lincoln county, North Carolina). These limits I have carefully examined and found them invariable. 4. *Tripetala* (Umbrella-tree). 5. *Acuminata* (Cucumber-tree). Flowers yellowish green. 6. *Cordata*. Flowers yellow; appearing twice in the year in the garden of Mr. Landreth of Philadelphia. Leaves subcordate-oval, never truly cordate. 7. *Auriculata*. Leaves rhomboid-lanceolate, auriculate at the base. Considerably allied to *M. Macrophylla*. 8. *Pyramidata*. Nothing more than a variety of the preceding, having leaves a little broader and shorter. See CUCUMBER TREE.

MAIDEN HAIR (*Adiantum*, derived from *adiantos*, dry. Pliny says, it is in vain to plunge the *adiantum* in water, for it always remains dry). These are elegant species of ferns with beautiful leaves. They succeed well in a mixture of loam and peat; but they appear to thrive best if planted in loose rock-work where there is a good drainage, and may be increased by divisions or by seeds. *A. Capillus veneris* is the only indigenous species. It is often supposed that the French syrup called *capillaire* is made from this plant; but it is from the *Adiantum pedatum*, a plant growing in the south of France. Our *adiantum*, however, would make as useful a syrup. It is a refreshing beverage, mixed with water, in fevers. See FERN.

MAIZE, MAIZ, or INDIAN CORN (*Zea mays*, from *zao*, to live, in reference to the nutritive properties of the plants belonging to the genus). A gigantic herbaceous annual plant, belonging to the family of grasses cultivated for their grains (*Gramineæ*). Although, in Europe, the word *corn* is synonymous with wheat, rye, and breadstuffs generally, in the United States the term, used alone, applies exclusively to maize.

In one of the counties of Pennsylvania, a man having been indicted for stealing so many bushels of "corn," exception was taken by his counsel, that this was not a perfect description of Indian corn; the exception, however, was overruled by the court, who thus decided that "corn" was the established name for Indian corn.

Maize is the crop, of all others, best adapted to the climate of the United States, where it is cultivated, on every variety of soil, from one extremity of the Union to the other. It constitutes the main stay of the cereal farmer, most depended upon to furnish food and provender for man and beast. The crop raised in the United States in 1839, has been estimated at nearly 400,000,000 of bushels. That of 1842 was much greater. Supposing it to have been 500,000,000, this at an average price of only 40 cents per bushel, would make the total value of the crop no less than 200,000,000 of dollars, which is considerably more than double the value of the wheat crop estimated at \$1 per bushel. The article on AGRICULTURE will show the states and districts where the largest proportion of this grain is produced.

The amount raised annually, increases in rapid progression.

Although America is doubtless the native country of a plant so important to her interests; still this has been a disputed point. Fuchs very early maintained that it came from the East; and Mathioli affirmed that it was from America. Regmir and Gregory have presented fresh arguments in favour of its Eastern origin. Among them is the name by which it has long been known in Europe: *Blé de Turquie*; and varieties, it is said, have been brought from the Isle of France, or from China. Moreau de Jonnes, on the contrary, has recently maintained, in a memoir read before the Academy of Science, that its origin was in America. The name *Blé de Turquie* no more proves it to be of Turkish origin, than the name of the Italian Poplar or Irish potato, proves that the tree and the plant grew wild in Italy and Ireland. It can only signify that it spread from Turkey into the neighbouring countries. Its general cultivation in Southern Europe, and the production of some new varieties, proves nothing with regard to the country of the species. In favour of its American origin, is the fact that it was found in a state of cultivation in every place where the first navigators landed. In Mexico, according to Hernandez; and in Brazil, according to Zeri; and that in the various countries it had proper names, such as *Maize*, *Flaolli*, &c.: whilst, in the Old World, its names were either all of American origin, or from the neighbouring region, whence it was derived. Immediately after the discovery of America, it was spread rapidly in the Old World, and soon became common, a fact not reconcilable with the idea of its former existence there. To these proofs, Aug. de Saint-Hilaire has added another. He has received from M. de Larranhaga, of Monte Video, a new variety of maize, distinguished by the name of *Tunicata*; because instead of having the grains naked, they are entirely covered by the glumes. This variety is from Paraguay, where it is cultivated by the Guaycurus Indians, a people in the lowest scale of civilization; and where, according to the direct testimony of one of them, it grows in the humid forests as a native production.

The early authors who have written about America, with few if any exceptions, mention maize as an indigenous grain. Thus Acoste, in his *Natural History of the West Indies*, calls it "Indian wheat, to make bread of," and says "that it was the only grain found, in the West Indies by the Europeans:—that it grows upon a long reed with large grains, and sometimes two ears on a reed, on one of which 700 grains have been told:—that they sow it grain by grain and not scattering, as is done with wheat; and it requires a hot and moist soil. There are two sorts of it" (says our author), "one large and substantial, the other small and dry, which they call 'moroché.' The leaves of it and also the reed are very good food for cattle, green; and dry, it serves as well as straw. The grain is better for beasts than barley, but they must drink before they eat it; for if they drink after it, it swells and gives them pain. The Indian eat it hot, boiled, and call .

note, and sometimes toasted. There is a sort of it large and round, which the Spaniards eat toasted; they also grind it and make cakes, which they eat hot; and these, in some places, they call '*arepas.*' They also make bread, to keep, and sweet cakes of it."

As Acoste died in 1600, at Salamanca, in his 60th year, this must be regarded as very early testimony upon the subject. He surely would not have been so very particular in his description of this grain had it been previously known in Europe. Indeed entire ears of Indian corn have been found enveloped in Peruvian and Mexican mummies, preserved long before the discovery of America.

It is probable that some inferior species of the genus to which maize belongs, have been found in Guinea, Turkey, and other portions of the Old World; but that the kinds now so highly valued and generally cultivated were of American origin, there can be no doubt, both from the strongest negative and positive evidence. Maize is now extensively cultivated in Asia and Africa. In Europe, it is only in the extreme southern parts, France, Spain, and Italy, that the crop can be raised so as to be profitable.

Varieties of Indian Corn. The varieties of corn cultivated in the United States are very numerous. A list embracing many of these has been furnished by P. A. Brown, Esq., in an interesting Essay on Indian corn. (See *Farmer's Cabinet*, vol. ii.) The following varieties, distinguished by peculiar characteristics of the grain, cob, &c., are included in Mr. Brown's enumeration. It is an interesting fact, that the rows of grains on a cob, however numerous or limited, always present even numbers.

Yellow Corn. No. 1. The yellow gourdseed, so called from the resemblance of its long, narrow grains to the seed of the gourd. This has 24, and occasionally even more rows. Mr. Brown makes 7 varieties of this according to the number of rows regulated by admixture with other kinds of corn. No. 8. The genuine King Philip corn, so called from the celebrated chief of the Wampanoags. It has 8 rows, the lowest number found on any kind of Indian corn. It is a hardy plant, the seed of which was originally obtained from the Northern Indians. No. 9. The *Sioux* or yellow-flint corn with 12 rows, derived from the Sioux tribe of Indians which formerly resided in Canada. No. 10. The *Sioux* variety grown in Pennsylvania. No. 11. The *Sioux* and gourdseed mixed—16 rows.

White Indian Corn, a division in which Mr. Brown includes the *white flint*, *white flour-corn*, and white sugar, or sweet corn. He has omitted the white gourdseed, which is by far the most common corn raised in the South, where it is sometimes found with from 24 to 36 rows of grains upon the ear. No. 12. Genuine white-flint, 12 row corn raised in Virginia. No. 13. White-flint,—10 rows. No. 14. Early white flint, and white *flour* corn,—12 rows. No. 15. Peruvian corn,—8 rows. No. 16. Pennsylvania, 8 rows,—called in Maryland, Smith's early white. No. 17. New Jersey—8 rows. No. 18. New York, 10 rows, and Mandan In-

dian corn. No. 19. Mandan corn, and white sugar corn. No. 20. Early sugar corn, with shrunken grains and 12 rows.

Hæmetite, or Blood-red Indian Corn. 21. Common sized hæmetite, with 12 rows and red cob. 22. The red cob with white grains. 23. Red cob with yellow grains. 24. Red cob with brown grains. 25. Red cob, with white gourdseed. 26. Red cob with gourdseed and yellow flint. 27. White cob with red grain. 28. Speckled red and yellow grains on a white cob. 29. The same on a red cob. 30. The dwarf hæmatite, commonly called Guinea corn. 31. Blue corn, with 10 rows. 32. Texas corn, each grain of which grows enveloped in a distinct covering or tunic, the whole ear being also enveloped in a husk. 33. Mexican corn, found in the envelope of a mummy. 34. Corn raised in England by William Cobbett. 35. The celebrated Dutton flint corn.

The remarks of the late John Lorain, in his *Practice of Husbandry*, convey so much information relative to the kinds of corn chiefly cultivated in the United States, the various merits of each kind, and the modes of culture, that we cannot refrain from giving a condensation of them.

There are five original corns in use for field planting, in the Middle and Southern States, to wit: the *big white* and *yellow*, the *little white* and *yellow*, and the *white Virginia gourdseed*. The cobs of the two first mentioned are thick and long, the grains are much wider than deep, and where the rows of grains meet and unite with each other, their sides fall off almost to nothing. This gives the outside ends of the grain a circular form; and communicates to the ear an appearance somewhat like a fluted column. This formation greatly diminishes the size of the ends and sides of the grains; and is the cause of the hard flinty corns being less productive, in proportion to the length and thickness of their cobs, than the gourdseed corn. As the little white and yellow are formed much in the same way, and the cobs considerably smaller, they are still less productive than the big white and yellow, but ripen earlier.

The grain of those four flinty kinds are very firm, and without indenture in their outside ends. The two smaller kinds seem to be still more hard and solid than the larger; and the colour of the little yellow deeper than that of the big.

The ears of the Virginia gourdseed are not very long, neither is the cob so thick as that of the big white and yellow. But the formation of the grain makes the ear very thick. They frequently produce from thirty to thirty-two, and sometimes thirty-six rows of very long narrow grains, of a soft open texture. These grains are almost flat, at their outside ends, are also compactly united from the cob to the surface of the ear, without any of that fluted appearance between the rows of grain, which causes the flinty corns to be much less productive in proportion to the size of the ears.

The gourdseed corn ripens later than any other, but is by far the most productive. It is invariably white, unless it has been mixed with the yellow flinty corns. Then it is called the yellow gourdseed, and too many farmers

consider it and most other mixtures original corns. I have often heard of original yellow gourdseed corn, but after taking much trouble to investigate the fact, could never find any thing more than a mixture.

So prevalent are mixtures, says Mr. Lorain, that I have never examined a field of corn, (where great care had not been taken to select the seed,) which did not exhibit evident traces of all the corns in general use for field planting, with many others that are not used for this purpose.

None can be longer or more readily traced than the gourdseed. If the smallest perfectly natural indenture appear in the grain of the hardest corns, those grains, with their descendants, may be grown, until a perfectly white gourdseed is obtained, be their colour what it may.

In the northerly divisions of the United States, they frequently plant the small Canadian corns.

These are solid and very early, but have been generally thought too small to be very productive, and are seldom planted in fields, where the larger corns ripen.

These corns and others which are still much smaller and earlier, are grown by many for early boiling or roasting while green.

The Canadian corn plant is considerably smaller than the corns in general use for field planting. It is also productive in ears. Therefore, the intervals, as well as the clusters in the row, might be closer together. If the soil were as well manured for this kind of corn as is done for the larger corns (when the farmer is well informed and able to do it), very valuable crops might be obtained from it: particularly if it were only slightly mixed with the gourdseed corn.

There are also red, blue, and purple corns, but none of these are used for field planting; still, having been introduced, they too often appear in our fields, either in their native colours or in variegated or enamelled grains. The leaves of the plant are also sometimes variegated from the same cause. It is said that a good purple dye is formed by using the purple corns for this purpose; and the stalks and leaves of this plant are purple, or a shade between that colour and green. I have also seen corn with red stalks and leaves, but mixed with more or less green.

As novelty and other causes have introduced such a great variety into our fields, they will continue to appear in them until farmers generally give more attention to the economy of maize, and see the necessity of growing out inferior kinds, so far as it may be practicable. Although they may be divided almost ad infinitum, they cannot be entirely eradicated. They may, however, be readily reduced and kept under, so as not to do any material injury to the crops, provided the cultivator very carefully and annually selects his seed. It may be from the latent remains of these mixed varieties, that nature, from combining causes, sometimes produces plants and animals more perfect than the class from which they sprang.

This variety, as it regards corn, proceeds from the farina fecundans, a light minute sub-

stance of a mouldy colour, seen on the clothes of those working among the plants, when it is disengaged from the tassels. This is wafted far by high winds, and is the cause of distant and unthought-of mixtures. However, in general, it is lightly and plentifully diffused through the field, and lodges in sufficient quantities on the silky fibres which project from the ears. A single fibre proceeds from each grain. This has been so constructed as to convey the principle of *life* contained in the farina fecundans to the grain from which the fibre springs, even to the further end of the cob. This is done with so much certainty that we rarely see abortive grains, when the plants have been rendered healthy and vigorous by a sufficiency of nutriment and good cultivation. The change produced by this mysterious cause is generally gradual. We first see scattering, whitish looking grains on the ears of the yellow corn growing among the white, and the reverse on the ears of the latter, when grown near to the yellow corns.

The foregoing facts have induced me to make experiments. The result seems to determine, that if nature be judiciously directed by art, such mixtures as are best suited for the purpose of farmers, in every climate in this country where corn is grown, may be introduced. Also, that an annual selection of the seed, with care and time, will render them subject to very little injurious change; provided the desirable properties of any of the various corns be properly blended together. They do not mix minutely, like wine and water. On the contrary, like mixed breeds of animals, a large portion of the valuable properties of any one of them, or of the whole five original corns commonly used for field planting, may be communicated to one plant; while the inferior properties of one, or the whole, may be nearly grown out.

When this object is obtained, and we become acquainted with the proper arrangement of the plants in our fields, so as to promote the utmost product, the crops of maize will by far exceed any estimate which would at this time be considered probable by those who have not carefully examined the economy of this plant.

It should, however, never be forgotten, that a sufficiency of nutriment and good cultivation are quite as necessary to increase and perpetuate the size of grain as plentiful and nutritious food, and proper care and management, are to accomplish the same in animals.

My ears of maize are now at least one-third larger, on an average, than were the ears procured three years ago from Huntingdon for seed. The same may be also said of some white, flinty corn, procured by my neighbour, Mr. H. Philips, from near Erie, for seed.

The quantity of the gourdseed corn mixed with the flinty yellow corns, may be determined, so as to answer the farmer's purpose. When the proportion of the former greatly predominates, the grains are pale, very long and narrow, and the outside ends of them are so flat that but little of the indenture is seen. As the portion of gourdseed decreases in the mixture, the grains shorten, become wider, and their outside ends grow thicker. The indentures

also, become larger and rounder, until the harder corns get the ascendancy. After this, the outside ends of the grains become thicker and more circular. They also grow wider, and the fluted appearance between the rows increases. The indentures also decrease in size until they disappear, and the yellow, flinty variety is formed. But, as I believe, not so fully but that the latent remains of mixture will forever subject it to more or less change.

It is more difficult to determine the quantity of big and little yellow corns, which may happen to be mixed with the gourdseed; and at the same time with each other. However, by attention, a tolerably correct opinion of this may be formed. The grain of the big yellow is much wider, and nothing like so deep as that of the gourdseed; and although the grain of the little yellow is not so wide and deep as that of the big, still it is wider than the gourdseed; and its colour is deeper than that of the big yellow, and its cobs are much slimmer, as well as shorter.

When a mixture with the big yellow and gourdseed is desirable, care should be taken, in growing out the little yellow, to preserve as much as possible of the deep yellow tinge and solidity communicated to the grain by this variety, and also of its property to ripen early.

The soft, open texture of the gourdseed renders it unfit for exportation, unless it be kiln-dried. This has given rise to an unfounded prejudice among the shippers of this grain, in favour of the yellow corns, although they are not more solid than the white, flinty varieties. However, while this prejudice continues, it is best for those who depend on selling it for shipping, to mix the gourdseed with the yellow flints, and for those who consume the produce on their own farms, or can readily sell the white corns, to form mixtures with them and the gourdseed. It is thought that the white corns are the most productive, and ripen earlier than the yellow; but of this I know nothing certain, having generally grown the yellow. There can, however, be no question but that the white furnishes much handsomer meal for culinary purposes. It is also free from that strong taste so readily distinguished by those who have been accustomed to use the white; but as most of the Pennsylvania farmers, and cultivators still further north, have been used to eat the yellow, and habit causes most kinds of food to become agreeable, they seem generally to prefer the strong taste of this variety to the much milder and pleasanter taste of the white. However, in the countries where neither is grown, and to which it is often exported, there can be but little doubt that the white would find a readier market, and that the demand for this very nutritious grain would greatly increase, if none but the white were exported: especially, if laws were passed prohibiting the exportation of maize until it had been kiln-dried.

I believe there is no grain that will keep longer or safer than corn, if it be kept on the cob in open dry cribs, and the climate also be dry, unless the weevil be introduced by not carefully cleaning the cribs of every vestige of the grain and vegetable matters introduced with it.

Flinty corns, after they have been well dried in such cribs, may be shipped in tight, dry vessels, with tolerable safety, to the West Indies: but longer voyages subject this grain to greater injuries, although it may arrive in port in tolerable safety; a little damp communicates a musty taste to maize, and if this does not happen, it is often spoiled by lying in bulk after it arrives, and will be considered much less valuable on this account.

Either the big yellow or white should be mixed with the gourdseed, for planting in every climate where this mixture will certainly ripen. Their cobs being very long, and the grain so much wider and deeper than those of the little yellow or white, the mixture with them will be much more productive. It is also thought, that the length of the ear communicated by the big yellow or white will fully compensate for the shortening the grains of the gourdseed: therefore, if the mixture be properly formed, its product may even exceed that of the original gourdseed corn; I have measured the product from ears of this mixture, which, when shelled, yielded a full pint of corn, after they had lain twelve months in a very dry place, although the mixture had not been well improved.

The little yellow and white, being earlier than the big, they should form mixtures with the gourdseed corn for being grown in climates more unfavourable for maize. But whoever may form either of those mixtures, will find, that he must grow out either the big or little flinty corns, with many others, as they are more or less mixed.

The speediest and best way to form either of those mixtures, is to select one ear that may possess most of the desirable properties united in it, and to plant the seed where the farina fecundans from the general crop cannot readily obtain access. If it happen to the cultivators, as it has done with me, he will certainly find from the growth of this seed many ears in his patch, very much like the ear that grew the seed, and many very unlike it; however, it may be that he will find some ears approaching nearer to the variety which he wishes to form than the original ear; if so, he will of course select the best, and go on in the same way, until he has full enough for planting his general crop. After this, he should aim at an increased improvement, by carefully selecting his seed annually for the ensuing crop. (*Practical Husbandry.*)

Of these numerous varieties some are best adapted to the Southern States—the white and yellow gourdseeds: others to the Middle States—the gourdseed and flint varieties, pure or mixed; whilst the heavy flinty grained kinds are almost exclusively cultivated in the Northern and Eastern States—to which they are specially adapted by their disposition to grow and mature with great rapidity, and thus accommodate themselves to the shortness of northern summers. Like all early maturing corn, they are dwarfish, though very productive. The effect of the longer and warmer summers in more southerly situations is to favour greatly the growth of the stalk, which frequently attains 10 or 12 feet in height; but such luxuriance, however splendid in appearance, is by no means

attended by a corresponding increase in the product of grain. The time taken by different varieties in growing and maturing, differs exceedingly. In the Southern and Middle States the crop occupies the ground from 5 to 7 months, whilst in the Northern and Eastern States the ears come to maturity in 3 or 4 months, and some is even found so precocious as to ripen in 6 weeks. An interesting and plausible explanation of these facts is given in the article on CLIMATE, and its INFLUENCE ON THE FRUITFULNESS OF PLANTS.

Since Mr. Lorain wrote his excellent book, several demonstrations have been furnished of the practicability of improving corn. One of the most interesting is that made by Thomas N. Baden, Esq., of Prince George's county, Maryland, who, by carefully selecting the best seed in his field for a long series of years, having special reference to those stalks which produced the most ears, ultimately obtained a variety which yields 4, 5, 6, and even as high as 8 and 10 ears to the single stalk. The particulars of the plan pursued are as follows:

When the corn was husked, he made a re-selection, taking only that which appeared sound and fully ripe, having a regard to the deepest and best colour, as well as the size of the cob. In the spring, before shelling the corn, he examined it again, and selected that which was the best in all respects. In shelling the corn, he omitted the irregular kernels at both the large and small ends. He has carefully followed this mode of selecting seed corn for *twenty-two or twenty-three years*, and still continues to do so. When he first commenced, it was with a common kind of corn, for there was none other in that part of the country. At first he was troubled to find stalks with even *two good ears* on them, perhaps one good ear and one small one, or one good ear and a 'nubbin.' It was several years before he could discover much benefit resulting from his efforts; however, at length the quality and quantity began to improve, and the improvement was then very rapid. At present he does not pretend to lay up any seed without it comes from stalks which bear 4, 5, or 6 ears. He has seen stalks bearing 8 ears. One of his neighbours informed him that he had a single stalk with *ten perfect ears on it*. In addition to the number of ears, and of course the great increase in quantity unshelled, it may be mentioned that it yields much more than common corn when shelled. A barrel (10 bushels of ears) of his improved kind of corn measured a little more than six bushels. The common kind of corn will measure about 5 bushels only. He believes that he raises *double, or nearly so*, to what he could with *any other corn*. He generally plants the corn about the first of May, and places the hills five feet apart each way, leaving two stalks in a hill.

Some of Mr. Baden's seed-corn was sent to Illinois, with instructions how to manage it, and the product was *one hundred and twenty bushels on an acre*; there was no corn in Illinois like it, and it produced more fodder than any other kind. (*Farm. Cab.* vol. ii.)

The *Baden corn* is a white gourdseed, the stalks of which grow to an extraordinary

height, so that the ears are often 6 or 8 feet above the ground, and the summits twice that elevation. The grain is of excellent quality, but the ears are short and considerably under the average size of the common varieties of corn. When removed but little farther north, as for example to the vicinity of Philadelphia, it seldom matures perfectly. It does not answer well for high-land culture, but flourishes and produces abundance of grain and fodder in the rich flat lands of the Southern and South-western States. It verifies the observation that high-growing corn is the least disposed to ripen the ears, and consequently most liable to injury from autumnal frosts.

Varieties cultivated for particular purposes.—Among the varieties of corn cultivated for special purposes, we may mention the *white flint*, used for making the beautiful hominy sold in the Philadelphia market; the *flour corn*, with a round, thick grain, filled with a snowy white powder resembling starch, much used in New Jersey for grinding up with buckwheat, in the proportion of about one-fourth or one-fifth of the corn, giving the buckwheat-meal a lighter colour and otherwise improving it. The early Jersey truck corn, a middle-sized ear, with white and rather flinty grains, the earliest corn raised for the market, but not so sweet as the *Early sweet* or *Sugar corn*, which, when dry, has shrivelled grains; there are two varieties of this, the white and red cob kinds. The small flinty-grained corn usually raised for parching or popping is considered a distinct species of maize, under the name of *Zea Caragua*, or Valparaiso corn, to which a sort of religious reputation has been attached, from the circumstance of its splitting open when parched or roasted so as to present some resemblance to a cross. Its appearance under this form is peculiarly beautiful, and bears a strong resemblance to the flowers of a cruciferous plant. The flavour is pleasant, and it makes a very pretty dessert-dish.

Preparation of the Land for planting.—In the Middle States corn is planted in all conditions of the land, but in Virginia and Maryland, it generally follows the wheat crop, upon which all the farm-yard manure has been spread. In the upper portion of Delaware and in Pennsylvania, the crop is generally put upon a grass sward or clover lay. Where the soil is a stiff clay, much labour is bestowed in ploughing deep, then rolling and reducing to the finest tilth by means of harrows. As a general rule, after a sward has been turned, care is taken not to harrow so deep as to reach and drag up the sods, which are suffered to lie and decompose, thus furnishing nutriment to the corn, and keeping the ground loose and favourable to the spreading of the roots. Many farmers spread lime upon the land intended for corn, in the autumn or winter, previously to ploughing. Others put the lime dressing on the ploughed ground. Although the first may be considered a good plan, still there can be little doubt that lime operates most effectually when left upon the surface so as to be exposed to the atmosphere, and especially to the full action of rain water with its dissolving agent carbonic acid gas. But the best plan of all is to

spread the lime on the grass the year preceding the tillage in corn, as then the vegetation is greatly benefited, and the lime has full time to dissolve in considerable proportion and impregnate the soil. Where the land is light or sandy, shallow ploughing is frequently practised and much less labour is required to prepare the ground for the crop. In all cases, however, where there is a retentive clay below the soil, no doubt can exist of the propriety of stirring the earth as deeply as practicable, first by the common plough, and next by the subsoil plough, which loosens the earth or clay below the furrow run by the common plough, without turning it up. This effectual and deep breaking up of the earth allows the water to penetrate quickly into the soil charged with all its fertilizing gases and salts, which would otherwise be rapidly dispersed if exposed to the open atmosphere.

Season for Ploughing.—With regard to the best time for ploughing, this must depend much upon the character of the soil. Late fall or winter ploughing has been thought useful in turning up and exposing to perish, the grubs and other insects which have retreated below the surface for winter quarters; but in Pennsylvania this practice is now generally abandoned in favour of spring ploughing.

The roller, when used, must be drawn in the direction of the furrows, and never crosswise. Then follows the drag-harrow, in the same direction, being the last instrument which, on flushed ground, is employed preparatory to planting. The spikes of this implement should never be set so deep as to reach and drag up the sod, an observation which will apply to all other implements called in requisition during the working of the crop. The harrowing should be continued until the surface of the inverted sward is completely broken up and pulverized.

In the Middle States, it is a very general custom to prepare the ground for corn by a method called *listing* or double furrowing. This consists of ploughing so as at first to turn two furrow-slices together, leaving a middle space which is subsequently ploughed out by turning an additional furrow on each side. This places the ground in narrow lands or ridges, consisting of four furrow-slices with deep, intervening trenches. The width from the middle of one land to the other is generally about 4 feet. In signing out for planting, a plough is run across these narrow lands, so as to strike out rows generally 4 feet apart. The plough which performs this cross-ploughing, is immediately followed by a boy who drops 4, 5, or 7 grains of corn directly opposite the middle of each of the ridges, and the operation of planting is completed by a man who covers the seed with a hoe.

Farmers generally agree that corn should be planted as early in the spring as the weather will permit, and some of the best are not even afraid of having the young shoots nipped off by frost. The usual time of planting in the Floridas is early in March, whilst in Massachusetts it cannot be done before the middle of May,—facts which show the great range of climate in the United States.

Mr. Lorain, one of the best authorities upon this and most other agricultural subjects upon which he has treated, says,—When corn is planted very early, it is commonly severely affected by frost; so much so, that many of the plants are cut off by the ground. This is unquestionably an injury to which no judicious farmer would expose the plant, if the advantages obtained by very early planting could be had by planting later. Still if the roots remain unhurt, they are of consequence established, and very soon repair the injury done above the soil, after the frost ceases to act on the plants. Of course they take the lead, and will maintain their superiority over later planted corn. The ears also fill and ripen much better in northerly climates from this practice.

The shooting and filling of them take place when the heat of the sun is much greater; and when less cloudy, cold, dripping weather prevails, and the crop is nothing like so liable to be injured by frost. The grounds are also sooner ready for crops sown in the fall. This mode of management will often enable the cultivator to grow the large and more productive corns, in climates where they have been abandoned, from observing that they did not ripen when planted at the usual time.

When I introduced the large yellow gourd-seed corn, from seed procured from Huntingdon county, every farmer here ridiculed the idea of attempting to grow corn of this description. They considered the soil and climate hostile to the growth even of the smaller corns, and but little was planted. As they waited until the earth was warmed before they planted, the crops were frequently either destroyed, or greatly injured by frost. (*Pract. Husb.*)

In Pennsylvania, corn generally forms the first crop of the regular rotation, the sod being ploughed without manure, except the occasional addition of a light dressing of plaster of Paris (about one bushel per acre) or a full coat of lime (50 to 100 bushels per acre). The plan of listing and ploughing out, so common in the Southern and Middle States is not followed by Pennsylvania farmers, who flush up the ground so as to present a uniform surface.

Planting.—After rolling, and then harrowing well, the rows are struck out very shallow, and the corn is planted in hills 3, 4, 4½, or 5 feet apart, or dropped in rows from 3 to 5 feet asunder, so as to leave the stalks, when thinned out, about 1 or 2 feet apart. In this last case the tillage has of course to be conducted in the direction of the rows, and never cross-wise, as is practised when the grain is in hills at regular distances. The distance of the corn hills or plants apart must be regulated by the kind of corn to be planted, and the nature of the soil. When the growth is high, and the soil rich, the rows should be farther apart than where the growth is low, as is the case with the Northern varieties, which may be planted 3 feet apart.

Whenever manure can be spared for the corn crop, it will always make a good return for maize cannot well be too highly manured. If the supply be sufficient, it may be spread broadcast upon the land previous to ploughing or, what is better, spread upon ground that has

been flushed up in the autumn or winter, and then lightly ploughed in. In the Northern and Eastern States where the summers are short, a liberal quantity of manure is generally required to assist in forcing the crop to early maturity. When not enough is at hand to afford a good dressing broadcast, it is advisable to apply a portion of short manure to each hill just before planting. Ashes are an excellent manure for Indian corn, and may be dropped upon the hills in the proportion of a gill to a pint. It is common to make a mixture of these with lime and plaster. But there is no doubt that the main benefit of the mixture proceeds from the live ashes. Almost every kind of artificial manure may be advantageously applied to corn, either in the hill or broadcast; and there is none perhaps which acts so promptly upon the young plants as the Poudrette manufactured in New York and other cities, the basis of which fertilizer is night-soil. A gill of this to the hill furnishes a fair dressing, and pushes the young corn forward with such rapidity as to place it very soon beyond danger from the grub, cut-worm, and other insect depredators, by which the plants, especially those on light and exhausted soils, suffer such destruction during their feeble and tardy growth. As conducing to the same end, soaking the seed for 24 or 36 hours in solutions of saltpetre, urine, the drainings of the stables and cattle-yards, &c. &c., have a very good tendency. To protect it from the depredations of insects, birds, and vermin, it is often coated with liquid tar, and subsequently rolled in ashes, plaster, lime, or saltpetre, which last is considered one of the most convenient, cheapest, and best of steepers. Strong solutions of copperas, blue vitriol, and even corrosive sublimate and arsenic, are sometimes used for the same purpose—which last, however, is only soluble in water by the addition of potash, or some other alkali. "The enemies to be combatted," says Buel, "are the wire-worm, brown grub, birds, and squirrels. Of these, the first and two last prey upon the kernels, and against these tar offers a complete protection. I soak my seed 12 to 20 hours in hot water, in which is dissolved a few ounces of crude saltpetre, and then add (say to 8 quarts of seed) half a pint of tar, previously warmed and diluted, with a quart of warm water. The mass is well stirred, the corn taken out, and as much plaster added as will adhere to the grain. This impregnates and partially coats the seed with the tar. The experience of years will warrant me in confidently recommending this as a protection for the seed."

Number of grains to the hill, and depth of planting.—Where there is reason to apprehend much mischief to the young plants from blackbirds, crows, vermin, and insects, it is always best to drop from 4 to 7 grains to each hill, so that some 2 or 3 may have a chance to escape. An old quaint couplet lays down a pretty good (though not sufficiently liberal) rule upon this subject, when it recommends 5 grains—

"One for the blackbird, and one for the crow,
One for the cut-worm, and two left to grow."

The deficiency is always attempted to be made up by replanting other grain, but the product of this replant is too often feeble, and so late in

maturing, as to be frequently injured by the frost in autumn. A much better plan is to replant with the surplus of other hills. But this requires a damp and very favourable condition of the weather. As to the proper depth of covering for the seed, much difference of opinion exists; some advocating shallow covering, that is to say, from an inch to 2 or 2½ inches, whilst others recommend from 3 to 6, 8, and even 10 inches. All covering which exceeds 4 or 5 inches must, under ordinary circumstances, be considered extravagant and detrimental. Those in favour of deep covering say that although the corn does not come up so soon, or appear so forward, it makes a much better growth later in the season; sends its roots lower, and of course is less affected by dry weather, whilst the stalks stand much better against the violence of storms, by which they are often prostrated. They also urge as additional recommendations, that the crows and blackbirds are unable to pull up the young shoots, so as to get at the grain from which it springs, whilst the cut-worm may sever the sprout in the common situation just beneath the surface, leaving enough still below to push up and continue the growth. See DRILL.

It cannot be doubted, that where the mould is of a light texture, moderately deep covering answers best as a general rule. To cover deep where the soil is a heavy clay loam, would either cause the grain to rot, prevent it from rising, or dispose it to come up twisted, unless opportunely assisted by rain, to soften the packed covering.

Tillage.—The corn once planted, its tender blade pushes through the ground, usually in about a week or ten days, and even sooner when the grain has been previously soaked. Although the field is generally left at rest until the plants have all fairly risen above ground before the tillage of the crop commences, some begin with the harrows even before the corn is up. The first objects to be effected are, to keep the ground stirred and free from grass and weeds. Where danger is apprehended from worms, by which it is so frequently attacked, many maintain that the tillage should not commence very soon, so that some other vegetation being allowed to start up, the young corn will thus be in a measure spared; whereas, if the ground is perfectly clean, the worms, having nothing else to feed upon, will, of course, destroy all the young corn. Instances may occasionally occur where this practice may prove advantageous, but as a general rule, the young corn cannot be kept too clean, or the ground about it too loose.

The modes of tillage vary exceedingly, not only with the variations in soil and climate, but with the views of different persons in the same locality. On stiff, clay soils, there is no doubt that harrowing just before the proper time for the corn to come up, favours this process, by loosening the tenacious soil, especially where a timely rain does not occur to soften the earth. After the corn appears, the harrow should be kept going until the ground is rendered perfectly loose, hands following with hoes or short rakes to clear the corn which may be covered. Then comes the plough-

which, in the Southern and lower portion of the Middle States, is often used to turn a furrow from the young corn. This operation is termed *bar-ploughing*, because the bar of the plough is run next to the plants. A few days after this, the process is reversed, and the mould-board being turned next the corn, the loose earth is thrown back again. Many think that this second ploughing, called *moulding*, ought not to be left longer than a few hours before the earth should be turned back again. In some places ploughs are still used for this last purpose with wooden mould-boards, as these serve best to push the loose earth before them, crumbling and spreading it about the plants more advantageously than ploughs furnished with smooth and polished iron mould-boards. Some use narrow, deep-cutting ploughs, which do this work with comparatively little labour to the horse, and render the soil near the corn much more permeable by the roots, and at the same time, quickly accessible to the rain and atmospheric influences. Whatever tends to favour the extension of the roots downwards, serves to place the crop beyond the vicissitudes of the season.

There is, perhaps, no plant which withstands the effects of drought so well as Indian corn, whilst young; but when its top blades begin to be heavy, its demands for moisture increase so as to cause it to suffer greatly from very dry weather. Heat and moisture are the great promoters of its luxuriant growth.

Mr. Lorain's comments upon the custom of *bar-ploughing*, as practised by a distinguished Maryland farmer and agricultural writer, are very judicious. Mr. Boardly, he says, ploughed from each side of the rows of the plants five inches deep, while the plants were young; he then let them rest 10 or 12 days on the narrow ridges formed by this practice; this was done, that the lateral roots should take their direction under the artificial surface of the ground formed by the ploughshare. If the corn-plant, when scarcely three inches high, be pulled up by the roots from an open free soil, the lateral roots will be found about 12 inches long, beside what remains in the ground; consequently these roots are cut off on each side of the rows, even by the first cultivation, while the plant is yet very young; they are also cut off by every succeeding cultivation. If the furrows made along each side of the rows, by the first cultivation, were kept continually open, and the lateral roots of the plants compelled by this means to cross the bottom of them, a little within the ground, this would not cause the roots to grow under the artificial surface of the ground formed by the ploughshare. Nature immediately after they passed the open furrow, would direct them up into the soil above, to take their natural range through it: especially in that part of it where the most genial heat and nutriment obtained. This is clearly seen when the lateral roots of trees cross ditches, or even deep gullies, at the bottom of them, a little within the ground. They immediately mount upward after they have crossed the bottom of the ditch, and take their natural growth at the same distance from the surface

of the soil as would have happened if they had met with no obstacles in getting into it.

The roots of the corn-plant which proceed downward from the stalk, also those that take their course along the rows, are not injured; neither are all those which grow the deepest within the soil in the intervals cut off. Therefore as the corn-plant is very hardy, it is supported by these roots, until nature repairs the damage done by this truly inconsiderate and barbarian practice. It is of consequence by no means wonderful, that Mr. Bordley, who was in many respects a judicious farmer, should by his general good management so far counteract the evils arising from this savage practice, as to grow, under all the disadvantages resulting from it, crops that were more than equal to the general crops of his neighbours. Reason, however, as well as practice, determines that crops obtained in this way must fall very far short of those that may be obtained from a rational system of management. It is also obvious, that his mode of cultivation is well calculated to cause an extensive, useless waste of the animal and vegetable matter contained in the soil. Likewise of the farm-yard manure, if that be applied for the growth of the crop. (*Lorain's Pract. Husb.*)

The farmers in some of the finest districts in Pennsylvania have of late years made much less use of the plough in cultivating their corn than formerly. They now generally content themselves with moulding, or throwing a single furrow on each side of the young plants, leaving a space between the rows of from 3 to 3½ feet untouched. The space left, is afterwards worked by means of shovel-ploughs, and cultivators, which completely destroy the grass, and loosen the ground. This mode of culture is more quickly and economically performed than the old plan of ploughing the whole space between the rows, and leaving the surface comparatively level. If the land be sufficiently loose and deeply stirred, there is little use in hilling it. It is sometimes said corn requires hilling to support it. Nature disproves this argument, by the stiff, bracing roots thrown out by this plant, at the time they are wanted, and for this very purpose. On wet lands, planting on ridges and hilling may be advisable, but such lands should never be chosen for corn. If wet, drain thoroughly in the first place. Allow no weeds to grow in your corn, says Buel, and do not fear to stir the surface in dry weather. Every weed absorbs nutriment enough to make a good ear of corn, and if any remain after the plough cannot be used, pull them up, or cut them with the hoe.

Thinning and Succouring.—As quickly as possible after it is ascertained that the plants are in a thrifty condition, and no longer in danger of being destroyed by the cut-worm and other enemies, they are thinned out, so as to leave only two or three in a hill. Or, should they stand in rows or drills, the plants are left about one or two feet apart. The operation of succouring takes place some time after thinning, and consists in tearing off the side-shoots which often sprout from the bottom of the main stalk. It is beginning to be thought that this practice

is much more hurtful than advantageous, injuring the growth and development of the corn, and lessening the produce of both fodder and grain. The truth of these opinions seem to have been confirmed by actual experiments. (See *Cultivator*, vol. viii. p. 90.)

Many farmers deem the use of the plough altogether unnecessary and even injurious, and conduct the tillage of the corn crop throughout first with the drag-harrow, and successively with the cultivator, horse-hoe, and hand-hoe. These are kept going very constantly until wheat harvest, after which further culture is suspended, and the corn crop, in common phraseology, is said to be *laid by*. The plants have now attained from 2 to 4 or 5 feet in height, and thrown out their side-shoots. These should be left to extend themselves uninterruptedly in all directions, which they will do with great rapidity provided the season be favourable and the soil loose and in good tilth. Should they be cut or torn asunder by late and too deep working, the crop must suffer serious injury.

The progressive growth and development of Indian corn are well described by Mr. Lorain.

The roots and stem of maize, he says, spring from the heart of the grain; the former grows from one to two or more inches long before the latter appears, and progresses so very rapidly, that if pulled up from a loose soil, they will measure about 12 inches long when the stem is only about 3 inches high, although their finer fibres must be left in the ground by this rude operation.

The stem protrudes itself through the soil in the form of a bodkin, and is composed of leaves rolled very compactly together; the first two leaves expand soon after the plant penetrates the soil, and other rolled leaves continue to unfold in succession from the crown of the plant, until the tassel appears wrapped up in its own leaves: these also gradually spread themselves, until the plant is fully formed.

The leaves increase in width and length from the ground up to where the most perfect ear is formed; after this they decrease in length and width, more rapidly than they increased below, and this decrease is regularly maintained even to the uppermost leaf, which forms itself a little below the tassel.

One leaf grows from every joint in the stalk, but in such a way as to alternate sides; the first formed leaf, and after this every leaf in regular succession, clasps the stalk closely, until it approaches near to the under side of the leaf above; after this it grows out from the stalk, and a beautiful fan-like appearance is at length produced, which is not equalled by any other annual plant cultivated for the value of its fruit; especially when the large luxuriant ears display at their points elegant tufts of silky fibres, which vary in colour when mixtures form the seed.

The height of this plant differs much. The smallest variety that has been noticed by me did not seem to exceed 3 feet in height. The largest plants which I have seen measured but 13 feet. I have, however, heard of some which attained the height of 17 feet. These

must have been grown on a very rich, as well as a very deep and open, free soil.

The lateral roots of maize soon spread through the whole soil. The finger-roots, as they are sometimes called, dip much deeper. I have seen them traced two feet below the surface of the soil by a grubbing hoe, in the hands of a rugged workman. How much further their finer fibres might have gone was not ascertained by me, but this convinced me that the roots of maize were capable of drawing very much moisture and some nutriment from a much greater depth than most of the plants cultivated by us. Also, that these manures and smaller roots were better calculated to effect this very interesting purpose than they would have been if nature had formed the whole of them into one single taproot, which extended no deeper. This is one cause, among many others, why maize is capable of contending so powerfully with poverty, and notwithstanding severe and continued drought, better than most other cultivated plants. This should convince us that a plant capable of drawing such important supplies from beyond the range of plants in general, will not prove peculiarly exhausting if it be treated fairly, by having as much manure or as good a soil appropriated for it as is commonly used for those plants which farmers in general have not learned to grow on poor soils without manure.

The prop roots of maize appear about, or a little before, the tassels may be seen. They proceed from the joint at or near the surface of the soil. They are numerous, and form a circle round the plant. That portion of them which grows outside of the ground is hard and woody, similar to the substance which forms the outside of the stalk; but so soon as they penetrate the soil they become softer, and spread through it in search of nutriment; this is just at the time the plant requires most of it. The tassel and the top of the plants have after this to attain their full size, and the farina fecundans, which impregnates the grain, is to be formed. The ears now begin to shoot, and they are also to be filled and perfected.

The prop roots are exactly calculated to support the weight of the tassels and ears during high winds, and when the grounds are softened by rain. But farmers too generally thwart this simple but wise arrangement of nature, by hilling or ridging up the plants. These inconsiderate operations not only cut and rend the roots, but also compel the plants to grow new sets of prop roots from the joints above. These seldom get sufficiently established in time to support the weight and height of the tassels and ears; and many of the plants are of consequence blown down, or fall by their own weight, when the grounds have been previously much softened by rain.

Maize, from its woody texture and commanding size, might (without straining the point very far), be called an annual bread tree, producing the best of all corns, and at the same time crops which in magnitude far exceed that of any other grain. Also tops, husks, and leaves which can be readily gathered, and furnish abundant fodder for cattle, equal to the

nest hay; and independent of this, the stalks supply much valuable litter for the cattle yard.

That part of the leaf which surrounds the stalk, and adheres so closely that it does not permit a particle of moisture to escape, is very interesting. The peculiar insertion of the leaf, together with the formation of that part of the stalk covered by it, forms a cavity for the reception of the rich moisture, which is gathered into it from the atmosphere by the leaves, and for which they are most admirably formed.

The shoots which form the ear commence at the joint in contact with the ground. If the soil be rich or highly manured, they issue from every joint up to where the uppermost ear is formed at the footstalk of the tassel. This last or highest up ear is almost invariably the largest, and ripens soonest. It seldom occurs that more than two ears are perfected on one stalk, unless the clusters of plants are very distant from each other, and but few plants stand in each cluster. If the plants stand thick on the ground, but one ear is commonly perfected by each of them. The abortive ear shoots are called suckers. These are commonly removed, so far as the farmer considers conducive to the welfare of his crop. This should be done so soon as they are large enough to be pulled off effectually. No part of them should be left adhering to the stalk, or they will grow again from the stub left behind.

If this operation be not early commenced and frequently repeated, they become so numerous and large in fields highly manured, especially if the plants stand thin on the ground, that they are greatly injured; not only from the loss of nutriment, but also from the many and large wounds inflicted by the removal of them.

After careful experiment in the removal of suckers, I now pull none above the joint in contact with the ground; and would not remove these if they did not take root in the soil, and by this means become powerful exhausters. Although it commonly happens that several ear shoots above this point prove abortive, no sucker can be removed without injuring the leaf which binds it to the stalk; and so much that it is commonly rendered altogether incapable of conducting moisture. If it be not so extensively injured, the receptacle formed by it is so much deranged by this operation, that it cannot retain the slight portion which may happen to be conducted by the leaf into it.

I am still further encouraged to let so many of these abortive ears stand, as I have observed that so soon as nature has determined the number of ears which existing circumstances may enable her to fill, all her efforts are directed to them, and the abortive ones immediately dwindle, and finally wither; and, for aught we know to the contrary, nature may cause them to part with the rich matters they had previously gathered, and apply this nutriment to assist in maturing her favourites.

I trust it will appear from what has been advanced, that in place of abusing this invaluable plant as an exhauster of the soil, we should consider it the pride and boast of American

husbandry, as mathematical demonstration cannot well afford stronger proof than has been produced that maize gathers a large portion of the nutriment necessary to perfect its fruit from the atmosphere.

Still, it should be remembered that sufficient nutriment, provided in the soil, is absolutely necessary to enable it to do this very extensively. Therefore, "let not what God has joined together, by man be put asunder," by vain philosophical theories and sophistical reasonings. Such as, that the chief use of the soil is merely to support the plants in their proper place, or that cultivation will supersede the necessity of keeping the soil well stored with animal and vegetable matter.

The middle path is certainly the path of reason and experience, and should be carefully and diligently pursued by the practical farmer, leaving those ideal speculations for the amusement of the learned.

There is no corn crop grown by us which is so certain as maize. Its diseases are few, and most, if not all of them, proceed from an inconsiderate cultivation. I do not recollect ever to have seen them so extensive in any field as to do any very material injury to the crop.

It withstands drought and contends with poverty better than most other plants cultivated by us, either for the value of their grain or roots. It may be advantageously grown in any soil fit for cultivation, not excepting blowing sands or retentive clay.

Still, this crop fails occasionally, especially in the higher latitudes, or situations rendered cold from local causes. It cannot withstand grass or weeds, and is too generally planted by far too late. The seed is also covered too deep, as well as oppressed with clods, stones, or any other rubbish near at hand, which prevents the plant from coming up. Too little seed is planted to secure a sufficiency of plants after birds and quadrupeds have taken that portion which even proper vigilance cannot prevent. (*Practical Husbandry.*)

Saving the Fodder, &c.—The tops of the Indian corn, when cut off for fodder, should be removed previous to stripping the blades from the stalks below the ear, which last operation should be delayed till near the time of maturity, indicated by some dryness of the leaves and hardness of the grain. The ears are gathered by hand, and the husks, when perfectly dry, stript off, and, together with the stalks, laid by for winter fodder, while the ears are conveyed to the granary. The green stems and leaves abound in nutritious matter for cattle, and in some places it is cultivated solely for this purpose, especially after early crops of other vegetables; when planted for this object, it should be sowed very thickly. Corn, when well dried, will keep good for several years, and preserve its capability of germination. It is eaten in various manners in different countries, and forms a wholesome and substantial aliment. Domestic animals of every kind are also extremely fond of it. According to Count Rumford, it is, next to wheat, the most nutritious grain. It is considered as too stimulating for the common food of cattle, and is found to be more stimulating than any other kind of

bread used by us. The fattening and invigorating qualities of Indian corn make it the best of all kinds of food for persons exposed to hard labour or fatiguing duty. In the United States, however, the preference so generally bestowed by the labouring classes upon Indian corn, is by no means confined to them, but shared alike by rich and poor, for the sweetness of the bread, and its wholesome and superior invigorating virtues. Mixed with rye meal, it forms the common brown bread of New England; mixed with water alone, it makes a very palatable species of extemporaneous bread. When pounded in a mortar, or ground very coarse and boiled, it forms the "hominy" and "grits" which are such great favourites at the south; and the fine meal, boiled thick in water, is the "mush" of Pennsylvania, and the "hasty-pudding" of the Eastern States. In the form of hulled corn, or *samp*, the whole grains furnish a very palatable, although rather indigestible luxury. Of the husks a beautiful kind of writing-paper has been manufactured in Italy; and when soaked in hot water, they make excellent mattresses. A grayish paper may be made from all parts of the plant.

Enemies and Diseases.—The bird, insect, and other depredators have been already referred to under the head of BIRDS, CUT-WORM, WIRE-WORM, PLANT-LICE, &c. Among the diseases, the chief one is a dark or blue-black spungy growth, which sometimes takes the place of the blighted ear of corn. The mass sometimes grows till 5 or 6 inches in diameter, and is to be considered a luxuriant or rank species of fungus. As the species of parasitic plants to which this belongs are so readily destroyed by applications of common salt, there is reason to believe that soaking the seeds well in salt-water previous to planting, or scattering salt over the ground, will prevent this disease.

In all the fields of maize, says Mr. Lorain, which have been examined by me, some plants entirely barren have been seen without any apparent cause.

The fungus appears to be principally occasioned by wounds inflicted during cultivation. The plants commonly bleed from these wounds, and a fungus is formed. This, when in contact with the ear, is certain destruction to it, unless the fungus be soon seen and removed. When it is formed on other parts of the plant, it frequently corrodes them so much that they are incapable of perfecting their fruit. The only remedy known to me is speedy removal, and repeating the operation if the fungus should reappear: which generally occurs. But even this tedious remedy is too often found insufficient. It is, therefore, far better not to create this disease, by mangling the plants, either by the savage practice of harrowing over them, or by covering them with clods, stones, or sods, as is too often done by the inconsiderate mode of hilling or ridging them up. Although many of the plants wounded by these injudicious practices survive and appear to flourish, even when the fungus is not removed, still, numbers of them become too debilitated to perfect their fruit.

A reddish kind of rust sometimes appears on the leaves, but seldom does much apparent injury to the ears, unless it becomes extensive.

However, the same rust sometimes fixes upon the stalks and causes them to decay.

When this is near the ear, or the decay is extensive, the plant produces little or no grain; but I have never seen very extensive injury done by this disease. The cause of it is unknown to me. It may, however, proceed from the bruises and wounds inflicted by an inconsiderate cultivation; especially as the tassel, wrapped in its own leaves, may be seen formed in the plant when it is quite young. Too many farmers think the health and vigour of the plants are greatly promoted by harrowing over them, and mangling their tops while they are young. Also, by cutting and rending the roots of them, provided this be not done after the tassels and ear shoots appear; than which nothing can appear more preposterous. (*Practical Husbandry.*)

It sometimes happens, as the effect of storms, that the pollen is blown or beaten off the tassel before all the silk has protruded from the ear. The consequence of this is a failure in the development of grains in the extremity or other portion where the silk was deficient. It has been urged, among the reasons for letting the suckers grow, that being later in tasseling and less exposed to high winds, they assist to promote the process of fecundation after the tassels of the main stalks have shed their pollen. As an evidence of this, it has been stated that the earliest ears are always best covered with grain, while those which push late often exhibit a quarter or a half of naked cob,—the consequence of imperfect impregnation.

Harvesting the Crop.—This is effected very differently in different portions of the Union.

1. In Pennsylvania, and the Northern and Eastern States, the corn is usually cut off at the surface of the ground, as soon as the grain has become glazed, or hard upon the outside, and whilst the blades are still green, put immediately into shocks, and thus left some time standing in the field. The corn after becoming sufficiently dry is husked and cribbed, and the stalks with all the attached fodder and husks are carted home and stacked for provender.

2. In the Southern and Southerly portions of the Middle States, the corn is commonly husked in the field, the stalks having previously had the blades stripped below the ears, and the tops lopped off above the ears. When, therefore, the ear has been separated, the naked stalk is left standing with the husk, which is soon afterwards eaten off by cattle.

There are some other modes of gathering corn and securing the fodder, but those described are by far the most general. In some parts of the fertile Western States, where the crops are extremely luxuriant, with the absence of facilities to get the grain to market, it is common to husk out and secure enough of the corn for family use and then turn the hogs and cattle into the field to consume the remainder.

By the first of these methods the crop may be secured before the autumnal rains, with all its valuable fodder, and the ground cleared in time for a winter crop of wheat or rye. The juices retained by the stalk are sufficient to nourish the corn to maturity. By the second mode there is always a loss in the grain pro-

duct, which is never so well filled after the blades and tops have been removed in a green state. This has been proven by actual experiments, for the particulars of which see *Buel's Farmer's Instructor*; also *Farmer's Register*, vol. ii. p. 91; and *Colman's Fourth Report*, p. 16.

All, or nearly all the accounts we have published of great products of Indian corn, agree, says the editor of the *Cultivator*, in two particulars, viz.: in not using the plough in the after culture, and in not earthing, or but slightly, the hills. These results go to demonstrate, that the *entire* roots are essential to the vigor of the crop; and that roots to enable them to perform their function as nature designed, must be near the surface. If the roots are severed with the plough, in dressing the crop, the plants are deprived of a portion of their nourishment; and if they are buried deep by hilling, the plant is partially exhausted in throwing out a new set near the surface, where alone they can perform all their offices. There is another material advantage in this mode of cultivating the corn crop—it saves a vast deal of manual labor.

There is another question of interest to farmers, which relates to the mode of harvesting the crop, that is, whether it is best to top the stalks, cut the whole at the ground when the grain is glazed, or cut the whole when the grain has fully ripened. Experiments made by Mr. Clark, of Northampton, one of the best practical farmers of Massachusetts, and of other gentlemen, show that the grain suffers a diminution of six or eight bushels to the acre, by topping the stalks; and there seems to be no counterbalancing benefit to the fodder, unless at the expense of carrying the stalks to the borders of the field, that they may be secured before the crop is gathered, and before they become blanched and half-ruined. And it is no protection against early autumnal frosts, but rather exposes unripened grain to be more injured. Hence so far as regards these two modes, all who have made a comparison seem to concur in the opinion, that stripping the corn of its tops and leaves is a bad practice.

The blades and tops of corn, if well cured, furnish an excellent fodder for neat cattle and horses, all kinds of stock being very fond of them. They serve greatly to increase the amount of manure, collected in the cattle-yard. In Pennsylvania, in the Southern parts of which the crops of corn are very luxuriant, the fodder is generally considered worth at least \$4 per acre as provender. A distinguished farmer in Whitmarsh, Montgomery county, obtained, in 1842, from a 30 acre field, sufficient corn-fodder to winter 30 large steers intended for spring beef. The stalks had been cut down with blades, &c., attached. Corn is occasionally sown broad-cast for the purpose of being mown down as green provender for milch cows, &c., for which it answers an admirable purpose. It has been also cured as hay, and on some highly fertile or rich spots has yielded 6 tons of hay or fodder.

Preserving Corn.—Corn is usually preserved by storing away the ears cleared from the husks, in small or narrow granaries called

cribs, the sides and ends of which are constructed of logs or laths, so as to leave interstices of about an inch, or rather more, permitting a free circulation of air. If the cribs be wider than 8 or 10 feet, the middle part is very apt to have the corn injured, especially when put away before becoming thoroughly dry. In the Southern States, corn in the crib is often seriously injured by the weevil when attempts are made to keep it over the summer. But in the Middle and Northern States, it may be preserved for many years on the cob. In the *Louisiana Register* it is stated that sprinkling the corn whilst housing, with a solution of common salt and water (in the proportion of about one pint of salt to a gallon of water), will entirely prevent the insect from breeding. The ears of corn are there frequently stored up in the husks, which are rendered much more grateful to stock by the addition of salt.

There is perhaps no plant—certainly none of such vigorous growth,—which will so long continue highly productive when raised year after year upon the same soil. In a communication to the *Farmer's Register*, by Mr. Shultice, of Mathews county, Va., he says that there are in the county named, small tracts of land which have been in corn, year after year, as far back as the recollection of the oldest inhabitants extends. The same fields planted in corn successively for more than half a century, at present yield fair crops. Such land, when new (judging by the product of contiguous recently cleared land), yielded from 3 to 5 barrels per acre. At present the product is from 2 to 3 barrels, with the occasional application of a very meagre dressing of manure. With a fair supply of manure, the land can be readily made to yield as much and even more than it did when first brought under cultivation. As, in the tillage of this crop, all vegetation is carefully destroyed, the materials constituting the soil or mould must have decomposed very slowly indeed. Where there is much sand in the soil, exhaustion takes place very quickly; but Indian corn can be cultivated on land, long after it has ceased to afford compensating crops of any other grain.

Expenses of Culture.—These are very differently estimated in different parts of the United States, being influenced by a variety of local circumstances. The following estimate and accompanying statement is from Jonathan Roberts, Esq., a very eminent agriculturist residing in Montgomery county, Pennsylvania:

“An estimate of the expense of cultivating an acre of maize 15 miles northwest of Philadelphia. Soil, a calcareous loam.

Ploughing sward	- - - - -	\$3 00
Harrowing to proper fineness	- - - - -	2 00
Marking out and planting	- - - - -	2 00
3 loads (2-horse wagon) manure to dress the hills	- - - - -	3 00
Horse-hoeing, at least three times	- - - - -	2 00
Moulding and horse-hoeing	- - - - -	2 00
Harvesting	- - - - -	2 00
Saving fodder	- - - - -	1 00
Rent of land	- - - - -	5 00
Wear of gears and plough	- - - - -	1 00
Amount of expense	- - - - -	\$23 00
Amount of crop 60 bushels, at 60 cts. per bushel	- - - - -	36 00
Fodder	- - - - -	4 00
		\$40 00
Leaving a balance in favor of the corn-crop of		\$17 00

MAIZE.

"This estimate," says Mr. R., "is predicated on practical husbandry, with a fair season. It is not found economical, in a regular course of cropping, to manure corn land beyond hill dressing. The decomposing sward will be found equal to its production. The renovating process of manure should be applied in putting in the winter crops with the cultivated grasses. Lime should not be immediately applied before sowing the winter crops. Its application ought to follow the maize in the fall, or at the latest in the following spring. By such a course of culture ground may be kept improving in fertility. It is not the part of practical farming to increase the crop of corn by an expensive manuring; it must be taken as one of a series of ploughed and green crops. On a good soil, and with a good season, corn may run to 70 and 80 bushels an acre. Good management will be directed to produce a series of good crops, with an improvement of soil."

With great deference to an agriculturist of such matured experience, we cannot help expressing an opinion that some of the items in the statement are rated too high, and that it would perhaps be more correct to bring down the expenses at least as low as those in the following estimate furnished by Judge Buel. This last, it must be remembered, does not include manure, so much more of which is usually required at the North, as greatly to increase the expense of the crop.

Estimated expense of cultivating an acre of Indian corn in the State of New York:

One ploughing (suppose a clover lay)	\$2 00
Harrowing and planting	2 00
2 hoeings, 4 days, and horse-team	3 75
Harvesting, 2 days	1 50
Cutting and harvesting stalks	1 50
Rent	5 00
	<u>\$15 75</u>

In the New England States the expenses of culture are stated to exceed these calculations considerably. Mr. Colman, in his *Fourth Agricultural Report to the Legislature of Massachusetts*, gives the following estimates for different townships.

"In Northfield, the estimate was made as follows:

Ploughing	\$4 00
Dragging	1 00
5 cords of manure in the hill	12 00
Getting out and putting in the hill	4 00
Seed corn 1 peck planted 3½ feet each way	37½
Planting	1 34
1st hoeing with man and horse	2 34
2d hoeing, \$1 17; 3d hoeing, \$1 17	2 34
Gathering and husking	5 50
	<u>\$32 89½</u>
Fodder equal to 1 ton of hay	10 00
40 bushels of corn, at \$1	40 00
	<u>\$50 00</u>
Balance in favour of corn	<u>\$17 10½</u>

"Another farmer in Northfield gives the following estimate of the expense of an acre of corn:

MAIZE.

Ploughing, \$2 50; harrowing, \$2 50; hoeing, 50 cts.	\$5 50
6 bushels leached ashes	10
1 bushel plaster or gypsum, 65	65
Seed, 10 quarts, \$1 00; putting on ashes and plaster, and planting, \$1 20	2 20
Harrowing, 30; weeding, \$1 50	1 80
Cultivating twice in a row, 30; 2d hoeing, \$1 10	1 40
Cultivating, 15; last hoeing, \$1 20	1 35
Gathering and husking, \$5 00; gathering stalks, \$1 50	6 50
	<u>\$19 50</u>
Corn fodder equal to 1 ton of hay	10 00
Crop 50 bushels corn, at \$1 00 per bushel	50 00
	<u>\$60 00</u>
Balance in favour of crop	<u>\$40 50</u>

"It will be seen," says Mr. C., "that in the above case nothing has been charged for manure, excepting ashes and plaster. The corn was raised after a stubble clover-crop ploughed in, or a green sward inverted. His corn usually averages 70 bushels per acre.

"The estimate of the expense of a corn crop in Deerfield is thus given by a very careful and successful cultivator:

Ploughing, \$2 34; harrowing, 50; hoeing, \$1 00,	\$3 84
4 cords of manure, \$8 00; spreading manure, \$2 67	10 67
Seed, 25; planting, \$1 00; weeding, \$2 00; horse, 25	3 50
2d hoeing, \$1 58; 3d hoeing, \$1 58	3 16
Topping stalks, \$1 00; husking, \$2 50	3 50
Cutting up and gathering butts, \$1 00	1 00
	<u>\$25 67</u>
Interest on land	6 00
Dr. the above crop	<u>\$31 67</u>

Proceeds of crop:	
Fodder equal to ¾ ton of hay, \$9 00	9 00
50 bushels corn	50 00
	<u>\$59 00</u>
Balance in favour of corn	<u>\$27 33</u>

"In Shelburn, the estimate of the cost of cultivating an acre of corn is given by a farmer, whose skilful and successful cultivation needs no commendation.

Ploughing, 3 50; 20 loads manure (7 cords), \$15 00	\$18 50
Getting out and spreading manure \$4 50; dragging or harrowing, \$1 00	5 50
Seed, 1 peck, 38; manure for the hills (8 loads), \$6 00	6 38
Planting and manuring in the hill, \$4 00	4 00
Weeding and hoeing, \$3 33; 2d hoeing, \$2 33; 3d hoeing, \$2 33	7 99
Cutting and shocking, \$2 00; husking, \$4 00	6 00
	<u>\$48 27</u>

Proceeds of above crop:	
Fodder equal to 1½ ton of hay	12 50
70 bushels corn, at \$1 00	70 00
	<u>\$82 50</u>
Balance in favour of corn	<u>\$34 23</u>

Several other estimates of the expense of cultivating an acre of Indian corn, varying from 14 to 25 dollars, are given by Mr. C. The above statements are from farmers of the highest respectability for intelligence and exactness, and may be relied upon.

Mr. Colman says, "that on the hilly portions of Massachusetts but little corn is raised, but that it makes a large product on the alluvial lands of the Deerfield and Connecticut. The largest amount I have known raised in one year, by one individual, has been 1400 bushels; but many farmers produce from 300 to 1000 bushels. The judgment of some of the most intelligent farmers in Deerfield places the average yield at 35 bushels to the acre, which seems to be underrated. I have," he says, "known upwards of 90 bushels grown on an acre in Deerfield meadows; an average yield of more than 70 bushels on several acres in Northfield; and other abundant crops, which show at least what might be obtained by good cultivation; and likewise how much more profitable is good than inferior cultivation."

It is evident that over that portion of the Middle and Southern States lying east of the Mountains, and where the lands have been so greatly impoverished by long and scourging culture, commencing with that greatest of exhausters, tobacco, the expenses per acre incurred in the raising of corn must be very much lower than either of the estimates furnished for Pennsylvania and the Northern and Eastern States. Large tracts of the light alluvial districts forming the tide-water sections of Virginia and Maryland, do not yield an average per acre exceeding from 10 to 20 bushels; and still corn continues to be cultivated, even when the price is below 50 cents per bushel. Such crops would be ruinous to the farmer, were he not able to cultivate his acres of light unmanured soil at less than 5 or 10 dollars each. In the rich prairies of the West it is stated that crops of corn, averaging 50 bushels to the acre, can be raised at an expense of only 3 or 4 dollars per acre.

Qualities of Corn.—Abundant experience has shown that the fattening qualities of Indian corn are exceedingly great; so that all who can obtain this grain prefer it to every thing else for fattening stock, all kinds of which eat it with avidity and advantage. It is rich in oil of a very pleasant and useful kind. That which is best known is obtained in the process of distillation for making whisky and alcohol—a great perversion of the use of so precious a grain. The temperance reform is correcting this evil, and another mode of manufacturing the oil is now in great vogue, namely, by passing the grain through the secreting organs of swine, and thus obtaining it in the modified forms of lard and lard-oil. As these commodities are both in great request at home, and more especially in Europe, a new and rich resource is thus opened to the corn planters of the United States, those especially who cultivate fertile Western lands too far from grain-markets, to be able to dispose of their crops in that form.

The chemical analysis of Indian corn has been lately effected by Dr. Dana, of Massachusetts, and published in the *New England Farmer*. For the purposes of comparing its nutritive and fattening qualities with those of some other articles extensively used for feeding stock, Dr. Dana has added the analyses of ruta-bagas and potatoes. The great difference of what

Dr. Dana calls the fat forming principles in favour of corn, will excite but little surprise in those who have witnessed the effects of the several substances on animals, and will go far to establish the position assumed by Payen and Boussingalt, that plants are valuable for giving fat to animals only in proportion to the vegetable oils ready formed such plants contain.

	100 lbs. of Corn.	Ruta Baga. Fresh dug.	Potatoes. Fresh dug.
Containing of flesh forming principles: gluten, albumen, &c.	1.26	1.	2.07
Fat forming principles: gum, starch, sugar, woody fibre, oil, &c. - - -	88.43	13.	24.34
Water - - - -	9.	85.	72.
Salts - - - -	1.31	1.	1.39

Table showing the average prices of Indian corn in Philadelphia market for each quarter of the year, and also the annual averages for the following years, viz.:

	1st Quar.	2d Quar.	3d Quar.	4th Quar.	Average for the year.
1827	56 cts.	48½ cts.	49 cts.	48½ cts.	51 cts.
1828	43½	39½	39½	49½	43
1829	46½	47	47	46½	49
1830	36½	39	48	55½	45
1831	61	67½	66	57	63
1832	46½	53½	67	71½	60
1833	49½	67½	61½	61½	64
1834	49½	57½	67	60½	59
1835	61½	79½	89	86½	78
1836	78½	82½	91	90	85
1837	96½	91½	101	85½	94
1838	72½	74	85½	80½	78
1839	86	89	78	62½	79
1840	53½	50½	55	53½	52
1841	42½	52	69½	60½	61
1842	52½	55½	52½	45	51
Average for 16 years -					63 cts.

The above average prices are for Southern flat yellow corn, commonly called gourdseed, which generally sells for about 3 cents less per bushel than the Pennsylvania round or flint corn, which last is heaviest by 3 or 4 lbs. to the bushel. The amount of white flat corn sent to the Philadelphia market is inconsiderable, being only occasionally in demand for shipment to Southern ports, where the white corn is preferred for bread, whilst in the North the preference is always given to yellow corn meal. White flat corn usually sells about 3 cents lower per bushel than the flat yellow.

Measuring Corn, Shelled or on the Ear.—The following rule for this purpose is given by William Murray, Esq. of South Carolina. It is not to be regarded as strictly accurate, but an approximation.

Having previously levelled the corn in the house, so that it will be of equal depth throughout, ascertain the length, breadth, and depth of the bulk; multiply these dimensions together, and their products by 4, then cut off one figure from the right of this last product. This will give so many bushels and a decimal of a bushel of shelled corn. If it be required to find the quantity of ear corn, substitute 8 for 4, and cut off one figure as before.

Example.—In a bulk of corn in the ear, measuring 12 feet long, 11 feet broad, and 6 feet deep, there will be 316 bushels and $\frac{8}{10}$ of a

bushel of shelled corn, or 633 bushels and $\frac{6}{10}$ of ear corn—as :

12	12
11	11
-----	-----
132	132
6	6
-----	-----
792	792
4	8
-----	-----
316,8	633,6

The decimal 4 is used when the object is to find the quantity in shelled corn, because that decimal is half of the decimal 8, and it requires two bushels of ear corn to make one of shelled corn. In using these rules a half bushel should be added for every hundred, that amount of error resulting from the substitution of the decimals. (*Southern Agriculturist.*)

Distances of Planting.—The following table furnished by Judge Buel, exhibits the difference in product of planting and serves to explain, in part, the manner in which large crops of this grain have been obtained. It is assumed in the estimate, that each stalk produces one ear of corn, and that the ears average one gill of shelled grain. This, says the judge, is estimating the product low; for while I am penning this (October), I find that my largest ears give two gills, and 100 fair ears half a bushel of shelled corn. The calculation is also predicated upon the supposition that there is no deficiency in the number of stalks, a contingency pretty sure on my method of planting.

	Hills.	bush	qts.
1. An acre in hills, 4 feet apart each way, will produce - - -	2722	42	16
2. The same, 3 by 3 feet - - -	4810	75	20
3. The same, 3 by 2½ feet - - -	5808	93	28
4. The same, in drills at 3 feet, plants 6 stalks, 1 inch apart in the drills -	29,040	113	14
5. The same in do., 2 rows in a drill, 6 inches apart, and the plants 9 inches, and 3 feet 9 inches from centre of drills, thus - - -	30,970	120	31
6. The same in do., 3 rows in a drill, as above, 3 feet from centre of drills -	43,560	170	5

The fifth mode I have tried. The ground was highly manured, the crop twice cleaned, and the entire acre gathered and weighed accurately the same day. The product in ears was 103 baskets, each 84 lbs. nett, and 65 lbs. over. The last basket was shelled and measured, which showed a product on the acre of 118 bushels 10 quarts. I gathered at the rate of more than 100 bushels the acre from four rods planted in the third method last summer, the result ascertained in the most accurate manner. Corn shrinks about 20 per cent. after it is cribbed. The sixth mode is the one by which the Messrs. Pratt, of Madison county, obtained the prodigious crop of 170 bushels per acre, the largest crop on record. These gentlemen, I am told, are of opinion that the product of an acre may be increased to 200 bushels.

I am told the Messrs. Pratt, above alluded to, used seven bushels of seed to the acre, the plants being subsequently reduced to the requisite number. (*Buel's Farmers' Instructor.*) See also **PLANTER'S TABLE.**

According to the mode usually adopted in Pennsylvania, and other States in which the high-growing varieties of corn are planted, the

cornhills will average a distance of 4 by 3 feet, which gives 3,600 hills to the acre, and allowing 2 stalks to each hill, this makes 7,200 stalks per acre. In more northern situations where they are compelled to rely upon the quick-maturing varieties, the lowness of the stalks admit of closer planting, the hills averaging about 3 by 2½ feet apart, with 4 stalks per hill, by which means an acre is made to contain 5,808 hills, and no less than 23,232 stalks—every stalk, in a good season and with proper tillage, yielding a good ear.

Sugar from Maize.—Every one familiar with Indian corn in its growth, must have observed the very great sweetness of the juice exuding from the green stalks, when broken or cut. This, together with the great resemblance between the true sugar-cane and maize, afforded ample ground for believing that sugar could be procured from its juice. But whether this can be manufactured with profit, still remains to be fully demonstrated. Partial experiments have afforded favourable results, among which the following may be mentioned. The juice of maize contains as much, if not a larger proportion of sugar than that of the sugar-cane. This sugar is precisely similar in its crystallizing and other properties to that of the cane.

The attention of scientific investigators has for some years been directed to this subject, and it has been regarded as an important discovery that the removal of the shoots forming the rudiments of the ears, before these have had time to fill, has caused the stalks to retain all their saccharine matter at an advanced stage of their growth. Very recently this has been contested. At a recent meeting of the French Academy, the distinguished philosopher, M. Biot, read the report of a committee, which paper contained the following statements: Of the corn stalks experimented upon, the ears had been removed from one portion, and left to grow on others. The juice obtained from the stalks which had been castrated, yielded 12 per cent. of sugar; that expressed from the stalks on which the ears had been permitted to grow, 13 per cent. It would hence appear that the results of former experiments showing great apparent advantages from castration, were fallacious, the operation being rather injurious than otherwise. The rapidity with which maize attains its growth, admits of its being removed from the soil sufficiently early to give place to a winter crop. This, in France, is reckoned among the great advantages it has over the sugar-beet, for which it is proposed as a substitute. In those countries where the climate is not sufficiently warm to bring the grain of Indian corn to perfect maturity, such as England and Northern France, it is probable that the plant might be brought sufficiently forward to admit of the manufacture of sugar. Mr. Webb, of Wilmington, Delaware, has made some interesting experiments upon this subject, which are highly worthy of attention. (*See Farmer's Cabinet, 1842, and Ellsworth's Report, 1843.*) The results afford reasons for believing that the manufacture of sugar from maize may be advantageously carried on in the United States,

especially in the Western States, where such luxuriant crops of maize can be raised at little expense.

MALE FERN. See **FERN.**

MALIC ACID. This vegetable acid exists in the juices of many fruits and plants, alone, or associated with the citric, tartaric, and oxalic acids; and occasionally combined with potash or lime. Unripe apples, pears, sloes, barberries, the berries of the mountain-ash, elderberries, currants, gooseberries, strawberries, raspberries, bilberries, brambleberries, whortleberries, cherries, ananas, afford malic acid; the house-leek and purslane contain the malate of lime.

The acid may be obtained most conveniently from the juice of the berries of the mountain-ash, or barberries. This must be clarified, by mixing with white of egg, and heating the mixture to ebullition; then filtering, digesting the clear liquor with carbonate of lead, till it becomes neutral; and evaporating the saline solution till crystals of malate of lead be obtained. These are to be washed with cold water, and purified by re-crystallization. On dissolving the white salt in water, and passing a stream of sulphureted hydrogen through the solution, the lead will be all separated in the form of a sulphuret, and the liquor, after filtration and evaporation, will yield yellow granular crystals, or cauliflower concretions, of malic acid, which may be blanched by re-dissolution and digestion with bone-black, and re-crystallization.

Malic acid has no smell, but a very sour taste, deliquesces by absorption of moisture from the air, is soluble in alcohol, fuses at 150° Fahr., is decomposed at a heat of 348°, and affords by distillation a peculiar acid, the pyromalic. It consists in 100 parts, of 41.47 carbon; 3.51 hydrogen; and 55.02 oxygen; having nearly the same composition as citric acid. A crude malic acid might be economically extracted from the fruit of the mountain-ash (*sorbus accenparia*), applicable to many purposes; but it has not hitherto been manufactured upon the great scale. (*Ure's Dict.*)

MALLOW (*Malva*, altered from the Greek *malache*, soft, which comes from *malacho*, to soften, in allusion to the emollient qualities of the species). This is an extensive genus of plants, some of the species of which are very ornamental. Among the most interesting of the hardy herbaceous species, are *M. moschata*, *M. munroana*, and *M. purpurata*. They should be planted in the flower-border, and increased by divisions of the roots, or by seeds. The annual species should be sown in the open ground; but few of these are worth cultivating.

In England, the indigenous species are three in number. 1. Common mallow (*M. sylvestris*), a perennial weed which is very common about hedgerows, roadsides, and in cultivated as well as waste ground. The root is tapering, branching, whitish; stem upright, much branched, widely spreading, 1½ to 3 feet high, in a barren soil recumbent; leaves deep-green, soft, and downy, with seven acute lobes; foot-stalks and flower-stalks hairy; the flowers, which appear from May to August, are numerous, of

a shining purple, veiny, on simple aggregate stalks. The leaves are mucilaginous and emollient, like the marsh-mallow; and were formerly often used in food to prevent costiveness. The fruit is a depressed disk, and is called by the country people "cheeses."

2. Dwarf mallow (*M. rotundifolia*). This species is also very common in waste ground, and by footpaths near towns and villages. It is annual in habit; has a tapering root. The whole plant is smaller than the last, and is quite prostrate, with numerous stems scarcely branched. Leaves roundish, heart-shaped, with five, often seven, shallow lobes. Flowers pale lilac-coloured, several together on axillary hairy stalks; the stalks when in fruit are bent downwards.

3. Musk mallow (*M. moschata*). This is a less common perennial species, found in the grassy borders of fields, &c., on a gravelly soil. The root is tough and woody; the herbage is bright green, more or less rough, with spreading, simple, not starry hairs, unaccompanied with any short, dense, woolly pubescence, and exhaling a musky odour, especially in hot weather, or when drawn tightly through the hand. Stems about two feet high, leafy, round, but little branched. Radical leaves kidney-shaped, cut, soon withering away; the rest in five deep, pinnatifid, jagged segments. The flowers, which appear in July and August, are on long, axillary, simple stalks, rose-coloured, large and handsome; calyx hairy, its outer leaves linear-lanceolate.

Five North American species of the genus *Malva* are described by Nuttall. One of these, the *M. coccinea*, is very beautiful, with scarlet flowers disposed in dense racemes, and is found from the confluence of the river Platte and Missouri, often extending over the plains in such quantities as to communicate a brilliant redness to thousands of acres. Dr. Darlington describes two species as found in Chester county, Pennsylvania, one of which is the woodland or wild malva (*M. sylvestris*), sometimes called high mallows. It is a naturalized foreigner, met with in fields and waste places, whither it has escaped from gardens. The other species is the round-leaved malva (*M. rotundifolia*), commonly called low mallows, and running mallows. This is common in yards, gardens, and grass-lots. It is also a foreigner, and so extensively naturalized as to be somewhat troublesome. It is a popular ingredient in domestic practice for poultices, drinks, &c. "The *M. crispa* and *M. moschata* are frequent in our gardens, and the latter has in a few instances strayed beyond the garden limits, but can scarcely be considered as naturalized. Several species have been recently found in the distant territories of this Republic, and in British America; but it is doubtful whether any genuine malva is indigenous in the old thirteen states." (*Flor. Cestrica.*)

MALLOW, THE MARSH. See **MARSH-MALLOW.**

MALLOW, THE TREE. See **TREE-MALLOW.**

MALT (Fr. *mal*; Ital. *malto*; Lat. *maltum*). The term malt is applied to designate grain which, being steeped in water, is made to ger-

minate to a certain extent, after which the process is checked by the application of heat. This evolves the saccharine principle of the grain, which is the essence of malt. Rice, and almost every species of grain, has been used in malting; but in Europe, and especially in England, malt is prepared almost wholly from barley. It is the principal ingredient in the manufacture of beer and of ardent spirits.

The process of malting is performed by steeping any quantity of good barley in cold water for a period which (as regulated by law) must not be less than forty hours; but beyond that period the steeping may be continued as long as it is thought proper. The proportion of water imbibed depends partly upon the barley, and partly upon the length of time that it is steeped; but the result of a good many trials proves that the medium increase of weight from steeping may be reckoned at 47 lbs. in every 100. The average increase of bulk is about one-fifth. After the grain has remained a sufficient time in steep, the water is drained off, and the barley thrown out of the cistern upon the malt floor, where it is formed into a heap, called the *couch*, about 16 inches deep. In this situation it is allowed to remain about 26 hours. It is then turned by means of wooden shovels, and diminished a little in depth. This turning is repeated twice a day or oftener, and the grain is spread thinner and thinner, till at last its depth does not exceed a few inches. The temperature which it is wished to preserve by these frequent turnings varies from 55° to 62°, according to the different modes of malting pursued. Soon after the rudiments of the future stem, called *acrospire* by the maltsters, has appeared, the process of germination is stopped by drying the malt upon a kiln. The temperature at first does not exceed 90°, but it is raised very slowly up to 140°, or higher according to circumstances.

Barley, by being converted into malt, generally increases 2 or 3 per cent. in bulk, and loses at an average about 20 per cent. in weight, of which 12 are ascribed to kiln drying, and consist of water which the barley would have lost had it been exposed to the same temperature; so that the real loss does not exceed 8 per cent.

The following is Dr. Thomson's analysis of barley, and the pale malt made from it.

	Barley.	Malt.
Gluten - - - -	3	1
Sugar - - - -	4	16
Gum - - - -	5	14
Starch - - - -	88	69
	<hr/>	<hr/>
	100	100

The gluten in this case is a most important component, as by its transformation, when the malt is converted into wort, ferment is generated; whilst the saccharine matter, which is increased fourfold, is the origin of the alcohol of the beer. Oxygen is appropriated by the gluten at the same time that the transformation of the sugar is going on; and thus carbonic acid and yeast are disengaged simultaneously.

In brewing ale, porter, and table beer, three different kinds of malt are employed: 1, pale or amber malt, which yields the saccharine or

fermentable extract; 2, brown or blown malt, which is not fermentable, but is used to impart flavour; 3, roasted, black, or, as it is sometimes called, patent malt, which is employed instead of burnt sugar, merely as a colouring matter for porter.

The manufacture of malt has been carried on in England to a great extent from a very early period; but it is singular that notwithstanding the products obtained from it have always formed the principal beverage of the great bulk of the people, instead of increasing with the progressive wealth of the population of the country, it remained nearly stationary for more than a century, and it is only within the last 8 or 10 years that there has been any increase in the manufacture. This extraordinary result is most probably to be attributed to the introduction and universal use of tea, coffee, &c., and to the heavy duties that were formerly levied on beer and malt. The present duty on malt from barley is 2s. 7d. per bushel, and from bere or bigg, 2s. The quantity of malt charged with duty in the United Kingdom during the three years ending 1838, was 41,814,811 bushels; and the revenue derived from it averaged in the same period 5,282,975l.

The following is the quantity of malt consumed by the brewers of London and its vicinity from the 10th of October, 1830, to the 10th of October, 1840.

	Qrs.		Qrs.
1831 -	622,549	1836 -	754,313
1832 -	601,477	1837 -	714,488
1833 -	578,568	1838 -	742,597
1834 -	662,713	1839 -	750,176
1835 -	702,533	1840 -	776,219

The 6 Geo. 4, c. 107, s. 52, enacts that "malt may not be imported into the United Kingdom for home use under pain of forfeiture; but it may be warehoused for exportation." The importation of malt is, however, now allowed under very high duties, fluctuating with the price of home produce; but under no state of the market can any addition be thus made to the quantity of malt in this country, because barley which has undergone a voyage of much length is unsuited to the process of malting. See BARLEY, BEER, and BREWING.

MALT-DUST. The dust or substance that separates from the malt in the act of drying, or during its preparation. It is sometimes called malt-combs, and has been found useful as a manure or a top-dressing when sown over the cereal grasses in the early spring season.

The proper quantity of this dust is, if top-dressed, for wheat, 36 to 40 bushels; if drilled with the crop, for barley and turnips, 30 to 34 bushels. It is also eminently calculated for grass lands; and if applied in the latter proportion, it will produce a very considerable increase of the best feed. The common price at most malt-kilns is from 5s. to 6s. per quarter. Malt-dust is also in some places employed in the feeding of milch cows and pigs.

MALUS (Lat. *malum*, an apple). The wild crab (*Pyrus malus*, see CRAB-TREE) is the only apple indigenous to England, and it is on this stock that most of our valuable apples have been grafted and raised by the ingenuity of the gardeners, who have, by sowing the seeds and studying the soil, so improved and multi

ed the varieties of this most excellent fruit, that it has now become of great national importance, affording an agreeable and wholesome diet, in a thousand shapes, to all classes. Leonard Mascall was the first who introduced the common or cultivated apple into England, about the year 1525. The varieties of the apple are now so numerous that the Horticultural Society's catalogue includes more than 1400. The apple, like most other hardy trees, may be propagated by seeds, cuttings, suckers, layers, or engrafting; by seeds for obtaining new varieties, and by the other modes for extending the number of such as are in esteem.

In every garden and private orchard, apples for ten different purposes are desirable:

1. For summer culinary use, the codlings, while not fully grown or imperfectly ripe, are fit for using in June, July, and August.

2. For summer eating or table use, the jenneting pomroy, &c., which ripen in the end of June or in July. Margaret, summer pearmain, &c., (July). Kentish fill-basket, Hawthorn dean, &c. (August).

3. For autumn baking, the codlings and Burknott's red-streaks, Eve apple, court pender, nonsuch, &c., which ripen in September. Piles's russet, Carlisle codling, catsheads, embroidered, &c. (October). Wormsley pippin, golden Harvey, queening, golden russet (November).

4. For autumn table use, the Kirton and Dalmahoy pippins, Loan's pearmain, Colville, Kent, Godolphin, &c., which ripen in September; orange and ribstone pippins, gray rennet, fameuse, violet, &c. (October). Franklin's golden, and Borsdorf pippins, Dredge's russet, margil, &c. (November).

5. For winter culinary use, the Nimier's dumpling, Burknott, John apple, Mansfield tart, &c., which are fit to use in December. Hall-door, royal pearmain, Dutch queening, Aclam's russet (January). Brindgwood pippin, cockagee, tankerton, box-apple (February).

6. For winter table use, the golden and Kentish pippins, golden and Canadian rennets, brandy, &c., which are fit to eat in December. The Norfolk storing, Hubbard's Sykehouse, white court pender, &c. (January). Dredge's Queen Charlotte, Feams, Skenn's kernel, and Dalmahoy pippins, royal pearmain, &c. (February).

7. For spring culinary use, the quince, white Colville, Lord Camden's rennet, winter pearmain, which keep till the end of March. Spencer pippin, Trevoider rennet, Macdonald's Scotch nonpareil, Spaniard, &c. (April). Norfolk paradise, Loan's pearmain, English rennet, &c. (May).

8. For spring table use, the hollow-eyed, Cornwall rennet, Hughes's new golden pippin &c., which will keep till the end of March. Cockle and Whitmore pippins, golden and Piles's russet, Wheeler's extreme, &c. (April). Stone and Spencer pippins, Royal George, Ward, &c. (May).

9. For summer culinary use, till the apple season returns, the Lord Cheney's green, Baxter's pearmain, stoup codling, &c., which will keep till the end of June. Norfolk beaufin, Norfolk storing, French crab (July).

10. For summer table use, till the apple season returns, the Dredge's fame, oaken peg, carnation, &c., which keep till the end of June. Nonpareil, Yorkshire greening, Norfolk Colman, which keep till the end of July.

Although the apple flourishes in every part of the United States, if we except the extreme southern portions, the fall and winter varieties commonly come to the greatest perfection in the Northern States and northern portions of the Middle States, where this fruit constitutes a very profitable resource to the farmer, both for the home markets and exportation to the Southern States, the West Indies, and Europe, and even to Asia. Good judges assert that the apples of England and France are not to be compared, for excellence of flavour, to those produced in the United States.

The following directions for the culture and subsequent management of apple trees, is from the valuable manual published in 1842 by William Kenrick, nurseryman, near Boston.

The seeds or pomace of the apple should be sown in autumn in a rich soil. When the young plants appear in spring, they should be carefully thinned to the distance of 2 inches asunder, and kept free from weeds by carefully hoeing during the remainder of the season, or till of sufficient size to be removed.

At 1 or 2 years of age they are taken up, their tap-roots shortened, that they may throw out lateral roots; they are transferred to the nursery, set in rows about 4 feet asunder, and at 1 foot distance from each other in the row, in a rich and loamy soil. In the summer following they are inoculated, or they are engrafted or inoculated the year following.

Size and age for transplanting to the orchard.—An apple tree, when finally transplanted to the orchard, ought to be at least 6 or 7 feet high, with branches in proportion, and full 2 years from the bud or graft, and thrifty. Apple trees under this size belong properly only to the nursery.

Distance.—The distance asunder to which apple trees should be finally set, when transplanted to the orchard, depends upon the nature of the soil, and the cultivation to be subsequently given. If the soil is by nature extremely fertile, 40 feet distance may be allowed, and even 45 and 50 feet in some very extraordinary situations; for before the trees become old, they will completely shade the ground. If, however, the soil is not very extraordinary by nature, or so rendered by art, this distance would be too great; for the trees would become old, and their growth would be finished, before the ground could be covered by their shadow: 30 feet only may therefore be allowed in land usually denominated of good quality, and but 20 to 25 feet in land of ordinary quality. But where economy of time, of land, and of all things else is consulted, but one-half this distance will answer for a series of years.

The quincunx mode is recommended for close arrangement, and short-lived trees may be set in the intervals.

The size to which an apple tree may attain, and the ground which should be allotted to it, depend also, in some measure, on the particular variety of apple; some sorts being well

known to attain to a much greater size than that of others.

The period of growth, or the duration of the apple tree is comparatively limited; this is sufficiently evident from the perishable nature of its timber. Those species of trees only will continue living and growing for centuries, whose timber may be preserved incorruptible during the lapse of a long succession of ages.

Soil and situation.—A rich soil, rather moist than dry, is that adapted to the apple tree; but what is usually termed a deep pan soil is to be preferred.

On such a soil, whether on the plains, or in the valley, or on the sides and summits of our great hills, which almost always consist of good land, and even in situations the most exposed, the apple tree will flourish.

One of the most productive apple-orchards in the immediate vicinity of Boston is situated on the north and north-west sides of a hill, the most exposed to cold winds. The soil of great hills is generally of far superior quality to that of the plains; and it is a very mistaken opinion, which seems adopted by some, that the soil of all hills must of necessity be dry and deficient in moisture. It is the plains and the knolls that are but too generally thus deficient, not the great hills, which almost always abound in springs.

Land half-covered with rocks, and incapable of being cultivated with the plough, is in some respects admirably suited to the apple tree; for, in such situations, they are not liable to suffer from drought; they receive nearly a double portion of moisture from the rains that fall, and a greater degree of heat by the reflected rays of the sun.

They may even flourish on sandy plains, if, where the tree is to be placed, an excavation is formed 6 or 8 feet in diameter, and 3 or 4 feet in depth, and half-filled either with useless small stones, intermixed with rich loam, mud from the low grounds, clay, or gravelly clay, or mixtures of any of these substances with a portion of manure, and the remainder of the excavation filled to the surface with rich loam.

Management of the Land.—If the ground intended for the orchard cannot conveniently be kept wholly in a state of cultivation during the first years, a portion, at least, ought to be.

A strip of land to each row, of 8 or 10 feet in width, well manured, may be kept cultivated, and the vegetables which may here be raised will amply repay the expense and labour bestowed during the first 4 or 5 years. After this, if the trees have grown well, as they probably must have done, cultivation at a distance in the intervals becomes even more important than within the limited distance of a very few feet from the trunk of the tree; for, on examination, it will be found that the small fibres or spongelets, by which alone the tree derives all the nourishment it receives from the earth, are now remote from the trunk of the tree; they are now to be found seeking pasture beyond the limits of its shade, and it becomes necessary that the whole ground should be kept in a high state of cultivation for the 4 or 5 following years. After this period it may occasion-

ally be laid to grass, which, however, should be broken up at frequent intervals, the land being always kept in good heart.

Pruning.—If the branches of a young tree, issuing at and above the requisite height, be made, by pruning, to diverge from the trunk in every direction above the horizontal, and the interior of these be carefully kept from any interference with each other for a few years, little pruning will ever afterwards be necessary.

Heavy pruning is seldom necessary or advisable; but when, as in the case of grafting, or of heading down for a new growth, it becomes unavoidable, it should always be performed in that interval between the time the frost is coming out of the ground in spring, and the opening of the leaf.

For that moderate pruning, which alone is generally needful, June and July, and during the longest days of summer, is the very best time: for wounds of all kinds heal admirably at this period, the wood remaining sound and bright; and even a tree debarked at this season recovers a new bark immediately.

Trees ought not to be pruned in February and March, at the time the frost is coming out of the ground. This is the season when most trees, and particularly the vine and sugar-maple, bleed most copiously and injuriously. It causes inveterate canker; the wounds turn black, and the bark, for perhaps several feet below, becomes equally black, and perfectly dead, in consequence of the bleeding.

The lower side limbs of young trees in the nursery should be gradually shortened, but not suddenly close pruned; they are essential for a time to strengthen the trunk, and to the upright and perfect formation of the tree.

These directions are particularly applicable to the apple tree. I would only add, that when these directions have been followed,—when large and profitable crops are desired,—our cultivators generally avoid robbing their trees unnecessarily of a particle of bearing wood.

Those limbs which interfere with other limbs by galling, the suckers, and dead wood, are alone removed; for they consider that the warmth of the atmosphere is of itself sufficient in our climate to ripen the fruit, without attempting to admit the sun to every part of the tree.

These directions are to be more especially observed in regard to old trees in their declining years: their trunks being too old for the reproduction and sustenance of a crop of new and fruitful wood, nothing should be taken away but the dead branches and suckers. We have seen old trees, whose branches were annually loaded with fruit, despoiled at once by the hand of man of half their bearing wood, under the mistaken idea that the destruction of the one half of the tree would confer a benefit on the remainder, and render it still more productive. We noticed, however, that the effect thus produced was directly the reverse, as their total destruction usually followed, as a consequence, not long after.

Insects.—See BORERS, CATERPILLARS, CURCULIO, &c. (*Kenrick's New American Orchardist.*)

The same publication may be referred to for a descriptive list of apples in cultivation in the United States, together with select foreign varieties. From more than 200 kinds, our limits will only admit an enumeration of a list recommended by the experienced author, as a moderate selection of the kinds best known and most valued at the present day. The numbers refer to the entire catalogue.

SUMMER APPLES.

3. *Benoni*, a medium-sized, red, and good early apple.—July.

4. *Early Sweet Bough*. Size from medium to large, form oblong, skin yellow, juicy, and flavour excellent.—Early in August.

8. *Maiden's Blush*, or *Hawthornden* of the English. A large and beautiful fruit, shape flattened, colour yellowish-white, with a red blush on the sunny side. An excellent apple for market, and also for drying.—August to September. A popular fruit in the Philadelphia market.

9. *Porter*. Size medium, oblong, light-yellow, with pale blush next the sun, very beautiful; flavour lively and pleasant; productive and profitable; a popular fruit in the Boston market. Origin, Sherburne, Massachusetts.

10. *Pumpkin Sweeting* of New England. Large, round, flattened, and colour yellow-russet; the flavour sweet and excellent.—August to October.

11. *Red Astracan*. An eminently beautiful and very early apple, of medium size, nearly globular, of a rich crimson colour, covered with a fine bloom. Crisp, juicy, and agreeable. The tree a great bearer, originally from Russia.

18. *Williams Apple*. A beautiful fruit, of medium size and oblong form; colour deep-red; flavour lively and very pleasant.—First of August. A native of Roxbury, Massachusetts.

AUTUMN APPLES.

22. *Erabant Belle Fleur*. Very large and handsome; of great solidity; shape rather conical; slightly ribbed; yellow with reddish stripes; juicy and of very pleasant flavour. A fine fruit.—November.

28. *Emperor Alexander*. The fruit of this Russian variety is very large, cordate, narrow at the crown; the eye is in a broad, deep cavity; colour greenish-yellow, slightly streaked with red in the shade, and beautifully marked and streaked with bright red and orange next the sun. Flesh yellowish-white, crisp, tender, juicy, rich, and of aromatic flavour. Excellent for dessert.—October. Keeps till Christmas.

30. *Faneuse*. Pomme de Neige. A middle-sized fruit; shape globular, flattened; skin light green, tinged with light-red and dark-red streaks; deep red next the sun. Flesh white as snow and very tender; juice sweet, with a musky perfume.—October. A most beautiful dessert fruit. Origin Canada.

33. *Gravenstein*, said to be the best apple in Germany. Shape large, round, and angular at the crown; the eye sunk in a broad, deep, knotty cavity; colour clear straw yellow, with broken stripes of red next the sun. Flesh pale yellow, crisp, high flavoured and delicious. Good for dessert and cider. Ripens in autumn and keeps till winter.

35. *Kenrick*, a large round fruit, pale green, with bright red next the sun. Flesh tender and occasionally stained with red. A native of Newton, Massachusetts.

38. *Lyscom*. Sometimes called Osgood's Favourite; a large fruit, striped with red; of excellent quality. Origin Worcester, Massachusetts. Ripens in October.

39. *Monmouth Pippin*. A superior, large, and handsome fall fruit. Productive and saleable, from Monmouth, New Jersey.

41. *Orange Pippin*, called also Marigold Pippin, and Isle of Wight Orange; in size, form, and colour, much resembling a middle-sized orange. Flavour pleasant and good for dessert. Excellent for cider. In Monmouth county, New Jersey, considered one of the most saleable, profitable, and productive of all fall apples.

42. *Orange Sweeting*, or *Golden Sweet*; rather large, flattened at the base and summit; colour yellow or orange; flesh sweet and excellent. In high estimation at Providence, Rhode Island, where it is brought from Connecticut.—September. Keeps till December.

44. *Red Calville*; of medium size, and very beautiful; form conical; colour fine red, and on the sunny side, deep crimson; flesh stained with red; of a vinous sweet taste, and perfume of violets. Ripens in September, and keeps till winter.

49. *Spice Sweet*. Fruit large, very sweet and excellent. Native of Taunton, Massachusetts. Sometimes called Spurr Apple.—September.

53. *York Russeting*; remarkably large, conical-shaped, and swollen towards the base; colour russet-yellow; juicy, subacid, and good. Valuable for market, cooking, &c.—October to December.

WINTER APPLES.

55. *Æsopus Spitzenberg*, large, very beautiful, and excellent; shape oblong; colour deep scarlet, deepening to dark crimson next the sun; flesh juicy and high-flavoured. A very celebrated fruit, ripening in December, and keeping till March. The *Flushing Spitzenberg* differs from this in being round or flat.

56. *Baldwin*. This capital variety is a native of Massachusetts, a large, beautiful, and famous fruit. Shape round, of a pale colour in the shade, and fine scarlet crimson on the sunny side; sometimes entirely red. Flesh white, juicy and sugary, and of an agreeable acid flavour. The most popular winter apple in the Boston market. Ripens in November, and keeps till February and March.

59. *Bellflower*, or *Yellow Bellflower*. A large and beautiful fruit, of an oblong or conical form, colour bright yellow, with an occasional blush next the sun. Rich and finely flavoured; excellent for dessert and cooking, and a prime favourite in the Philadelphia market. Ripens in October and November, and will keep nearly all winter. The seeds are so loose as to rattle in the middle when shaken.

62. *Blue Pearmain*. A large, beautiful apple, of a dark-red colour, covered with a thick bloom.—October. Keeps till January.

63. *Chandler*, a superior variety from Con-

necticut, where it is deemed one of the best of winter fruits. Large, flat, with dull red stripes next the sun. Eye large and in a deep cavity. Flavour equal to the Baldwin. Keeps till March.

67. *Danvers' Winter Sweet*, or *Epses Sweet*. Large and beautiful. Colour bright yellow, with a faint blush next the sun. Fine for dessert and baking. Native of Danvers, and a popular market fruit.

74. *Golden Ball*. Size rather above medium; ribbed at the sides; colour golden yellow. A very popular apple in Maine.

81. *Lady Apple*, or *Pomme D'Api*. Very small and beautiful. Skin bright and yellow, with a red blush on the sunny side.—November. Keeps till March.

85. *Minister*. Large, oblong, and tapering towards the eye, like the *Bellflower*; with large ribs, or calville-formed; striped, with bright red on a ground of pale greenish-yellow. Flesh yellow and high flavoured. Esteemed by Manning one of the first fruits New England has ever produced.—November to January. Origin, Rowley, Massachusetts.

86. *Late Pound Sweet*. Very large; form flattened. Colour pale yellow. Origin Vermont.

87. *Mela Carla*, or *Malcarle*, Charles Apple, *Pomme Ferivale*. One of the most famous of fruits; size rather large; form globular, but slightly ovate. Eye and slender stem both inserted into deep cavities. Skin beautiful waxen, a little marbled with faint green near the eye. Splendid crimson colour on the sunny side. Flesh white, delicate sweet, with rose perfume.—September. Keeps till spring. In Italy this is considered the best of all apples in the world. It is there cultivated extensively for exportation. Near Boston, this apple proves good but not excellent.

88. *Monstrous Pippin*, or *New York Gloria Mundi*; a fruit of uncommon size. Colour yellow with numerous spots of white; eye very deep. Excellent for cooking. Origin, Long Island.

90. *Murphy*. A large and splendid fruit, resembling in appearance the *Blue Pearmain*, but more oblong and rather smaller. Colour pale red, streaked or blotched with darker red, and covered with bloom. Keeps till February. Origin, Salem, Massachusetts.

94. *Pownal Spitzenberg*. Origin, Vermont. Resembles the *Æsopus Spitzenberg*, and highly esteemed.

97. *Ramsdell's Red Pumpkin Sweet*; a beautiful fruit; over medium size; round or oblong; colour a dark and beautiful red, covered with a dense blue bloom. The tree a prodigious bearer, native of Connecticut. Fruit saleable and profitable; keeps till January.

98. *Rhode Island Greening*; Jersey or *Burlington Greening*; a very large apple, flattened at both ends; colour yellowish green at maturity, covered with dark clouds or blotches; ripens in September, and keeps till March. A highly esteemed and profitable fruit. Tree bears abundantly every other year, and, in the New England States, is preferred for its productiveness to the *Green Newtown Pippin*.

99. *Ribston Pippin*, also called *Formosa Pippin*, and *Glory of York*; in England esteemed very highly; medium size, and globular form; colour pale yellow, mottled with red next the sun. Keeps till February.

100. *Red Seek-No-Farther*. A large round fruit, contracted towards the summit; colour fine deep red; flavour sweet and excellent. Keeps till March. A Rhode Island fruit.

101. *Roxbury Russeting*. A fine old native of Massachusetts; fruit large and of a slightly flattened form; colour, brownish yellow russet, with an occasional blush next the sun; skin rough. Keeps well till June and July. Raised in great quantities near Boston, for exportation, &c.

102. *Scolloped Gillyflower*. Said by good judges to far excel the *Black Gillyflower*, and much resembling the *Cornish variety*.

103. *Swaar*. This and the *Jonathan apple* are esteemed equal, at least, if not superior to, the *Newtown Pippins* and *Spitzenbergs*. Size, medium; shape, round; skin, greenish yellow, with a blush next the sun, and thickly dotted with brown specks, intermixed with some scarlet. Keeps till April.

104. *White Spitzenberg*. A beautiful, fair, and fine flavoured fruit, about the size of the *Æsopus Spitzenberg*. Keeps all winter, and sells well in the Albany market.

105. *Wine Apple*, or *Hay's Apple*; also called *Large Winter Red*, and *Fine Winter*. Fruit very large and beautiful; colour, bright red on the sunny side, with sometimes a few stripes and blotches of yellow on the shady side. Flesh rich and excellent. Keeps till February and March. Tree very productive, and fruit very saleable in the Philadelphia market.

106. *Winter Sweeting*; called also *Seaver Sweeting*, and *Grafton Sweeting*. Fruit large, round and conical; colour, pale yellow, with a blush on the sunny side. Flesh yellow, sweet and fine-flavoured. Keeps till March.

107. *Winter White Calville*, or *Bonnet Carré*. Fruit large and of a bright yellow colour, with a bright red blush on the sunny side; form rather flat and ribbed; flesh white, tender, and pleasant. Keeps till March.

108. *Yellow Newtown Pippin*. A large flat fruit, of a bright yellow colour, and faint blush next the sun. Keeps all winter, and flourishes better in the New England states than the *Green Variety*.

CELEBRATED CIDER APPLES CULTIVATED IN THE UNITED STATES.

109. *Harrison*, or *Long Stem*. A native of Essex, New Jersey. The celebrated Newark cider is made from this apple; one tree in Essex county, New Jersey, produced 100 bushels in one year, and 10 bushels make a barrel of cider, which will yield 14 quarts of brandy. The fruit is below the medium size, rather long, and deeply indented at the ends; stem very long; colour yellow, covered with black spots. Fruit ripens 1st of November. Flesh yellow, firm, tough, and dry.

110. *Taliaferro*. A Virginia fruit, about the size of a grape-shot, or from 1 to 2 inches in diameter; colour white, streaked with red.

111. *Virginia Crab*, or Hewes's Virginia Crab. A very small round cider apple, of a small, red colour, with streaks of pale yellow.

VARIETIES FOR PRESERVING OR ORNAMENTAL PURPOSES.

112. *Red Siberian Crab*. Tree a profuse bearer, and very beautiful when the fruit is at maturity, resembling at a little distance a plum or cherry tree; fruit in clusters of a bright scarlet colour, with long stems. Much used for preserving.

113. *Yellow Siberian Crab*. The tree, foliage, and fruit equally beautiful with the preceding kind, which it even excels in productiveness. The little apples grow in clusters, with long stems; colour golden yellow.

114. *Chinese Double Flowering*. Tree small, bearing very double flowers in clusters, resembling small roses; very superb when in full bloom. Fruit very small, but tolerable for eating.

SOUTHERN APPLES.

The following are stated to be some of the most esteemed varieties of native apples of Virginia. Part are described from the authority of Mr. Coxe, and the remainder on the authority of a Virginian.

115. *Beverley's Red*. The fruit is very large, the skin smooth, of a crimson colour; flesh very white, of a pleasant flavour. A winter fruit.

116. *Cart House*, or Gilpin. The tree is a great bearer. The fruit hangs long on the tree in autumn. A small fruit, rather oblong; the skin smooth, of a deep crimson colour, with occasional yellow stripes; the flesh yellow, tender, and of good flavour. A native of Virginia; highly esteemed for its excellence as a table fruit in spring; also a good cider fruit. *Coxe*.

117. *Curtis*. The skin is smooth, of a red colour; flesh juicy and pleasant. Ripe middle to end of August.

118. *Gloucester White*. The tree is of vigorous growth, and beautiful form, and very productive; the fruit of medium size, its form varying from flat to oblong; of a fine yellow colour, clouded with spots of black; the flesh yellow, breaking, juicy, rich, and delicious. It ripens early in October; and, according to Mr. Coxe, is not only a most excellent dessert fruit, but makes exquisite cider. Much cultivated and of high reputation in the lower counties of Virginia.

119. *James River*, or *Limber Twig*. Branches drooping or pendent; the fruit is of a greenish colour, with a blush next the sun; the flesh very juicy, and pleasant at maturity. Winter. It keeps a long time.

120. *Lippincot*. A fruit of Maryland. Very handsome, and striped; excellent; one of the best of all early apples. July and August. *R. Sinclair*.

121. *Pryor's Red*. The fruit is very large; colour brownish red; its flesh at maturity juicy, and very fine. A winter fruit.

122. *Rawle's Janet*, or *Rockrimmon*. The form is globular, flattened; the colour red and green; flesh very fragrant, more juicy, and of superior

flavour to the Newtown Pippin, and keeps equally as well.

123. *Royal Pearmain*. Fruit fine, of a large size, flattened; skin rough, of a fine russet colour, but red next the sun, and faintly streaked with russet; flesh a rich yellow, firm, but at maturity, tender, sweet, and of very sprightly flavour. A good table apple; excellent for cider; and highly esteemed by the planters of Virginia, near Richmond, from whence Mr. Coxe procured it. The tree bears uniformly and abundantly. It ripens in October, and will keep till February or March.

124. *Striped June Apple*. The fruit is as fragrant as a pine-apple melon. It ripens the last of June and beginning of July.

125. *Virginia Greening*. The fruit is of medium size; colour green, striped with red; flavour very superior. A winter fruit.

GATHERING AND PRESERVING THE FRUIT.

Various theories have been offered for preserving apples in a sound state for winter use, or for distant voyages. Some have proposed gathering the fruit before it is ripe, and drying it on floors before it is put up; this has been tried; the apples lose their sprightly flavour, and keep no better than by some less troublesome modes. Dr. Noah Webster has recommended that they should be put down between layers of sand which has been dried by the heat of summer. This is without doubt an excellent mode, as it excludes the air, and absorbs the moisture, and must be useful when apples are to be shipped to a warm climate.

Chopped straw has also been highly recommended to be placed between the layers of fruit; but I have noticed that the straw, from the perspiration it imbibes, becomes musty, and may probably do more hurt than good. When apples are to be exported, it has been recommended that each be separately wrapped in coarse paper, in the manner oranges and lemons are usually put up. This is, without doubt, an excellent mode. And Mr. Loudon has recommended that apples destined for Europe should be packed between layers of grain. Packing in oats is said to succeed very well.

Great quantities of fine winter fruit are raised in the vicinity of Boston, and put up for winter use, for the markets and for exportation. The following is the mode almost universally adopted by the most experienced; and by this mode apples, under very favourable circumstances, are frequently preserved in a sound state, or not 1 in 50 defective, for a period of 7 or 8 months. The fruit is suffered to hang on the tree to as late a period as possible in October, or till hard frosts have loosened the stalk, and they are in imminent danger of being blown down by high winds; such as have already fallen are carefully gathered and inspected, and the best are put up for early winter use. They are carefully gathered from the tree by hand, and as carefully laid in baskets. New, tight, well-seasoned flour-barrels, from the bakers', are usually preferred: the baskets, being filled, are cautiously lowered into the barrels and reversed. The barrels, being quite filled, are gently shaken, and the head is gently pressed down to its place, and

secured. It is observed that this pressure never causes them to rot *next the head*, and is necessary, as they are never allowed to rattle in removing. No soft straw or shavings are admitted at the ends; it causes mustiness and decay. They are next carefully placed in wagons, and removed on the *bulge*, and laid in courses in a cool, airy situation, on the north side of buildings, near the cellar, protected by a covering on the top, of boards, so placed as to defend them from the sun and rain, while the air is not excluded at the sides. A chill does not injure them; it is no disservice; but when extreme cold weather comes on, and they are in imminent danger of being frozen, whether by night or day, they are carefully rolled into a cool, airy, dry cellar, with openings on the north side, that the cold air may have free access; they are laid in tiers, and the cellar is in due time closed and rendered secure from frost. The barrels are never tumbled or placed on the head. Apples keep best when grown in dry seasons, and on dry soils. If fruit is gathered *late*, and according to the above directions, repacking is unnecessary; it is even ruinous, and should on no account be practised till the barrel is opened for use. It has been fully tried.

When apples are to be exported, Mr. Cobbett has recommended that 'they should, if possible, be carried on deck; otherwise between decks.' Between decks is the place, and in the most dry, cool, and airy part.—(Kenrick.)

INSECTS INJURIOUS TO TREES AND FRUIT.

Among the insects that have been brought to America with other productions of Europe, may be mentioned the *Apple-worm*, as it is commonly called, which has become naturalized wherever the apple tree has been introduced. This mischievous creature has been sometimes mistaken for the plum-weevil, from which, however, it may be easily distinguished by its shape, habits, and transformations. Although the plum-weevil prefers stone-fruit, it is sometimes met with in apples. On the other hand, Dr. Harris says he has never known the apple-worm to be found in plums. It is, he observes, not a grub, but a caterpillar, belonging to the *Tortrix* tribe, and in due time is changed to a moth, commonly called the *Codlingmoth*, or fruit-moth of the apple. An anonymous writer, in the *Entomological Magazine* of London, has well remarked that this moth "is the most beautiful of the beautiful tribe to which it belongs; yet, from its habits not being known, it is seldom seen in the moth state; and the apple-grower knows no more than the man in the moon to what cause he is indebted for his basketfuls of worm-eaten windfalls in the stillest weather."

Some interesting facts collected by Dr. Harris, serving to establish the difference between the plum-weevil and apple-worm (*codling caterpillar*), will be found under the head of **PLUM-WEEVIL**.

The apple-worm has been long known in Europe, and its history has been written by some of the ablest naturalists. Accounts of it have also been furnished in the *New England Farmer* and other good American periodicals.

The apple-worm moths may be found in the early part of summer, about the time of the first ripening of the fruit. They are sometimes seen in houses in the evening, trying to get through the windows into the open air, having been brought in with fruit while they were in the caterpillar state. Their fore-wings, when seen at a distance, have somewhat the appearance of brown watered silk; when closely examined, they will be found to be crossed by numerous gray and brown lines, scalloped like the plumage of a bird; and near the hind angle there is a large, oval, dark-brown spot, the edges of which are of a bright copper colour. The head and thorax are brown, mingled with gray, and the hind-wings and abdomen are light yellowish-brown, with the lustre of satin. Its wings expand three-quarters of an inch. This insect is readily distinguished from other moths by the large, oval, brown spot, edged with copper colour, on the hinder margin of each of the fore-wings. During the latter part of June and the month of July, these fruit-moths fly about apple trees every evening, and lay their eggs on the young fruit. They do not puncture the apples, but they drop their eggs, one by one, in the eye or hollow at the blossom-end of the fruit, where the skin is most tender. They seem also to seek for early fruit rather than for the late kinds, which we find are not so apt to be wormy as the thin-skinned summer apples. The eggs begin to hatch in a few days after they are laid, and the little apple-worms or caterpillars produced from them immediately burrow into the apples, making their way gradually from the eye towards the core. Commonly only one worm will be found in the same apple; and it is so small at first, that its presence can only be detected by the brownish powder it throws out in eating its way through the eye. The body of the young insect is of a whitish colour; its head is heart-shaped and black; the top of the first ring or collar and of the last ring is also black; and there are eight little blackish dots or warts, arranged in pairs, on each of the other rings. As it grows older, its body becomes flesh-coloured; its head, the collar, and the top of the last ring, turn brown, and the dots are no longer to be seen. In the course of three weeks, or a little more, it comes to its full size, and meanwhile has burrowed to the core and through the apple in various directions. To get rid of the refuse fragments of its food, it gnaws a round hole through the side of the apple, and thrusts them out of the opening. Through this hole also the insect makes its escape after the apple falls to the ground; and the falling of the fruit is well known to be hastened by the injury it has received within, which generally causes it to ripen before its time.

Soon after the half-grown apples drop, and sometimes while they are still hanging, the worms leave them and creep into chinks in the bark of the trees, or into other sheltered places, which they hollow out with their teeth to suit their shape. Here each one spins for itself a cocoon or silken case, as thin, delicate, and white as tissue-paper. Some of the apple worms, probably the earliest, are said by Kōl lar to change to chrysalids immediately after

their cocoons are made, and in a few days more turn to moths, come out, and lay their eggs for a second generation of the worms; and hence much fruit will be found to be worm-eaten in the autumn. Most of the insects, however, remain in their cocoons through the winter, and are not changed to moths till the following summer. The chrysalis is of a bright mahogany-brown colour, and has, as usual, across each of the rings of its hind-body, two rows of prickles, by the help of which it forces its way through the cocoon before the moth comes forth.

As the apple-worms instinctively leave the fruit soon after it falls from the trees, it will be proper to gather up all wind-fallen apples daily, and make such immediate use of them as will be sure to kill the insects, before they have time to escape. Mr. Burrelle says that if any old cloth is wound around or hung in the crotches of the trees, the apple-worms will conceal themselves therein; and by this means thousands of them may be obtained and destroyed, from the time when they first begin to leave the apples until the fruit is gathered. By carefully scraping off the loose and rugged bark of the trees, in the spring, many chrysalids will be destroyed; and it has been said that the moths, when they are about laying their eggs, may be smothered or driven away by the smoke of weeds burned under the trees. The worms often found in summer pears appear to be the same as those that affect apples, and are to be kept in check by the same means. (Harris.) See CIDER and ORCHARD.

MANDRAKE (*Mandragora*; the name is derived from *mandra*, an ox-stall, something relating to cattle, and *agauros*, cruel; on account of its poisonous effects on cattle, when accidentally gathered with their fodder in the countries where the plants abound). These plants, which are natives of the south of Europe, thrive well in a light soil, in a shaded situation. They can only be increased by seeds. The roots are very apt to rot during winter. The root has an uncouth form, which is supposed to resemble the human shape; on which account it was imagined to be capable of preventing barrenness. It is, however, an acro-narcotic poison, and when taken proves fatal by the extreme purging which it causes. The common people still believe in its properties; but the root of a species of Bryony (*Tamus communis*) is usually sold for it in the herb shops.

MANGE. A cutaneous disease, which attacks several domestic animals, especially the dog, and which is attended with an eruption and loss of hair.

In the horse it is known to exist by the animal's constantly rubbing or biting himself, so as to remove the hair, and sometimes produce ulceration; the hair of the mane and tail frequently falls off, and small scabs may generally be observed about the roots of those which remain. This disease is seldom met with, except in common stables where scarcely any attention is paid to the horses, and where their food is of the worst quality; horses highly kept, if not properly attended to, are also subject to this disease, which is very contagious.

The causes of mange are, sudden changes of temperature, hot stables, bad diet, joined to want of cleanliness. The perspirable matter being never properly removed by friction, and being frequently mixed with dust, &c., completely plugs up the external exhalents, whereby they become obstructed, and a diseased action takes place. It may also be caused by infectious matter coming in contact with the skin; as when a sound horse rubs himself against the stall in which a mangy horse has been kept. The principal symptoms are, the horse growing very thin, without any apparent cause, attended with a staring of his coat. This is soon followed by eruptions, which discharge a thick yellowish matter, forming a kind of scurf, which peels off, and is succeeded by fresh eruptions, and the hair falls off. This, though partial at first, soon spreads all over the body, is attended with an itching, and causes the horse to rub against every thing he comes near. In this disease great attention to cleanliness is necessary.

In the horse the following will be found the best remedy. Bleed to the extent of two or three quarts, according to the constitution of the animal, and after first preparing the horse by bran mashes, give the following dose of physic:—

Barbadoes aloes	- - -	6 drachms
Powdered ginger	- - -	2 —
Castile soap	- - -	2 —
Oil of carraways	- - -	20 drops.

Honey or treacle sufficient to form a ball. After which give the following alterative balls: 2 ozs. each of powdered black antimony, powdered nitre, flour of sulphur, Castile soap, and aniseed powder, 1 oz. of rosin, added to a sufficient quantity of honey to make eight balls, one to be given every night.

The following ointment may be applied externally:—

Black sulphur	- - - -	8 ozs.
Strong mercurial ointment	- - -	2 —
Soft soap	- - -	4 —
Traïn oil	- - - -	1 pint.

These ingredients to be well mixed, and one third part carefully rubbed in daily. If the above ointment should be found ineffectual, 4 ozs. of spirit of tar may be added.

Dogs and swine are frequently subject to mange. For the common scabby variety in the dog, the following ointment is recommended:—

Powdered sulphur	- - - -	4 ozs.
Muriate of ammonia, powdered	- - -	$\frac{1}{2}$ —
Venice turpentine	- - -	$\frac{1}{2}$ —
Lard, or other fatty matter	- - -	6 —
Well mixed.		

MANGEL WURZEL. Field Beet, or Root of Scarcity. (Germ. *Mangold Wurzel*.) The root of the *Beta hybrida*, or *B. albissima*, Linn. This is a kind of red beet, which, according to Von Thaer, is a mongrel between the red and white beet. It has been long cultivated in France, Germany, and Switzerland, partly as food for cattle, and partly to be used in distillation, and in the extraction of sugar. Its culture in Great Britain is more recent; but its value is now becoming very generally appreciated, and the cultivation likely to become more extensive. So far back as the year 1811,

General Beatson, then Governor of St. Helena, writing to the English Board of Agriculture, and describing the extraordinary produce of some plants, the leaves of which had been repeatedly cut to serve as a substitute for spinach, says:—It certainly possesses advantages over every other plant hitherto introduced in field culture. Its produce is immense; and I have found it to grow, with considerable luxuriance, upon land where no other vegetation was ever seen. It has also the singular property of being unmolested by the dolphin-fly, which is here extremely destructive to cabbages, turnips, and radishes. I have very often observed, where alternate plants of cabbage and mangel wurzel were growing in the same rows, and touching each other, that whilst the former were absolutely annihilated by the destructive insect, not one was to be seen on the mangel wurzel leaves."

Lord Spence reports the result of a trial on the comparative feeding properties of mangel wurzel and Swedish turnips. "Believing," says his lordship, "that mangold wurzel contained more saccharine matter than Swedish turnips, and ought, consequently, to be the more nourishing root of the two, I determined to try, practically, whether an ox fed upon mangold wurzel increased in weight more than one fed upon Swedish turnips, in proportion to the quantity of each consumed. In order to have rendered my experiment perfectly accurate, I ought to have ascertained the weight of hay consumed by each beast during the progress of the trial; but I did not do this, although I am pretty confident that the quantity consumed by each was nearly the same. I selected two steers, tolerably, and at least equally, well bred. No. 1, calved March 29th, 1823, and No. 2, calved May 6th of the same year; and on the 24th of December, 1825, I put No. 1 to Swedish turnips, and No. 2 to mangold wurzel. I ascertained their weight by measurement, and both of them measured the same, viz. 4 ft. 10 in. in length by 6 ft. 5 in. in girth, making them to weigh 668 lbs. each. On the 23d of January, No. 1 had consumed 1624 lbs. of Swedish turnips, and measured 4 ft. 10 in. in length by 6 ft. 7 in. in girth, making him to weigh 703 lbs., and to have increased in weight 35 lbs., or at the rate of 48½ lbs. for every ton of Swedish turnips consumed. No. 2 had consumed 1848 lbs. of mangold wurzel, and measured 4 ft. 10 in. in length by 6 ft. 8 in. in girth, making him to weigh 721 lbs., and to have increased in weight 53 lbs., or at the rate of 65½ lbs. for every ton of mangold wurzel consumed.

"This difference, however, might have arisen from No. 2 having a greater propensity to feed than No. 1. I therefore now put No. 1 to mangold wurzel, and No. 2 to Swedish turnips. On the 20th of February, No. 1 had consumed 1884 lbs. of mangold wurzel, and measured 4 ft. 11 in. in length by 6 ft. 8 in. in girth, making him to weigh 734 lbs., and to have increased in weight this month 31 lbs., or at the rate of 36¾ lbs. for every ton of mangold wurzel consumed. No. 2 had consumed 1880 lbs. of Swedish turnips, and measured 4 ft. 11 in. in length by 6 ft. 8 in. in girth, making him to weigh also

734 lbs., and to have increased in weight during this month 13 lbs., or at the rate of 15½ lbs. for every ton of Swedish turnips consumed. I then put both to mangold wurzel, and divided the food equally between them. On the 19th of March, they had each consumed 1792 lbs. of mangold wurzel; No. 1 measured 5 ft. in length by 6 ft. 10 in. in girth, making him to weigh 784 lbs., and to have increased in weight 50 lbs.; No. 2 measured 5 ft. in length by 6 ft. 9 in. in girth, making him to weigh 765 lbs., and to have increased in weight 36 lbs.

"It would appear, therefore, as if the propensity to feed of No. 1 was greater than that of No. 2 in the proportion of 50 to 31; but, notwithstanding this, in the first month, when No. 1 was upon Swedish turnips, and No. 2 upon mangold wurzel, No. 2 beat No. 1 in the proportion above stated of 65½ to 48½. It appears as if there could be no great inaccuracy in estimating the relative weight of the animals, as, soon after the experiment was concluded, I sold No. 1 to a butcher in the country for 24l. 3s., and No. 2, at Smithfield, for 24l.

"It will be for practical men to decide upon the value of this trial; what appears to me to be the most conclusive part of it is, that No. 2, who had during the first month, when he was feeding upon mangold wurzel, increased in girth 3 inches, in the next month, when his food was changed to Swedish turnips, did not increase in girth at all; and when, in the third month, he was feeding again upon mangold wurzel, he again began to increase in girth; because it is very well known, that, if an animal is changed from more to less nutritious food, the probable consequence will be that his growth will be stopped. The result appeared to me so decisive that I have not tried the experiment with the same accuracy since; but I did try, the following year, the feeding a cow alternately on Swedish turnips and mangold wurzel, and though I have not by me the details of the trial, I remember that the result confirmed the experiment of the previous year."

Mr. Miles of Kingsweston, in the same volume of the *Journal*, p. 298, commenting on the communication of Lord Spencer, describes so fully and explicitly the best mode of culture, &c. of this root, that I cannot do better than adopt his paper entire.

"Notwithstanding the favourable results of Lord Spencer's experiment with mangold wurzel, the consideration will naturally suggest itself to the mind of the farmer, previously to his adopting the cultivation of this root, whether, although the mangold wurzel may bring on his cattle faster and better than the Swedish turnip, it is not more difficult of culture, more tender in its habits, and less productive in bulk per acre than the Swedish turnip; and I think, therefore, it may not be unprofitable to lay before the readers of the journal, first, the chemical analysis of the highest or lowest order of turnip and of mangold wurzel as given by Sir H. Davy, and of the sugar beet and orange-globe mangold wurzel as lately obtained on the same plan by the celebrated Bristol chemist Mr. Herepath; and then to point out the system

adopted by myself in the west of England in the cultivation of mangold wurzel, which has been attended with complete success.

Species.	Quantity of Nutritive Matter in 1000 parts.				
	Mucilage or Starch.	Saccharine matter or Sugar.	Gluten or Albumen.	Extract.	Total soluble or nutritive matter.
Swedish turnip	9	51	2	2	64
White turnip -	7	34	1	-	42
Mangold wurzel	13	119	4	-	136
Orange-globe -	25 $\frac{1}{2}$	106 $\frac{1}{2}$	1.20	less than 1	135 $\frac{1}{2}$
Sugar-beet -	17 $\frac{1}{2}$	126 $\frac{1}{2}$	1 $\frac{1}{2}$	1	146 $\frac{1}{2}$

"By this table, it is apparent that equal quantities of Swedish turnip, orange-globe, and mangold wurzel contain very different proportions of nutritive matter, the latter more than doubling the former in quantity; and should the mangold wurzel be of equally easy culture with the Swedish turnip, it seems almost unaccountable that it should not yet have come into more general cultivation. I have grown the common red sort for six, the sugar beet for four, and the orange-globe for three years; these kinds have regularly come into course with Swedes upon light land; the product has always been equal, in most cases far heavier. The Swedish turnip has enemies innumerable; I have never observed the mangold wurzel attacked either by fly, slug, or wireworm. Equally a cleansing crop with the Swede, it stores better, and lasts good for a longer period. In the summer of this year I was using sugar beet with stall-fed cattle, which cut perfectly good and crisp in August. The mode of culture I adopt, up to depositing the seed in the ground, is the same as that adopted in Northumberland for ridging the Swede; great care, however, must be taken that the seed of the mangold wurzel is not buried too deep, or it will not vegetate. Dibbling, as you never can insure an equal depth, does not answer; nor does the seed drill well, if properly prepared by steeping, which I should recommend, for at least 24 hours before planting. To insure, therefore, a proper depth, I have been in the habit of using an iron wheel, round the outer circumference of which, 18 inches apart, iron points project, broad at the base and tapering towards the point, about 2 $\frac{1}{2}$ inches long; this is wheeled upon the top of the ridge, the man walking in the furrow, and thus holes are formed which can never run into the excess of great depth, and into which the seeds are deposited by women and boys following the wheel, and generally covering the seed by drawing the foot as they advance at right angles with the ridge over the holes; the roller follows, and thus the sowing terminates. One man with the wheel will keep six persons well employed in depositing the seed after him. This system was recommended me by my friend Mr. Webb Hall, and since I have adopted it my crop has never failed.

"The after-culture and the storing is similar to that of the Swede; great care, however, should be taken in never permitting two plants to grow in the same spot, which will be the case frequently, should only one capsule even be deposited in each hole, as every capsule

contains many seeds. Should the tops remain uncut, the plant will stand a considerable degree of frost; it should, however, be stored early in November; the best and cheapest method is to build it up against some high wall contiguous to your beast sheds, not more than 7 or 8 feet deep, carried up square to a certain height, and then tapering in a roof to the top of the wall; protect the sides with thatched hurdles, leaving an interval between the roots and the hurdles, which fill up with dry stubble; cover the roof with about a foot of the same, and then thatch it, so as to conduct all moisture well over the hurdles placed as a protection to the sides. In pulling the plants care should be taken that as little injury be inflicted upon them as possible; cleansing with a knife should on no account be permitted, and it is safer to leave some of the leaf on than by cutting it too close to impair the crown of the root. The drier the season is for storing the better, although I have never found the roots decayed in the heap by the earth, which in wet weather has been brought from the field, adhering to them. As to the productiveness of the different sorts, in one year I have grown a larger quantity of sugar beet per acre, in another of mangold wurzel; both these, however, I consider exhaust the land in a greater degree than the Swede; but I have formed a very high opinion of the orange-globe, though not so large a producer generally as the two other sorts; it appears always to throw at least two-thirds of its weight above ground, neither is its tap-root larger nor its fibrous roots greater than those of the Swede turnip. Care should be taken in giving cattle every species of this root, as if taken in excess it is apt to scour; indeed, from the avidity with which cattle eat the sugar beet, and from its viscous properties when quite fresh from the ground, it should be stored so as to come into consumption the last of the roots.

"In feeding store cattle I should commence with Swede turnip, proceed with the orange-globe, then with mangold wurzel, and finish off with the sugar beet; thus not only frequently varying the food, but using them in the order corresponding exactly with the nutritive matter contained in each description of plant. I have found, indeed, equally with Lord Spencer, that it will not do to return from any sort of mangold wurzel to Swede turnips, as even beasts in the straw-yard have for two or three days refused such a change. I may add that the earlier in April your mangold wurzel is sown the better, the deeper the tith the greater probability of a heavy crop, but that although both the mangold wurzel and sugar beet require a deeper and stronger land than the Swede turnip, yet that the orange-globe will flourish wherever the latter will succeed."

Mangel wurzel may be grown on stiffer soils than those adapted for the turnip, and it is better food for milch cows, as it does not, like turnips, give to the milk a taint. It cannot bear the cold, however, so well as the Swedish turnip, and hence is more cultivated in the southern portions of England than in Scotland.

Mr. W. Lester (*Quar. Journ. of Agr.* vol. iii. p. 365) describes a method of making ale from this root.

MANGER. A trough or crib in the stable, in which corn or cut provender for the horse is placed. The usual method is to have them the whole breadth of the stall; but this is unnecessary, as, if 18 or 20 inches in length, and 14 or 16 in breadth, they will be sufficient for every useful purpose. In the fixing of them, they should be so contrived as to admit of being removed for the purpose of being cleaned. This could, however, never be done in the old method of fixing them, but by a little contrivance may be easily effected. It is, in many cases, a convenient plan to have them in the corners or angles at the heads of the stalls. See **STABLE** and **STALL**.

MANHADEN (*Clupea manhaden*). A species of herring frequenting the waters of the New England States and Long Island, where it goes under the various names of *Bony Fish*, *Moss* or *Mossbanker*, *Hardhead*, and *Paukaugen*. The usual length of the manhaden is from 10 to 14 inches. From July to the last of August, the shores of the sea swarmed with shoals of this fish, which, being very oily, is but little resorted to for food, though the better adapted for manure, to which purpose it is most extensively applied, and with such beneficial effects that lands formerly worn out so as hardly to compensate for their tillage, now yield abundant crops of wheat, grass, &c. It is taken in large numbers upon the coast of Massachusetts, where it is used for mackarel-bait, manure, and is also becoming an article of commerce. For the former purpose it is worth from \$2 to \$4 per barrel, in proportion to the demand. At Lynn, in 1836, 1500 barrels were used for bait for other fishes, and as many more were thrown upon the land. At Provincetown they are used only for mackarel-bait. At Sandwich, where they are very abundant, the inhabitants strew them upon their lands by the cart-load; and thus, for miles, immense quantities enrich the soil. It is computed that a single manhaden of ordinary size is equal in richness to a shovelful of barn-yard manure. It is getting likewise to be thought worthy of preservation as an article of food. In 1832, 300 bbls. were inspected; in 1833, 480; 1834, 1008; 1835, 1443; 1836, 1488.

Mr. John Wells, of Long Island, in a communication to the editor of the *Cultivator*, gives the following information in relation to the mode of applying this fish as a manure, and the good effects derived from the practice.

"I have," he says, "used fish manure 40 years successively, and my land is much better than when I first commenced fishing. I make use of from 50,000 to 150,000 of fish, known here by the name of mossbankers, per annum; and could I get a million, I should have none to spare. There is no manure that I use equal to fish for a crop of wheat, and all kinds of roots; but they do not have that effect after repeating that they have at first. But this is the case with all kinds of manure. Thence the necessity of mixing manures. 10,000 mossbankers per acre are sufficient for a crop of wheat, without any other manure. My practice is, to put on 12 or 15 large wagon-loads of litter, and 5,000 fish per acre; and then I calculate for a good crop of wheat, and after the wheat a good burden of grass for 3 or 4 years.

The same quantity of manure makes a good crop of Indian corn. The manure fishery is the making of the east end of our island. I think I may say that the production of our land is 3 times as much as it was before we commenced fishing. But it must not all be attributed to fish. We exert every means to make and collect manure, for without it we cannot raise our bread. For a farmer to break up a piece of land, and lay it down poorer than it was at first, is like borrowing money to pay his interest. It is astonishing to me that there are some few farmers yet, who will let their manure lie and ferment in the yard, when they must know that they lose half its virtue; for there is no time that it brings forth vegetation so well as when in a state of fermentation under the soil. I might say that our soil is a sandy loam."

The best history of the manhaden, which is a favourite food of the whale, is by Latrobe, published in *Transactions of the Am. Phil. Society*, vol. v.

MANNA (Fr. *manne*; It. *manna*). The concrete juice of the *Fraxinus ornus*, a species of ash growing in the south of Europe. The juice exudes spontaneously in warm, dry weather, and concretes into whitish tears; but the greater part of the manna of commerce is obtained by making incisions in the tree, and gathering the juice in baskets, where it forms irregular masses of a reddish or brownish colour, often full of impurities. Manna consists of two parts; one a saccharine, crystallizable principle, named *mannil*, closely resembling sugar; the other an acrid, uncrystallizable principle, which is the purgative agent in the manna. This substance is now seldom used, except as a purgative for infants.

MANIOC. The Indian name of the starchy, nutritious matter obtained from the shrub *Jatropha manihot*, from which *cassava* and *tapioca* are made in the West Indies. See **TAPIOCA**.

MANURES. The word manure, according to Todd, is derived from the French *manourer*. Lemon gives the derivation as follows: "Manure, 'omnia a manu operando.'" Skinner,— "All improvements in agriculture brought in by the hand." Webster, *Eng. Dict.*, says, "Manure, Fr. *manœurer*, but in a different sense; Norm. *mainoverer*, to manure; *main*, Lat. *manus*, hand, and *owrer*, to work, Lat. *operor*." A manure may be defined to be any fertilizing compound or simple ingredient added to a soil, of which it is naturally deficient; and as cultivated lands should contain the earths, silica, carbonate of lime, alumina, decomposing organic matter, and certain saline substances, it is evident that in cases where any one of these is contained in the land in insufficient quantities for the supply of cultivated vegetables, that then the addition of that substance, either in its simple or in a compound form, constitutes the great art of manuring.

Fertilizers therefore naturally divide themselves into 3 classes: 1. The earthy, which are by far the most permanent portions of a soil, and are usually applied in the largest proportions; 2. The organic (vegetable and animal), which are the least permanent, and are used in

much smaller quantities than the earthy; and, 3. The saline, which are the most sparingly applied of all fertilizers, are the most readily absorbed by plants, and whose period of duration in the soil is longer than the organic, but less than the earthy. A manure is either useful to vegetation, by affording, in its simple or decomposed state, direct food or constituents, or else it is a fertilizer, by adding to the soil additional power to absorb and retain atmospheric gases and moisture. We shall see, hereafter, that most manures which are commonly applied to the land assist the growth of plants in both ways. Looking at the question abstractedly, it must be evident, that as animals receive almost the whole of their nutriment either directly or indirectly from the vegetable kingdom, their excrement, or their decomposed bodies, returning these to the soil, must form the best manure.

With regard to inorganic substances, clay of the earthy manures, and some of the saline fertilizers, act principally by their absorption and retention of moisture. Gypsum, it is true, enters into the composition of some of the grasses, and, in minute proportions, other salts do the same; but, if we except phosphate of lime (the earthy salt of bones), none of the salts can be considered to be a very general direct food of plants. Davy very clearly explains the desirable objects in the fertilization of soils: he says, "The plants growing in a soil incapable of supplying them with sufficient manure or dead organized matter, are generally very low, having brown or dark-green leaves, and their woody fibre abounds in earth. Those vegetating in peaty soils, or in lands too copiously supplied with animal or vegetable matter, rapidly expand, produce large bright-green leaves, abound in sap, and generally blossom prematurely. Excess of poverty or riches is almost equally fatal to the hopes of the farmer; and the true constitution of the soil, for the best crop, is that in which the earthy materials, the moisture, and manure are properly associated, and in which the decomposable vegetable or animal matter does not exceed one-fourth of the weight of the earthy constituents." (*Elements of Ag. Chem.* p. 264.)

Of the organic manures, those which the most readily putrefy are the most rapid in their effects; but then they are the most speedily exhausted: thus oil and fish, the most rapid of fertilizers, are exhausted by the few first crops; while bones, which decay more slowly, will last some time longer. The effect of chopped woollen rags is excellent for two years in the rich clay hop-gardens of Kent, and for three or four in the light, chalky, arable soils of the valley of the Kennett. Farm-yard dung, when applied in different states of freshness, illustrates the same position. M. Hassenfratz manured two pieces of the same kind of soil, the one with a mixture of dung and straw highly putrefied, the other with the same mixture newly made, and the straw almost fresh; he observed, that during the first year the plants which grew on the land manured with the putrefied dung produced a much better crop than the other; but the second year, the ground which had been manured with the unputrefied dung pro-

duced the best crop: the same result appeared the third year; after which both seemed to be equally exhausted. "Another experiment of the same chemist," adds Dr. Thomson, "renders this truth still more evident. He allowed wood-shavings to remain in a moist place for about 10 months, till they began to putrefy, and then spread them over a piece of ground as a manure. The first 2 years this piece of ground produced nothing more than others which had not been manured at all; the third year it was better; the fourth year it was still better; the fifth year it reached its maximum of fertility; after which it declined constantly till the ninth, when it was quite exhausted."

It is of the highest importance to the cultivator that he obtains a correct knowledge of the mode in which those manures operate which are found to be advantageous to the growth of his crops. He must discard from his mind all those false conclusions which are sometimes drawn with regard to an imaginary power assigned to plants of generating vegetable substances, for they can effect no such miraculous results. It is true that they can combine the gases or elements of vegetable matters together, and form gluten, starch, gum, sugar, woody fibre, &c.; they can absorb and arrange with these the earths and saline bodies; but the oxygen, the carbon, the nitrogen, and the hydrogen, of which the first-named are composed, and which plants usually obtain from either the atmosphere or by the decomposition of organic matter, they can no more create than they can form the lime or the silica, which are as commonly present in most vegetables as sugar, gum, or woody fibre. Davy proved this when he made a plant of the oat grow in pure carbonate of lime, and watered it with pure distilled water. It grew but languidly, and although it had a free supply of the atmospheric air, yet the access of all dust was carefully prevented. Upon analyzing the plant, it was found to have much increased in carbonate of lime, but its silica or flint was rather diminished, a grain of oat being found to yield more: this Davy attributed to the loss of its husk during vegetation. (*Lectures*, p. 312.) Whatever earthy or saline matters, therefore, are found in vegetables, must have been either derived from the natural soil or furnished by the manures added to it—whether it be carbonate of lime (chalk), or silica (earthy matter of flint), alumina (clay), sulphate of lime (gypsum), or phosphate of lime (earthy salt of bone). It should also be a received axiom with the farmer, that there is no part of any decomposing animal or vegetable manure but what is, either in its gaseous or solid state, the natural food of plants: thus the gases emitted by the putrefaction of a dunghill are so much lost to the vegetable matters of the soil, and such an injury is never submitted to by the intelligent cultivator, but from an unavoidable necessity. Hence the value of green manures; for in these cases every portion of the decaying and fermenting fertilizer is gradually absorbed by the roots and leaves of the succeeding crop.

When the cultivator is in doubt with regard to the possible advantages of any manure, whether earthy, saline, vegetable, or animal,

he need only ask himself this question: Does this manure contain any constituents found in my crops, and is the land I cultivate deficient in any of them? An inattention to this consideration has been the cause of much disappointment and many mistaken conclusions: for instance, on many soils the application of gypsum to artificial grasses, and even to turnips, is very useful; on others it produces no effect. Strange opinions were in consequence long entertained with regard to this manure, until it was found that the soils on which it was valueless naturally contained it in abundance, and that those soils in which it did so much good were nearly or entirely deficient in this essential ingredient of clover, lucern, &c.; for it was now evident, that to add gypsum to a soil which already contained it in sufficient quantities, was as needless as to add sand to a sandy, or clay to a clayey soil.

There is little doubt but that plants derive all their constituents from the soil or the air, in either the gaseous or liquid state; that in the light they absorb carbonic acid gas and emit oxygen is well known; by this means, therefore, they readily obtain the necessary supply of carbon. The hydrogen of vegetable substances is most probably furnished by the decomposition of either water or the carburetted hydrogen emitted during the putrefaction of animal and vegetable substances. This latter seems peculiarly grateful to plants in those situations where it is copiously emitted, as near to stagnant pools, over drains, &c., where vegetation is always rank; and when present in the atmosphere, as in coal-mines, the green colour of plants growing in it is preserved even when they are deprived of light. The earthy or saline matters of vegetables, such as silica, carbonate, phosphate, and sulphate of lime, &c., are all in minute proportions soluble in water; they are found more or less in all cultivated soils, and when they are deficient, their addition, as I have before observed, constitutes the great art of manuring: but there are such endless varieties of soils, that there is hardly a manure that will suit every description—each soil must be separately examined—practice is the only substitute for chemical investigations.

Thus, wood-ashes of the beech or bone-powder form excellent manures for soils deficient in the phosphates; lime, where chalk is altogether absent, and so on; and whilst we attend to the nature of the soil, we must also ever recollect, as one of the most important principles of agriculture, that whatever is completely removed from a soil by crops, must be in some way or other restored by artificial means.

That various earthy, animal, and vegetable substances, when applied to the roots of plants, accelerate their growth, has been known from a very early period; but in what manner these fertilizers serve as the food of vegetables has not been certainly determined. That they must all be in a fluid state, is supposed to be absolutely necessary: thus all the attempts of Sir Humphry Davy to make plants absorb the fine impalpable powder of charcoal obtained by washing gunpowder entirely failed.

The soluble matters consumed by plants are probably, in general, absorbed by their roots unaltered, although, in other cases, decomposed during their absorption. In the experiments of Davy, he caused the roots of some plants of mint to be analyzed, which had grown both in pure water and in sugar and water. 120 grains of the roots of the mint which had grown in common water yielded $3\frac{1}{2}$ grains of deep olive extract, of a sweetish and astringent taste; 120 grains of the roots which had grown in sugar and water afforded 5 grains of pale greenish, sweetish extract, not so astringent as the other. (*Lectures*, p. 270.) These experiments, therefore, are evidently in favour of the opinion that plants absorb many of the constituents of manures in an unaltered state, and the experiments of the late Mr. G. Sinclair with saline substances are still more decisive. See SALTS.

The roots are the chief organs for absorbing the food of plants; and of the roots it is nearly established that the extremities, or spongioles, are the only parts which have the power of absorption; and hence one reason why they increase in length as the soil at their extremities is exhausted of nourishment. It is from this cause that *liquid* manure is so valuable a fertilizer; for in the dissolution of the excrements of animals in water, as practised so advantageously in foreign countries, and long ago recommended by Mr. Knight, the late president of the Horticultural Society, for the adoption of the English farmers, the dung is merely rendered more easily soluble by the plant, and better diffused in the land. No new compound is formed by the mixture; the action of the dung, mixed with four or five times its weight of water, is apparently much less energetic; and yet this plan is decidedly advantageous, successfully produces the most luxuriant crops, is an old practice on the Continent, is gaining ground in England, and the more it is known the oftener it will be adopted. Yet hitherto in England much too little general attention has been paid to liquid manures; by many farmers the drainage of the farm-yard and the house is generally disregarded, and allowed to escape in the best way it can, into the nearest ditch or river, being supposed to contain nothing that is the food of plants; and this, too, by the very same persons who are particularly careful in the preservation, as food for their hogs, of every portion of a miserable dish of cabbage-water. See LIQUID MANURE.

There are certain properties in which all fertilizers, to a certain extent, agree:—thus they all contain one or more vegetable constituents, and they have all a strong attraction for atmospheric moisture (the insensible vapour always contained in the atmosphere). This property is of very considerable advantage to vegetation. The comparative powers, in this respect, of various manures may be judged of from the results of my experiments, which will be found in the following table. In these the animal matters were employed without any admixture of straw. (*Essay on Salt*, p. 8—19.)

1000 parts of horse-dung, dried in a temperature of 100°, absorbed by exposure for three hours to air saturated with moisture of the temperature 62°	145
1000 parts of cow-dung, under the same circumstances, absorbed	130
1000 parts of pig-dung	120
1000 parts of sheep-dung	81
1000 parts of pigeons' dung	50
1000 parts of a rich alluvial soil, worth 2 guineas per acre	14

The following were dried at 212°.

1000 parts of fresh tanners' bark	115
1000 parts of putrefied tanners' bark	145
1000 parts of refuse marine salt, sold as manure	49½
1000 parts of soot	36
1000 parts of burnt clay	29
1000 parts of coal ashes	14
1000 parts of lime	11
1000 parts of sediment from salt parts	10
1000 parts of crushed rock-salt	10
1000 parts of gypsum	9
1000 parts of chalk	4

There is reason to conclude that some manures act as stimulants to plants, and excite them to a more vigorous growth: it is probable that the saline matters of farm-yard compost operate in this way, and that saltpetre and other saline fertilizers do the same. I have often had occasion to notice the increased luxuriance and productiveness of fruit trees, such as cherries and pears, by the application of common salt. (*Essay on Salt*, p. 4.) Priestley made similar observations. "It seems pretty plain," to give the words of Dr. Thomson, "that the vessels of plants are made to contract by various *stimuli*: the experiments of Coulomb and Saussure render this probable; and an observation of Dr. Smith Barton makes it next to certain. He found that plants growing in water vegetated with much greater vigour, provided a little camphor was thrown into the water. (*Chemistry*, vol. iv. p. 338.)

Of the organic manures, the richest abound in azote, or nitrogen; and, in fact, there are, as Dr. Liebig observes (*Organic Chem.* p. 70), "numerous facts showing that the formation in plants of substances containing nitrogen, such as gluten, takes place in proportion to the quantity of this element, which is conveyed to their roots in the state of ammonia, derived from the putrefaction of animal matter. Ammonia, which is composed of 14.15 of nitrogen and 1 of hydrogen, is capable of undergoing such a multitude of transformations, when in contact with other bodies, that in this respect it is not inferior to water, which possesses the same property in an eminent degree." "The employment of animal manure," he adds (p. 86), "in the cultivation of grain, and the vegetables which serve for fodder to cattle, is the most convincing proof that the nitrogen of vegetables is derived from ammonia. The quantity of gluten in wheat, rye, and barley is very different: these kinds of grain also, even when ripe, contain this compound of nitrogen in very different proportions. Proust found French wheat to contain 12.5 per cent. of gluten: Vogel found that the Bavarian contained 24 per cent.: Davy obtained 19 per cent. from winter, and 24 per cent. from summer wheat, from Sicilian wheat 21, and from Barbary wheat 19 per cent. The meal of Alsace wheat, according to Bousingault, contains 17.8 per cent. of gluten; that of wheat

growing in the Jardin des Plantes 26.7; and that of winter wheat 3.38 per cent. Such great differences must be owing to some cause, and this we find in the different methods of cultivation. An increase of animal manure gives rise not only to an increase in the number of seeds, but also to a most remarkable difference in the proportion of the gluten which they contain." And he adds (p. 175), when speaking of the action of manures, "according to the common view, the action of solid animal excrements depends on the decaying organic matters, which replace the humus, and in the presence of certain compounds of nitrogen, which are supposed to be assimilated by plants, and employed in the production of gluten and other azotized substances. But this view requires further confirmation with respect to the solid excrements of animals; for they contain so small a portion of nitrogen, that they cannot possibly, by means of it, exercise any influence upon vegetation."

The following table of manures, constructed from the experiments of MM. Payen and Bousingault, showing the number of loads required in both the moist (or ordinary) and dried (or prepared) states to equal 100 loads of farm-yard dung, so far as the quantity of the nitrogen they contain is concerned, will be interesting, I think, to the farmer. It is a very common error to suppose that manures of a vegetable or animal nature impart any sensible warmth to a soil; the analogy sometimes attempted to be drawn between the action of a fermenting dung-heap and some 15 or 20 loads of fermented dung, or half a ton of chopped woollen rags, spread thinly over an acre of ground, is too absurd to be admitted. Yet, although the dung does not sensibly increase the warmth of the land, the temperature of the earth, and the free access of the gases of the atmosphere have a very material influence upon the duration of the manure in the soil. Thus, in the heavy clay and deep alluvial soils it remains much longer than in the sandy, chalky, or gravelly. In the first its good effects may be traced for three or four years; in the last it is usually consumed in one, two, or at the utmost three years. To the last description of land, therefore, the judicious cultivator usually applies his compost in a half-putrefied state, in order that it may remain longer in the soil: this is now the practice of some of the most enlightened agriculturists.

Too little attention is paid, in general, to the mixture of manures by the farmer. This remark not only applies to those of the farm-yard,—little care being usually taken to spread evenly those of the horse, the cow, and the pig, although it is notorious to the best cultivators, what was stated by the late Mr. Blakie, in his *Essay on the Management of Farm-yard Manure*, that this chief of fertilizers is very considerably improved by an even mixture,—but the remark applies to almost all other manures. Thus, old heaps of weeds, pond-mud, scourings of ditches, and all the earths in which there is any organic matter, are best applied to the soil after being mingled with lime or common salt. Peat, saw-dust, wood-chips, and tanners' bark, nearly inert substances in themselves, become excellent manure when mixed with stable-dung. Sprats, and all other fish, are successfully and economically added to three or four times their bulk of mould; and even bone-dust is successfully applied with a third of its weight of the dung of the sheep, and may be then drilled as advantageously with the turnip-seed as the bones in their simple state. Then, again, mixing together some kinds of manures produces, by their chemical action, a third or fourth, which

MANURES.

is more valuable than either. Thus, when salt and lime are united together, in the proportion of one part of the former to two parts of the latter, a chemical action takes place; the mass swells, and the salt is gradually decomposed; and in the course of three months, if the heap is suffered to remain undisturbed, both the salt and the lime nearly disappear, and two new substances are formed by the combinations into which their constituents have entered, viz. soda and chloride of lime; both excellent manures. In other cases, the mere mixture of two well-known fertilizers, without any chemical action between the two, produces much greater effects than that of both when used separately. Thus, a compound of salt and soot possesses the most extraordinary fertilizing effects. The late Mr. G. Sinclair, in his *Prize Essay on Salt*, describes it "as remarkable," when applied to carrots; a fact which I have often witnessed myself. (*My Essay on Salt for Agriculture*, p. 145.) The Rev. Edmund Cartwright was the first to notice the same result with potatoes (*Com. to Board of Agr.* vol. iv. p. 376); and the same benefit is evident when the mixture is used as a top-dressing for wheat; in which observation my experience is confirmed by that of others. (*My Essay on Salt*, p. 41.) There are a few instances, however, in which substances used as manures are best employed in their simple state. Thus, seaweed, which many of the farmers on the sea-coast throw on their dung-heaps, is much better employed by itself, turned into the earth in the freshest and greenest condition: and to all green manures, and to those which contain salts of ammonia, such as urine, or the liquor from gas-works, the same remarks are applicable. See MIXTURE OF SOILS.

The proportion in which fertilizers are applied is generally unnecessarily large, even of organic manures; and although this bad practice has been regularly diminishing as agriculture has become better understood, yet much remains to be done, in preventing that wasteful expenditure of dung which is continually taking place.

It is more than probable, that the use of the improved manure-drills, by the even distribution of the fertilizer, and bringing it more closely into contact with the crop, will effect much towards this very desirable saving; for it must be evident to the most careless, that in the manner in which compost is commonly spread over a field,—suffered to be dissipated by long exposure in heaps to the sun and wind, and afterwards spread over spaces in which there are not any plants to absorb, during its fermentation, the disengaging gases, a very considerable portion of it is lost to the farmer's crops. See MANURES APPLICABLE BY THE DRILL.

It is almost needless to remark upon the importance of such investigations as these both to the cultivator and to the land-owner, or of the caution necessary in drawing conclusions from experiments in which vegetation is concerned. "Life," said Davy, "gives a peculiar character to all its productions: the power of attraction and repulsion, combination and decomposition are subservient to it; a few elements, by the

diversity of their arrangements, are made to form the most different substances, and similar substances are produced from compounds which, when superficially examined, appear entirely different." And, as he well remarks in another place, when speaking of the subject of this article—"The doctrine of the proper application of manures offers an illustration of an important part of the economy of nature, and of the happy order in which it is arranged. The fermentation and putrefaction of organized substances, in the free atmosphere, are noxious processes; beneath the surface of the ground they are salutary operations. In this case the food of plants is prepared where it can be used, and that which would offend the senses and injure the health, if exposed, is converted by gradual processes into forms of beauty and of usefulness." (*Agr. Chem.* pp. 54—309.) All researches like these carry with them their own reward; for not only does a successful experiment do so, but even an unsuccessful one is not unattended with advantages: it at least serves as a beacon to other cultivators, and is sure to afford to the farmer that pleasure and increased power which ever accompanies the acquisition of knowledge. (*Johnson on the Fertilizers*, p. 32.) See GASES, EARTHS, SALTS, WATER, FARM-YARD MANURE, BONES, CHALK, LIME, LIQUID MANURE, &c.

Weight of a Cubic Yard of various Manures.

(*C. W. Johnson "On Fertilizers,"* p. 90.)

MANURES, on rendering them more portable and applicable by the Drill.—The application of manures in a more concentrated form than that in which they naturally present themselves for the cultivator's service, was an effort reserved for modern agriculturists; an improvement chiefly induced by the increase of population, which almost compelled the farmer to force into cultivation the poor inland soils of England and the Continent: lands which could only be enriched by fertilizers brought from other districts, and from places where men congregated together in large masses. This necessity was, some years since, first felt and acted upon by many of the large continental cities, such as Paris, Berlin, Frankfort, and some of the other chief German towns. The contents of the cesspools were, in consequence, collected; their fertilizing matters were mixed with drying, disinfecting substances, and when thus reduced to powder, or into cakes, sold at a considerable profit. The enlightened constituted authorities of these places felt that they were, by so doing, conferring great and important benefits not only on their fellow-citizens, but upon the distant cultivator. They did not confine their attention to the farmers in their own direct vicinity; because they well knew that those, in common with the immediate agricultural neighbours of all large cities, have a ready access to an abundance of organic manures, since the cultivators so favourably

situated carry their produce with facility into such populous places, and return with their carriages loaded with manure. And yet, when the German and French authorities thus husbanded,—thus rendered more portable, the manure of their large towns, they made no discovery; they merely practised what the Chinese had preceded them in from time immemorial, and what, in Flanders, is an old and long-cherished custom. The only improvement which the citizens of Paris and Frankfort have made is, that they form with their night-soil an enriching powder; while those of China and of Belgium still make theirs into cakes, with a portion of either clay or marl; so that the powder of Paris can be either applied with the drill or dibble, but the Chinese and Flemings are obliged to dissolve theirs in water, before it can be used as a liquid manure with advantage. In England, however, notwithstanding the example of our neighbours, little or nothing has yet been done to render the commonest manures, such, for instance, as night-soil, more portable. The nightmen and scavengers are still compelled to hurry away their collections only at stated hours and in the dead of the night; are fined for any neglect, and harassed in all possible ways, rather than that this, the most powerful of all the animal fertilizers, should be preserved for the use of the farmer in any way that might endanger the olfactory nerves of the citizens. But an endangerment upon sensitive noses is not essential; the night-soil might be preserved without any offence to the most sensitive. But this manure has been hitherto little known or employed in this country; its powers have been misrepresented; all sorts of prejudices have been created against it. I propose here briefly to show, first, the composition and fertilizing powers of various manures; and, secondly, to examine the modes which have been recently adopted to render them inodorous and more easily portable, so as to bring them within the reach of even the farmer who has to contend with the poorest, the most upland soils of Britain, far away from its great towns. And, although I confine my attention in this essay chiefly to one fertilizer, yet there are other manures, now well known to, and extensively employed by the cultivator, whose powerful action, when judiciously used in very small proportions, well illustrates the truth of what I have so often ventured to urge upon the farmer's attention, viz., that a much smaller quantity of manure, composed of any description of organic decomposing matters, is sufficient, when applied in a skilful manner, to produce more luxuriant effects than is commonly believed. The very great importance of applying fertilizers in immediate juxtaposition with the young plant, even in very small proportions, as by the drill, is only now beginning to be considered with even patient attention; and yet there are many circumstances with which the farmer is well acquainted, which ought to convince the most inattentive that such is the fact. The small quantity of oil-cake drilled with the seed; the few bushels of bones successfully applied in the same way per acre; the woollen rags of the Berkshire farmers (half

a ton per acre only); the 2 cwt. of gypsum applied to sainfoin and clover; the 1 cwt. of salt-petre, or of nitrate of soda, used on the same extent of land, all indicate the truth of the case, that it is not absolutely necessary to apply fertilizers of any kind in such great masses as are commonly deemed essential by the cultivator. I was told not long since by an excellent farmer of Middlesex, Mr. George Sherbourn, that he had succeeded in producing the finest crops of turnips by merely mixing about 30 bushels of coal-ashes per acre with 3 gallons of train-oil, and drilling these oiled ashes with the seed. It is a folly, therefore, to contend that the careless way in which organic manures of all kinds are usually employed is the most economical, and susceptible of no improvement. Such complacent feelings have ever been the bane of agricultural improvement; for it is then certain to follow as a natural result, that the system which the cultivator deems perfect will, in his hands, remain as he found it. Having no hope for better things, better modes will by him never be discovered.

Some recent experiments on a very broad scale, in the forest of Darnaway in Scotland, have shown that the application of a quantity of lime under each seedling tree, even so small an amount as 4 bushels per acre, has been productive of the most excellent effects, imparting to the plantation a degree of luxuriance hardly credible. The same advantage, therefore, which is derivable from the application of a very small quantity of organic manure, in immediate contact with the growing plant, is evidently also derivable from a much smaller quantity of earthy manures than the farmer commonly supposes.

There are several advantages derivable from placing the seed in direct contact with the manure, to which the farmer very rarely attends. For instance, the germinating seed in the immediate neighbourhood of the fertilizer is by this means well nourished at the very period of its growth when it most needs assistance to enable it to develop its fibres, and to extend its roots. The young plant, so situated, is not exhausted in its extension; it avoids the usual fate of those crops which tenant poor soils, whose roots are obliged to penetrate some distance in search of the requisite degree of nourishment. On the contrary, the strength of the plant is thrown into the stem and the leaves, and the crop flourishes luxuriantly; for the leaves and roots of the invigorated and healthy plant are enabled to absorb the gases and aqueous vapour of the atmosphere, by which the plant is nourished in the most complete manner. The very mechanical effect, too, of placing the decomposing organic manure in direct contact with the roots of vegetables, facilitating the free access to them of the atmospheric gases and vapour, would be alone a sufficient reason for the adoption of the manure drill system, even if we say nothing of the other certain advantages of the plan, such as, in the case of decomposing fertilizers, the presentation of the gases of putrefaction to the roots of the plant, at the moment of their extrication, and the economical and forcing

effects of this mode of distributing the manure. The farmer, in fact, tells us that the plan is probably a good one, but then his explanation of the derived benefit is very erroneous. He informs us, that thus to push forward the growth of the young crop is very likely to be good husbandry, especially on light soils, since, by this means, where the ground is well covered with the crop, "the moisture is kept in, and the sun is kept out." If the cultivator would but remember, that the quantity of moisture transpired by a given surface of a growing crop is considerably greater than that emitted by the most naked fallow, he would no longer be content with such an explanation as this.

Dr. Hales ascertained that a cabbage transmits into the atmosphere by insensible vapour, about half its weight of vapour daily; and that a sunflower, three feet in height, transpired, in the same period, nearly two pounds weight. Dr. Woodward found that a sprig of mint, weighing 27 grains, in 77 days emitted 2543 grains of water; a sprig of spearmint, weighing 27 grains, emitted, in the same time, 2558 grains; a sprig of common nightshade, weighing 49 grains, evolved 3708 grains; and a lathyrus, of 98 grains, emitted 2501.

If I were asked to produce any evidence of the extreme difficulty with which agricultural improvements, even of the most undoubted value, are introduced, I should at once instance the manure-drill, the progress of which has been slow—for it has shared the fate of very many other scientific efforts: it has been zealously opposed by the ignorant, neglected by the indolent, and ridiculed by the bigoted farmer, as an innovation upon the good old system of the days of the patriarchs of agriculture, when the earth brought forth its fruits in abundance, and the very seeds were not sown by man. But even here this solitary argument of the adherent to old customs fails; for the Chinese (the most expert of farmers) and the cultivators of Japan and of Arabia have drilled and dibbled in their seed from time immemorial. The natives of the Carnatic do the same; and after they have thus deposited their seed, the Hindoos use a kind of subsoil-plough, which passes under, and loosens, to the depth of about eight inches, the soil under, about three drills' breadth at a time. And so prejudiced are the natives of those empires, too, in favour of the customs of their ancestors—so rarely do they introduce new modes of cultivation, that it has been very reasonably concluded that the drill system, so far from being entitled to the appellation of "the new husbandry," ought rather to be classed with those branches of the sciences which degenerated, or were lost in the dark ages.

Sir George Staunton, in his *Account of Lord Macartney's Embassy to China*, says (vol. ii. p. 375)—"Near Sanchoo, wheat was perceived growing for the first time in China. It was, though on a dry sandy soil, where no rain had fallen for the three preceding months, looking remarkably well. It was very neatly sown in drills, or dibbled, according to the method used of late in some parts of England. A gentleman of the embassy calculated that the saving of the seed alone in China by this drill husbandry;

which would be lost by that of broadcast, would be sufficient to maintain all the European subjects of Great Britain."

In a communication to the Board of Agriculture, dated at Junacondah, December 31, 1795, Captain Halcott says,—“The drill-plough, I find, is in general use here, and has been so time immemorial, in the culture of all grain (except horse grain), and also of tobacco, cotton, rice, and the castor-oil plant.”

The first drill introduced into Europe seems to have been the invention of a German, who made it known to the Spanish court in 1647. (*Harte's Essays on Husbandry*.) The Roman farmers endeavoured to attain the advantages of row-culture by ploughing in the seeds.

It is useless to search in the works of Jethro Tull for any recommendation of the drill as a means of applying manure; for all Tull's arguments and experiments are directed to proving that the application of manure of any kind is utterly needless. And yet he had the discernment, when thus suffering his enthusiasm to carry him much too far, to make the observation, that “almost the only use of all manure is the same as of tillage, viz., the pulveration it makes by fermentation, as tillage doth by attrition or confusion; and with these differences, that dung, which is the most common manure, is apt to increase weeds, as much as tillage (of which hoeing is chief) destroys them.” (*New Husbandry*, p. 166, 1st edit. 1731.) The advantage, thus glanced at by Tull, of the manure keeping the ground light and porous, is much greater than the cultivator commonly suspects, and this benefit is mainly owing to the free access which is thus secured of the watery vapour and gases of the atmosphere to the roots of the plants. Now, for the vapour of the atmosphere, all well-pulverized fertile earth has a strong attraction: the richer and the better divided the soil, the more copiously does it absorb vapour; but the power of the richest cultivated soils in this respect is very much inferior to that of even the most ordinary manure. In my own experiments, I have never found, in a given space, say three hours, that 1000 parts of the richest soil, previously dried, absorbed more than from 14 to 20 parts of moisture; but in the same time, under similar circumstances, 1000 parts of horse-dung absorbed 145 parts; cow-dung, 130; pig-dung, 120; sheep-dung, 81; pigeons' dung, 50. (*My Work “On Fertilizers,”* p. 41.) It is evident, therefore, that for the mere purpose of withstanding long-continued dry weather, those plants whose roots have immediate access to organic manures will be much better enabled to absorb the necessary supplies of atmospheric moisture than those merely vegetating in the unmanured soil.

The merit of the introduction of the drill to general notice in England, is, however, to be ascribed, in a great measure, to Jethro Tull. Yet Jethro Tull certainly thought himself the inventor; for he tells us so very clearly, in the preface to the first edition of his *Horse-hoe Husbandry*, published in 1731, and even whence he derived the hint for his drill; he says,—“When I was young, my diversion was music; I had also the curiosity to acquaint myself

thoroughly with the fabric of every part of my organ; but as little thinking that I should ever take from thence the first rudiments of a drill, as that I should ever have occasion for such a machine, or practise agriculture; for 'twas accident, not choice, that made me a farmer.” But he was certainly not the originator of the idea of thus applying the seed; for, nearly a century before his time, John Worlidge ineffectually, in 1669, laboured hard to draw the English farmers' attention not only to the drill, but to the *manure-drill* also. And little can be now added to what, 175 years since, honest John Worlidge urged in its favour, when he said, after describing the seed-drill,—“By the use of this instrument, also, you may cover your grain or pulse with any rich compost you shall prepare for that purpose, either with pigeons' dung, dry or granulated, or any other saline or lixivial substance, made dispersible, which may drop after the corn, and prove an excellent improvement; for we find, experimentally, that pigeons' dung, sown by the hand on wheat or barley, mightily advantageth it in the common way of husbandry: much more, then, might we expect this way, where the dung, or such like substance, is all in the same furrow with the corn; whereas, in the other vulgar way, a great part thereof comes not near it. It may either be done by having another hopper on the same frame behind that for the corn, wherein the compost may be put and made to drop successively after the corn; or it may be sown by another instrument to follow the former, which is the better way, and may both disperse the soil and cover the manure and seed.”

Worlidge was well supported by Evelyn, who, in a communication to the Royal Society, dated in February, 1669, urged the advantages of a drill-plough, which, first invented in Germany, had thence been introduced at Madrid under the auspices of the Spanish monarch, and had been forwarded from Spain by the Earl of Sandwich, as the invention of a Don Leucatilla. It is there described as “the Spanish sembrador, or new engine for ploughing, and equal sowing all sorts of grain, and harrowing at once.” Leucatilla saw very clearly the errors of the broadcast system: he observed,—“*Even at this day* (1669) all sorts of seeds are sown by handfuls, heedlessly and by chance, whence we see corn sowed in some places too thick, in others too thin.”

It was between the years 1720 and 1740 that Jethro Tull laboured thus hard, and with a success little equal to his merits, to introduce the drill system: the honour, however, was reserved for the present Lord Leicester, in the early part of the present century, of inducing its general employment, for which the soils of the greatest portion of Norfolk are so very well adapted. It then naturally followed, that various manures were found easily applicable at the same time with the seed. Powdered oil-cake was one of the first substances that was used as a manure, and the discovery of the value of crushed bones as a fertilizer for turnips, opened another wide field for the useful application of this invaluable machine. The manure-drill, in fact, thence received an im-

netus which it will probably never lose, for with its use is now almost inseparably connected the cultivation of some of the most extensive districts of the poor light lands in the north of England; such as on the Wolds of Lincolnshire, and the sands of Nottinghamshire. See BONES.

The most recent improvement in the manure-drill is that of Mr. Grounsel of Louth, for which the English Agricultural Society awarded him, in 1839, their silver medal. It is an attempt, and an excellent one too, to imitate the dibbling system, so as not only to save seed, but the manure also. And although, in all researches of this nature, it is especially necessary to proceed with great care, and to regard single experiments with caution, yet what has been yet experienced of its powers is certainly of a nature to induce farther and more extended trials; since it is evident that this drill can apply, and evenly too, as small a quantity of crushed bones or ashes as six bushels per acre. In reply to some inquiries of mine, the inventor says,—“My drill will deposit from 6 to 100 bushels per acre of any kind of compost that may be prepared for drilling, from 10 inches to any greater distance apart in the rows, with turnips or grain, and either in a wet or dry condition; but I recommend, from experience, ashes to be applied in a wet state, especially in a dry turnip-seed season, for then the seeds vegetate much sooner. Another equally excellent drop, and common drill, is that made by Mr. Hornsby of Grantham.” See DRILL.

Admitting the truth of these experiments, that one-half the quantity of organic manures usually spread on the land is sufficient, when applied by the drill, in immediate contact with the seed, what a field is thus opened for the manuring of much larger breadths of land than has hitherto been deemed possible. The complaints of the deficiency of manures, which are now so prevalent with farmers, need then no longer be heard. Their crops will be properly nourished, and the manure applied with them will be not only bestowed in the most scientific manner, but it will lead to other improvements; it will enable the farmer to mix his manures, according to the nature of his soil and his crop, with much more facility than at present: he will then study, not merely the economy to be regarded in its distribution, but also its quality, or chemical composition, and to what soils the manure is best adapted.

There is one class of fertilizers, however, whose application by the drill requires great caution; I allude to the saline manures, for they are often much too powerful in their operation to be safely applicable in their pure state or in large proportions. Common salt has, in this way, carried great destruction by being drilled in with the seed, and I have witnessed equally disastrous effects from applying the lime of the gas-works (sulphuret of lime) in the same way. Yet when the seed-wheat is wetted with a nearly saturated solution of salt, and then rolled in lime, or the salt and lime are not used until they have been mixed together for three months, and then sown on the land broadcast, or when the gas-lime is previously

mixed with four or five times its bulk of sifted mould or ashes, then I have seen the most excellent effects produced by its being drilled with the turnip-seed: the same remarks apply to the chloride of lime of the calico-bleachers. Other salts, whose action is less energetic, or which are applied in very small proportions, are perhaps best applied by the drill; for instance, saltpetre, which is rarely applied in larger proportion than $1\frac{1}{4}$ cwt. per acre, may very likely be still further reduced in quantity, especially if mixed with other substances, such as three or four times its bulk of mould. Mr. Beadel of Witham, in Essex, a very excellent farmer, has found, that where saltpetre was applied to his turnips broadcast as a top-dressing, it did not succeed, but it did so very decidedly when it was drilled with the seed.

In those situations where night-soil, or sprats, or bones cannot be obtained at a sufficiently reasonable rate, very great effects may be produced by the careful collection of the excrements of domestic animals, and mixing them with merely a sufficient quantity of dry ashes, mould, saw-dust, or, what is best of all, recently prepared finely powdered charcoal, to render them sufficiently friable to pass the drill: this is very easily accomplished, by making the preparation under cover some months before it is used, and, if necessary, by causing it to be spread in the sun. By the adoption of these means, a very recent mixture will be found available by the farmer; the excrements of the horse, cow, and especially the sheep (still more so if fed with oil-cake), will be found excellent for this purpose. And in very small proportions the Peruvian farmers, according to Humboldt, employ the guano, or excrements of seafowl (which abound in phosphate of lime, or earthy salt of bones), which is brought in sailing vessels, from the rocky islands of the Pacific, expressly for the use of the cultivators of that republic. See GUANO.

And that bones might be very profitably mixed with other fertilizers, so as to materially reduce the expense of the manure, is indicated by more than one successful experiment. To give another instance, which has recently been communicated to me, in the trials made by Daniel Dixon, Esq. of West Clandon, in Surrey. “On a poor chalk soil,” observed an excellent and scientific friend of mine, “he has used a compost for a manure-drill for turnips with great advantage. He puts 8 bushels of ground bones with 24 bushels of any ashes he can get together in a dry place, and from time to time (as often as possible) he empties the liquid sewerage of the house upon it. In two or three months it is fit for use, working well out of the drill. The above is the quantity for an acre. The effect of drilling this mixture with the seed was very remarkable, and as bone-manure was drilled by the side of it, the contrast was at once visible; the difference was more than double. In fact, the bones by themselves seemed comparatively useless. The soil on which the mixture has been applied is poor, chalky, and flinty, abutting upon the sheep-walks and Guildford race-course. Whenever the mixture is too wet for the drill, it is spread to dry for a day or two.” (Letters

of Henry Dixon, Esq. to the Author, November, 1839, and March, 1840.)

"A friend of ours, a farmer in Northumberland," says the excellent editor of the *Quarterly Journal of Agriculture*, "the late Mr. George Brown, Hetton Steads, mixed any quantity of coal-ashes, kept dry, and finely riddled, with a quarter of bone-dust per acre, and raised as good a crop of turnips (of course drilled) of all kinds, on a clayey soil, resting on a retentive bottom (but drained), as he could with two quarters of bone-dust." Mr. Turner of Tring, in Hertfordshire, drilled with his crushed bones an equal quantity per acre of sheep dung, collected for the express purpose, at an expense of 2½d. per bushel paid to the collectors: this he prepared in the winter, by laying the bone-dust in alternate layers with sheep-dung, and suffering them to remain fermenting some months until the turnip sowing. By this plan, by the fermentation of the mass, the two manures are thoroughly incorporated; and he considers that 35 bushels of the mixture are fully equal in effect to 25 bushels of the bones. So that, allowing 3s. 6d. per acre for the expense of collecting the sheep-dung, there will be a clear saving of 12s. 6d. per acre in bones, valuing these at 2s. per bushel. The mixed bones and sheep-dung are invariably drilled in with the turnip-seed.

The application of rape-cake powder by the drill has never been so common as it ought to be, for it is not only a very powerful, but a very easily manageable fertilizer; it has, moreover, the advantage of being moderate in price, and easily attainable at all seasons of the year. There is no doubt of the advantage of feeding stock with this food, the manure they produce when thus fed being exceedingly rich. Many farmers, however, owing to the want of cattle, or an unwillingness to lay out the requisite money in a long course of stall-feeding, are deterred from using oil-cake to the extent they would otherwise do. The use of the oil-cake powder conveys to the land all the enriching ingredients of this fertilizer at once, and to the exact extent the farmer requires; there is neither the waste, the risk, or the trouble of stall-feeding to be dreaded. The oil remaining in the cake certainly constitutes its most enriching portion; the oil abounding in sprats is an instance familiar to the farmer, and when this oil is imperfectly crushed out, the cake produced (as is well known to the Swedish cultivator in the case of herring-cake) is found to be exceedingly enriching. A very small quantity of oil left by the crushers in the cake will produce very great results; even three gallons of train-oil, as I have mentioned in another place, has been found amply sufficient per acre, when mixed with earth or ashes, to produce a capital crop of turnips. It has been found (and this is another illustration of the value of the manure-drill), that when rape-cake is drilled with the turnip-seed, 3½ cwt. per acre is sufficient, but if it is applied broadcast, then double the quantity is required. My friend Mr. Davis, of Spring Park, in Surrey, is well aware of the powers of oil-cake as a manure; he has found it even an advantageous plan to drill common coal, wood, or turf-ashes, at the

rate of 40 bushels per acre, with his turnip seed; and this he has successfully practised for some years, so much is he in favour of bringing the seed and the manure into immediate contact.

In proceeding to examine, as an instance of one of the least likely substances successfully applied by the drill, the properties of night-soil, and the modes which have been adopted to reduce its weight, without impairing its effect, many reflections will suggest themselves to the farmer. He will notice that such a process, by producing it in the state of powder, renders it capable of being readily drilled with the seed; and that the same remarks apply in a great measure to the excrements of the farm-yard, to whale-blubber, and to fish. The Essex farmers find, that when sprats are mixed with earth, finely divided, the mass, when these very oily fish are quite dissolved in the mould, forms a very powerful fertilizer, which is excellent as a drill-manure for turnips. They tell you, that the sprats lose none of their enriching powers, even when thus kept mixed with earth for some months.

Even earthy manures may be advantageously reduced in weight by exposure to the air, or by the application of artificial heat. Chalk, I have found by experiment, loses from 15 to 25 per cent. of its weight by being thus deprived of its water; and a cubic foot of calcareous sand, when thoroughly wet, contains, according to M. Schubler, more than 31 lbs. of water; the same measure of sandy clay, 38 lbs.; loamy clay, 41 lbs.; stiff clay or brick-earth, 45 lbs.; pure gray clay, 48 lbs.; garden-mould, 48 lbs.; and fine slaty marl, 35 lbs. By exposing the earths to an intense heat, their weight is still further reduced by the loss of their carbonic acid gas or fixed air; hence 100 parts of chalk, for instance, when thus treated, lose very commonly 24 parts of water and 34 parts of carbonic acid; so that 42 lbs. of lime, when well burnt, contain as much real earth as 180 parts of chalk. All these facts are such as the cultivator should be thoroughly acquainted with; for, in many cases, the earth which the farmer removes might be previously very advantageously dried, by exposure in spits to the action of the atmosphere. Even the difference of labour to the men and horses, between carting them after continued dry weather and in wet periods, is much more material than the cultivator commonly believes.

My attention, however, will, in this place, be principally confined to fertilizers of an organic nature, and more especially to night-soil. Night-soil has not, in any form, been employed by the farmers of England to the same extent as on the Continent, although it is certainly by far the most powerful of the organic manures, and the most easily rendered applicable by the drill of any of the class. To this neglect many causes have contributed. Its disagreeable odour, certain vexatious fiscal regulations with regard to its removal, to which I have before alluded, and the erroneous modes of applying it, either in excessive quantities, or mixed with other composts in such proportions that its powers could not be distinguished in the mass; its semifluid nature requiring for its removal

carriages of a peculiar construction; the extent and completeness of the sewerage of our large cities, and several other minor obstacles, have rendered its use not nearly so extensive as, even in a national point of view, is desirable. (See NIGHT-SOIL.) And yet the necessity for increasing the supplies of manures, in order to promote the fertility of the soil, will be self-evident to every one who remembers, not only the increasing population of the country, but the immense drains upon its organic fertilizing matters which are hourly pouring their contents into the sea. Thus, as I have elsewhere remarked, by carefully-conducted experiment it has been clearly ascertained that the principal London drains convey *daily* into the Thames 115,000 tons of mixed manure, consisting, on an average composition, of one part solid or mechanically suspended matter, and 25 parts absolutely fluid; but if we allow only 1 part in 30 of this immense mass to be composed of solid substances, than we have the large quantity of more than 3800 tons of solid manure daily wasted in the river from London alone. What might not the farmers of England effect if this mass of fertilizing matter was preserved, at a reasonable rate, for their use? 15 tons of this solid manure—nay, 10 tons, would render fertile an acre of the poorest cultivated, or even common or heath land. But allow, for the sake of argument, that 20 tons were required, even then 3800 would give a daily allowance of manure sufficient for 180 acres of the poorest land in England; and if we give 300 days on which this manure was collected, that would afford an annual supply for *fifty-four thousand of such acres*, which land would not again need manuring for 4 years; and in this calculation nothing is allowed for the *fluid* portion of the drainage. It is the reckless waste of the drainage of our large cities and towns, which has alone prevented the cultivated lands of England from becoming increasingly fertile, because yearly more abounding in organic decomposing matters. For such is the enormous yearly import of foreign products into this country, that it must tend to rapidly increase the natural fertility of the soil of England, since all their ingredients ought and do, in some measure, eventually find their way as a manure upon the land; thus, in 1834, were imported into the United Kingdom, according to a parliamentary report, now before me, of—

	Cwts.	qrs.	lbs.
Barilla - - - -	215,750	1	22
Bark for tanners - - - -	854,869	3	16

So that, including corn, oil-cake, timber, &c., &c., at least 1,000,000 tons of vegetable matters alone are yearly imported from foreign countries into the United Kingdom, and added to the riches of the soil: thus our merchants are annually fertilizing, while the Commissioners

of Sewers are in an equal ratio impoverishing the island. But against this great fertilizing import, we have at present to set off the large and ever-flowing drainage of the cities and towns of the United Kingdom; not only London, but Liverpool, Manchester, and a hundred others, are incessantly pouring the riches of the land into the sea; and to such an extent is this done at Bristol, that the Court of King's Bench was obliged, not long since, to interfere to protect the inhabitants from the nuisance created by the non-removal of the city drainage from the bed of the Avon.

On the Continent, the use of various manure powders made from night-soil is equally extensive and successful. An elaborate report upon these was made a short time since to the Directors of the Thames Improvement Company, by Dr. Granville, who had been commissioned to make the requisite inquiries and surveys; and from this we learn that the consumption of night-soil in Flanders is very large; but that the farmers, instead of employing it in the dry or powdered state, rather prefer to mix it with water, and thus form a rich liquid manure. Of late years, the French farmers have adopted the same views with regard to night-soil; but the practice of their farmers, in this respect, is somewhat different. They prefer, for the sake of easy and convenient transport, to dry the stercoral substances to powder, which, bearing the name of *poudrette*, is sent into the country from the neighbourhood of the capital, and is sold at a high price. The success of the establishment for the manufacture of *poudrette*, first formed near Paris about 40 years since, by a person named Bridet, has been such that in almost every part of the kingdom similar manufactories have been erected, and nothing now is wasted. The Parisians have at present several such large works. M. Bridet obtained a patent for his process of manufacturing the *poudre végétatif*. He proved, by experiments, that the *poudrette* is many times more valuable than the best sort of ordinary manure. It was found, after repeated trials, that 240 lbs. of the *poudrette* would manure an acre of ground with greater effect than 8 cart-loads of the best stable manure.

Under the name of "Alkalino-vegetative Powder," another preparation of night-soil was ushered into notice in France, and generally adopted, under the auspices of an agricultural lady, Madame Vivert Duboul, to whom, in consequence, the Royal Society of Agriculture, in 1814, awarded their gold medal. This lady obtained a patent of 15 years for her process, which consisted in promoting fermentation in the most liquid portion of the excrementitious substances, and treating them with slaked lime afterwards, so as to form a powder, which has been found to be very superior to the first named *poudrette* upon cold, light, or moist soils. Its action is very powerful, and it extends its influence over the soil for several years without requiring, during that period, a repetition of the manuring process. This is not the case with the *poudrette* of Bridet, the influence of which over any soil is only annual. "M. Hermstadt gave, in the *Monthly Journal of the Economic Society of Potsdam*, for August, 1832

as the result of his experiments instituted with the view of ascertaining the comparative fertilizing powers of farm-yard manure and *poudrette*, that *poudrette* is a complete substitute for common dung, whether with respect to price or quality."

In 1818 a company was formed near Paris (Messrs. Donat & Co.), for the manufacture of another kind of manure from night-soil. The name of "urate" (from the principal ingredient used) was given to it; and the Royal Society of Agriculture deemed it an object of sufficient importance to deserve being submitted to the examination of a joint committee of chemists and agriculturists, in which were included the names of Vanquelin, Dubois, &c. The report made by these distinguished men is full of interest to the agriculturist. Urine is the active ingredient, and plaster of Paris (gypsum), so common in the neighbourhood of that capital, the other constituent. This mixture is reported by the joint committee to be so powerful in its effects upon the dullest soil, that they recommend that it should only be employed by skilful and discriminating farmers. For this discovery the inventor received a gold medal from the government. A powerful manure of the same name is now extensively prepared by the "London Manure Company," of 40 New Bridge street. It abounds with the salts of ammonia, phosphate of lime, and the animal matters of urine. It appears, also, from the fine, dry state of powder in which the "urate" is delivered, that it is admirably adapted for application by the drill with the seed. The quantity applied per acre is about 5 cwt.; and, as it is almost entirely composed of organic matters, phosphate of lime (earthy salt of bones), sulphate of lime (gypsum), and various salts of ammonia, it is evidently a most powerful fertilizer, as well adapted for turnips as for the grass and grain crops. I have had an opportunity of inspecting the manufactory of this company, and from the care displayed in its preparation, the "urate" will, I think, be rapidly and extensively employed by the farmer.

In some recent reports of trials with this manure upon turnips, I observe that Mr. Anderson, of Oakley, Bedfordshire, describes it as proving "itself quite equal, if not superior, to the farm-yard manure. The land I used it on was a sharp gravel, and was much out of condition previous to the present crop. The 6 tons were drilled with Swedish turnip-seed, 18 inches apart, on 18 acres."

Mr. Manning, of Elstow, says, "I drilled a ton of urate upon 3 acres, in rows 17 inches apart, upon a very hot, gravelly soil; each side abutting on this was manured in the usual way, with good farm-yard manure, about 14 loads per acre. The turnips on the urate were fit to hoe 7 days before the manured part; from their first appearance, a stranger could point out the spot where it commenced and ended; the difference is still evident, and in its favour. Both the manured and urate pieces were sown the same day, about the 14th of June. I certainly consider it a good artificial dressing, and its fertilizing properties great."

In 1820, another patent was granted to a M.

Loques, by the French government, for a manure called "stercorat," consisting of a mixture of both the solid and liquid parts of the excrementitious matters, and some earthy substance. It is said to be particularly efficacious, and sells at a very high price.

M. Parmentier, a celebrated French agricultural writer, some years since expressed his surprise at the tardiness of his countrymen in adopting the practice of their Flemish neighbours, and in continuing so long to pay money for getting rid of that which other nations first, and the French themselves afterwards, found to be so productive of wealth. He quotes the case of an individual who in former times had amassed great wealth by the sale of a manuring powder, which he manufactured from the very soil he was annually paid by government to remove out of the extensive military barracks of Lisle.

There existed at one time much public prejudice against this mode of rendering the land more productive, on the wild supposition that the obnoxious principles of such a manure would form part of the plants raised by means of it; but the most accurate experiments have proved, that not the least vestige of such animal substances is to be detected either in the ascending sap, or in the more solid parts of the plants so cultivated. A great extent of the rich plains of Normandy are fertilized every year by the manure powder manufactured at present out of the cess-pools of Paris.

The *poudrette* sells for eight francs the *sestier* on the premises, and the whole is fetched away at that price as soon as ready, and principally distributed within 12 leagues of Paris. Now, as there are $7\frac{1}{2}$ *sestiers* in a ton, it is evident that the value of the latter is 60 francs, or 2*l.* 10*s.*; and yet the comparative agricultural value of this compost is not so great as that of the "Flemish manure." Messrs. Payen and Company, the patentees of the "engrais animalizé," or disinfected night-soil, sell their "*poudrette*" at $2\frac{1}{2}$ francs per ton under the market price of that of Montfaugon, and they have rarely any left on the premises.

The *engrais animalizé*, or disinfected night-soil, has recently been introduced into England by M. Poittevin, and a manufactory of it established in Whitechapel, near London. It is there produced by mixing the night-soil of the metropolis with a considerable quantity of recently prepared charcoal powder, and drying the mass in a very gentle heat. As thus prepared, its appearance somewhat resembles that of the friable, rich, vegetable mould of an old hot-bed; it is of very dark colour, and totally devoid of smell. Its introduction into England has been too recent for any very extensive trials to have been yet made with it; my own are only now carrying on; these, however, promise well. In some comparative experiments made last year with bones, they were found to answer very completely. These results have been confirmed by several communications with which I have been recently favoured, stating that, to use the words of Col Challoner, "this manure, in its effects upon the turnip crop, was fully equal to bones." And Mr. Beach, of Oakley Hall, near Basing

stoke, who had applied it by the drill with the seed, at the rate of 14 bushels per acre to a portion of a field of turnips; and, on another portion, drilled three sacks per acre of crushed bones, mixed with turf-ashes; and, on a third portion, with ordinary stable manure, says, in February last, "It is impossible to distinguish any difference between the three, some persons fancying one part, and some another, to be superior. In their early growth, the night-soil had a decided advantage. The seed came up as thick as rows of mustard-seed in a hot-bed, and the turnips were hoed out within a month." Mr. Beach adds a suggestion, which I think highly worthy of the attention of the turnip cultivators:—"I am so well satisfied with it for turnips, that I shall use a large quantity of the night-soil powder this season. I shall also mix 10 or 12 bushels with a quarter of crushed bones, which I am inclined to think will answer well." I have recently been shown a letter from Mr. Robert M'Crea, of Grange House, near Londonderry, in which he speaks of this manure in the highest terms, as a dressing for turnips; those thus treated having carried off last year the first prize offered by the Londonderry Farming Society.

A preparation of night-soil has been lately imported into Scotland and the north of England from Copenhagen, under the name of Owen's animalized carbon, which has answered, when applied by the manure drill, very well for turnips. Mr. James Waldie, in his recent prize communication to the Ayrshire Agricultural Society, describes it as a useful, auxiliary manure, and as likely, in a great measure, to supersede the use of bones, now that the latter have risen to the enormous rate of at least 3s. per bushel. He says, "One ton of carbon, the cost of which is 3*l.*, is sufficient for an acre of land; and from experiments which I have made this year, conjoined with what I have observed of two successive crops on a farm in this neighbourhood, where comparative trials were made with different manures, on a very extensive scale, it may be inferred, that one ton of carbon is equal to 25 bushels of crushed bones." These experiments are supported by the observations of Mr. M. Milburn, of Thorpefield, near Thirsk, when describing, in his report to the Yorkshire Agricultural Society, the various fertilizers advantageously employed on light lands in the cultivation of turnips; for, he observes, "Animalized carbon has been used advantageously; 16 bushels per acre, when drilled, is the quantity generally employed. Pigeons' dung is most valuable; rape-dust has been used successfully; malt-dust is useful as a top-dressing." There is a chemical "seed manure" prepared by Messrs. Hodgson and Simpson, near Wakefield, which is applied, mixed with water, as a liquid manure, or steep to the seed-corn, and seems, from a communication with which they favoured me in March, 1840, to be a kind of secret preparation, composed principally of saccharine matter, ammonia, common salt, and nitre. This seed manure is applied according to the following directions,—instructions which might be advantageously followed in the use of other fertilizers: "Dissolve 28 lbs. of this

manure in a pail, by adding water in small quantities, stirring it at the same time, until the mixture is of the consistence of thick cream; it is then to be poured over the quantity of seed intended to be sown on an acre of land, and the whole repeatedly turned over, so that it appears one uniform mixture; it is then to be spread out thin on the floor to dry for 10 or 12 hours, and mixed with a sufficient quantity of soot, or any kind of dry ashes, to render it sufficiently friable to be sown by the hand or by the drill." The quantity thus directed to be applied per acre, is certainly very small, and yet, according to the testimonials which I have seen, the effect it produces is considerable. Mr. Milburn, of Thorpefield, in one of these, tells us: "A new principle in the application of manure has been developed in the use of the chemical seed manure, which, by applying a chemical composition to the seed itself, not only secures immediate effect in the precise situation required, but highly economizes the quantity necessary. I have great pleasure in detailing a very successful experiment with it on a barley crop. The field had grown a corn crop the preceding year—part of the field was dressed with a coating of fermented farm-yard dung—the remaining part with the chemical seed manure, at the rate of 28 lbs. per acre. The result was, that the barley sown with the chemical manure exhibited a decided superiority over the rest of the field, in colour, healthiness, and general appearance, and maintained that superiority to the time of cutting, so much so, that it lodged considerably more than the rest of the field."

Various modes besides those to which I have alluded, have, at different times, been suggested, by which night-soil might be rendered more concentrated and more portable. Simply drying it has been attempted with some success; but though by this means about 70 per cent. of water is driven off, yet, at the same time, a considerable portion of ammoniacal and other gaseous matters are vaporized: thus the manure is impoverished, while the stench of the operation is intolerable. Then, again, it has been mixed with lime, in the way recommended by Davy; but judging by my own experiments, and those of my neighbours, I am fully persuaded that this is not the most economical way of using night-soil. The lime certainly dissolves, and partially decomposes it, but the fertilizing effect of a given weight of night-soil mixed with lime is clearly not so great as when a similar weight of it is used either by itself, or mixed with some merely drying odour-absorbing substance. There are several preparations of this kind made in large quantities in London, such as those of Mr. Clarke, and of Mr. Lance, the author of the *Golden Farmer*, all of which, I believe, are excellent manures; but I have not had an opportunity of examining any of their manufactures except those of the London Manure Company, and of the Messrs. Poittevin. The preparation of these gentlemen is the same as that so successfully carried into effect by M. Payen at Paris: it combines, and successfully too, the great object of driving off the water of urine and night-soil by a gentle heat, after all its gaseous matters have been

absorbed, by mixing with it a portion of newly prepared carbon, in the finest possible state of division, than which no known substance has such great powers of absorption of all gaseous matters like those which abound in and impart the disagreeable odour to night-soil. These purifying powers of charcoal have been long known: the medical man applies it in putrescent cases, the housewife rubs it powdered over her tainted meat, and the sailor chars the inside of his water-casks for a similar purpose. The presence of the carbon in the manure thus prepared is valuable in two ways; gradually it combines with the oxygen of the atmosphere, forming in the state of carbonic acid gas the food of plants; and, at the same time, all the gaseous matters of putrefaction with which it is saturated are thus preserved, stored up, as it were, for the service of the roots of the cultivator's crops; nothing is lost, the emission of the gases from the slowly dissolving charcoal being so gradual as to be almost, if not entirely, imperceptible to the senses.

Such, then, are the principal facts already ascertained with regard to the fertilizing uses of night-soil and other decomposing manures, in their ordinary form, and when reduced by various processes to such a state of dryness, so as to be easily applied in the state of powder to the soil by the drill. In thus investigating the advantages of rendering manures more concentrated, I have been induced chiefly to confine my attention to one only of the organic manures, night-soil, because, from its nature, cheapness, and powerful effects, it affords, perhaps, greater facilities for accomplishing this important object than any other excrement, and is, besides, more commonly wasted than any other fertilizer. I hardly deem it necessary to make any remarks upon the importance of all researches which tend to the better understanding of the powers and best mode of employing manures, for with such investigations is inseparably connected the gradual and steady increase of the productiveness of our country. Such improvements, too, are full of *interest*, not only to the cultivator, but to every one to whom the vegetable kingdom is an object of importance. And, as I have elsewhere had occasion to remark, it is hardly possible, in reflecting upon the essential use of organic fertilizers in the production of our food, to avoid being impressed with the wisdom and beneficence of the Creator, in thus making decomposing noxious organic substances the nutriment of vegetation, rendering the very animal substances which the grass once formed, its food when dead. This interchange of their elements, so essential to each, is equally incessant and remarkable, the death and decomposition of the one ever imparting fresh food and life to the other. Thus the same gases which are at one moment constituting the noxious products of putrefaction, are in the next existing in the exquisite aroma of the flower. These facts are, indeed, too apparent to escape our observation; and the marvellous rapidity and advantage to us of these magic vegetable combinations cannot but excite both our curiosity and our gratitude. (*Quart. Journ. of Agr.* vol. x. p. 142.)

MANURES, *History of.* See the heads ASHES,

FARM-YARD MANURE, BONES, CHALK, LIME, GREEN SAND, &c. The application of manures became one of the sustaining arts of life as soon as man was ordained to earn his bread by the sweat of his brow. From that time to the present, the art of manuring the soil has been steadily improving; and there is no doubt but that it will go on advancing, as long as mankind continue to increase.

The first manure used by man, as soon as he began to dwell in fixed habitations and till the land around him, would, of course, be that of his domesticated animals; but he is naturally averse to labour, and consequently this operation would be postponed until the rich alluvial soils, which would be certainly the first selected, were exhausted by over-cropping, and by the increase of population the poorer descriptions forced into cultivation; the occupier of the land would naturally avoid, if possible, the trouble of spreading the dung of his farm-yards over his fields. Instances of this kind have not been wanting in recent periods in the newly settled rich prairies of America, in which many cases have occurred where, in consequence of the enormous accumulation of dung around the farmer's sheds, he has been induced to remove his buildings to a new spot, rather than undertake the greater labour of removing the masses of fermenting manure which so deeply encumbered his old farm-yard. The first rude mode in which this was conveyed to the land, was naturally by hand-baskets, or by sledges or barrows; the use of beasts of burden was necessarily a later agricultural improvement; and, at first, there is no doubt but that manure was carried on their backs to the fields, as is even now practised in the mountainous districts of the Continent, and in some parts of the north of England, and in Devonshire. Dung-carts were a much later improvement; and the preparation of compost heaps, and exciting and regulating their fermentation by the use of the fork, has been a much more modern discovery than is usually believed.

Irrigation, which is a mode of applying the weakest of liquid manure, by the use of the waters of rivers, is of a very ancient date. It has been used from a very early period in Italy and the East; in fact, in many warm, sandy countries, as in China, a copious supply of water is an essential requisite for the successful cultivation of the earth. Water-meadows were first constructed in England, on a tolerably regular system, about the termination of the 17th century. Some of the most excellent of those in Wiltshire, such as those in the Wyley Bourne, were made between the years 1700 and 1705; and about half a century afterwards, the celebrated Craigintinny meadows were formed near Edinburgh, by which the town drainage is rendered available in the production of the most luxuriant crops of grass. These meadows were considerably enlarged towards the end of the 18th century, and again in 1821. These might be very advantageously imitated in the neighbourhood of other large towns.

Amongst the Egyptians and Israelites, whose climates were hot, a plentiful supply of moisture was necessary for a healthful vegetation;

and the simile of desolation, employed by Isaiah (chap. i. 30), is, "a garden that hath no water." In Egypt they irrigated their lands, and the water thus supplied was by an hydraulic machine, worked by men, in the same manner as the modern tread-wheel. To this practice Moses alludes, when he reminds the Israelites of their sowing their seed in Egypt, and watering it with their feet; a practice still pursued in Arabia. (*Deut. xi. 10; Niebuhr's Voyage en Arabie, i. p. 121.*)

Of their knowledge of manures we know little. Wood was so scarce that they consumed the dung of their animals for fuel. (*Parkhurst, p. 764.*) Perhaps it was this deficiency of carbonaceous matters for their lands, that makes an attention to fallowing so strictly enjoined. (*Levit. xix. 23; xxv. 3. Hosea x. 12.*)

Agriculture was too important and beneficial an art not to demand, and the Greeks and Romans were nations too polished and discerning not to afford to it, a very plentiful series of presiding deities. They attributed to Ceres, as the Egyptians did to Isis, the invention of the art of tilling the soil. Superstition is a prolific weakness; and consequently, by degrees, every operation of agriculture, and every period of the growth of crops, obtained its presiding tutelary deity. The goddess *Terra* was the guardian of the soil; *Sterculius* presided over manures, &c.

Xenophon recommends green crops to be ploughed in, and leguminous plants to be raised for the purpose; "for such," he says, "enrich the soil as much as dung." He also recommends earth that has been long under water to be put upon land to enrich it. Theophrastus, who flourished in the 4th century B. C., is still more particular upon the subject of manures. He states his conviction that a proper mixture of soils, as clay with sand, and the contrary, would produce crops as luxuriant as could be effected by the agency of manures. He describes the properties that render dungs beneficial to vegetation, and dwells upon composts. (*Hist. Plant. ii. c. 8.*) He also recommends the stubble at reaping-time to be left long, if the straw is abundant; "and this, if burned, will enrich the soil very much, or it may be cut and mixed with dung."

From the outline which we can draw from ancient authorities of the agriculture of the Romans, we shall be surprised to find how little they differed from the methods we now employ. We are superior to them in our implements, and consequently in the facility of performing the operations of tillage; but of the fundamental practices of the art they were as fully aware as ourselves. No modern writer could lay down more correct and comprehensive axioms than Cato did, in the following words; and whoever strictly obeys them will never be ranked among the ignorant of the art. "What is good tillage?" says this oldest of the Roman teachers of agriculture. "To plough. What is the second? To plough. The third is to manure." (*Cato, 61.*) In his 4th chapter he thus expresses his conviction of the utility of manure: "Study to have a large dunghill, keep your compost carefully; when you carry it out, scatter it and pulverize it; carry it out in

the autumn. Lay dung round the roots of your olives in autumn." And in his 29th chapter: "Divide your manure; carry half of it to the field when you sow your provender, and if there are olive trees, put some dung to their roots." In his 37th chapter he advises the use of pigeons' dung for gardens, meadows, and corn lands, as well as *umerca*, or *dregs of oil*: and recommends the farmer to preserve carefully the dung of all descriptions of animals. This was advice given 150 years before the Christian era; and now, after the lapse of 2000 years, the direction must be still the same. We learn from Columella (i. 6) and Pliny (xvii. 9; xxiv. 19) that they collected their manure and stored it in covered pits, so as to check the escape of the drainage; and sowed pulverized pigeons' dung, and the like, over their crops, and mixed it with the surface-soil by means of the sarle or hoe. (*Colum. i. 16; Cato, 36.*) They were aware of the benefit of mixing together earths of opposite qualities, and sowing lupines, and ploughing them in while green. (*Varro, i. 23.*)

Virgil is very particular in describing fertilizers. With common manure he mentions ashes (*Georg. lib. i. 80*), pumice-stone, and shells. (*Lib. ii. v. 346, 50, and in v. 250, 8.*) He advises the seeds of corn to be mixed with saltpetre and the dregs of olive oil, to make the grain swell. (*Lib. i. 195.*) Irrigation was employed in his days. (*Lib. i. 106, 9.*) The Italian farmers also fed down over-luxuriant crops (*lib. i. 3*), and burned the stubble. (*Lib. i. v. 84, 8.*)

Varro (*lib. i. c. 38*) mentions many kinds of animal manure, and is particularly minute in his enumeration of the dung of birds, and includes even that of blackbirds and thrushes kept in aviaries.

Columella (*lib. ii. c. 5*) advises the cultivator not to carry out to the field more dung than the labourers can cover with the soil the same day, as the exposure to the sun does it considerable injury; and he enumerates (*lib. ii. c. 15*), as well-known fertilizers, night-soil, the excrements of birds and sheep, urine (especially for apple-trees and vines), dregs of oil, the excrements of cattle, the ass, the goat, of pigs; ashes, chopped stalks of the lupine (or hop), leaves of trees, brambles, &c., and mud from sewers or ditches. Pliny also mentions that lime was employed as a fertilizer in Gaul, and marl in the same country and Britain; but we can only surmise thence, that they were also probably employed by the Romans. (*Pliny, xvii. 5.*)

Liquid manure is not a mode of fertilizing the land altogether of modern origin. For a fermented mixture of water and night-soil has from a very early period been employed by the Chinese farmers. Those of Italy certainly practised irrigation in the days of Virgil (*Georgic. lib. i. v. 106, 9*); and Cato adds, they employed a mixture of grape-stones and water to fertilize their olive trees. (*Lib. xxxvii.*) Columella praises very highly the use of stale, putrid urine for vines and apple-trees (*lib. ii. c. xv.*); commending also the lees of oil for the same purpose. More modern agricultural authors have united in praising various liquid preparations; thus Evelyn (whose ingredients most of

these authors recommend), in his *Treatise on Earth* (p. 123—160), gives several recipes, some of which have served as the bases for recent modes of preparing liquid manure; such as the dung of cattle, urine, *salt*, and *lime*, nitre.

The employment of *crushed bones* as a manure is but a very modern improvement; it is not one of the fertilizers even mentioned by the early agricultural writers; and to this neglect of bones several causes contributed. The necessary machinery for crushing them was, in the early ages of agricultural efforts, totally unknown; and bones when unbroken dissolve in the soil much too slowly to be of any apparent value as a fertilizer. The use of bones is an improvement, for which agriculture is entirely indebted to the enterprize of the English farmers. The refuse matters produced by the ivory and bone turners and cutlers of Sheffield, which speedily accumulated in very considerable heaps around their manufactories, first drew the Yorkshire farmers' attention to bone manure. The cultivators of the poor soils in the neighbourhood of that town, towards the conclusion of the last century, began to carry away these refuse matters with some readiness, and the turners were at first too glad to be relieved from this bone-rubbish, to think of charging them any thing for the valuable manure they had been the first to employ. As, however, the Yorkshire farmers soon began to scramble for these bone-turnings, the manufacturers of Sheffield speedily made a small charge for them, which has since gradually increased in amount. It required, however, some time to bring about this great and successful improvement. Mr. T. Ellin, late master cutler of Sheffield, well remembers, some fifty years since, the bone refuse carted into Sheffield Moor, and buried in pits as worthless rubbish; these old deposits, often found in digging foundations, are now carried off with much alacrity to the bone-crushing mills. The farmers at first gave sixpence a bushel for these parings and turnings; of these about 600 tons are annually sold in Sheffield. By the sole use of this fertilizer, great breadths of very poor land have been successfully brought into cultivation, and maintained in a state of the greatest fertility in the north and east of England and Scotland. Their effects upon the wolds of Lincolnshire has been magical. The first person, perhaps, who successfully used the roughly broken bones from the dog kennel as a manure was General St. Leger, in 1775. (*Evlyn's Sylva*, by Dr. Hunter.)

Manuring with *fish* was necessarily an improvement of an advanced state of agriculture; we have no mention of them as thus used in the early agricultural authors; the immense shoals of sticklebacks, and other small fresh-water fish, which once tenanted the fen counties of England, first gave the farmers of Lincolnshire an opportunity of using this rich oily manure; they were towards the latter end of the eighteenth century sold by the fen fishermen at about sixpence a bushel; and Arthur Young tells us, that at one village on the borders of Cambridgeshire, 2000*l.* have been taken for these fish in one season. It is not often that

a glut of herrings, pilchards, or other valuable fish, enables the farmer to obtain them at a rate sufficiently reasonable for his land, a purpose for which they have often, however, been employed with the most luxuriant effect on the coasts of Scotland and Cornwall. Sprats, and the fish called five-fingers, are used to a great extent by the Essex farmers; the demand for these has of late years been fully equal to the supply, although from the evidence given before a Committee of the House of Commons in 1833, it seems that during the season more than 400 boats are employed in catching these fish, for the purpose of selling them as manure.

Manuring with *calcareous sand* was practised very early in the middle ages by the English farmers. This they obtained not only from inland pits, but from the sea-shore, especially in Norfolk and Cornwall. The privilege of freely taking it from the sea-shore, the West of England farmers enjoyed under a grant from Richard Duke of Cornwall, confirmed by another of 45th of Henry III., A. D. 1261. This is expressed in the preamble of the act of the 6th James II. c. 18, A. D. 1609, which says, "Whereas, the sea-sand by *long trial and experience* hath been found to be very profitable for the bettering of land, and especially for the increase of corn and tillage within the counties of Cornwall and Devon, where the most part of the inhabitants have not commonly used any other *worth* for the bettering of their arable grounds and pastures." This act, which empowers the farmers to take this sand free from any toll, was, after being several times renewed, made perpetual by the 16th Charles I., c. 4. This wise encouragement of the use of manures by the legislature of England has not been confined to the sea-land of Padstow harbour: thus, uncrushed bones passing through a turnpike to be crushed for manure are exempt from toll; and carts loaded with common manure are equally free; or even when going empty to fetch it; but this exception does not extend to lime. And in authorizing the construction of railways, parliament has carefully provided, that the tolls levied upon the manures conveyed by them shall be much smaller than those demandable for any other description of goods: thus, in the Birmingham and Gloucester Railway Act, the authorized toll is, for manure of all kinds, only one penny per ton per mile; while coals, &c. are to pay three-halfpence, sugar twopence, cottons and other manufactured goods, threepence per mile. The same proportionate rate of tolls are authorized to be taken on several other railways, such as the Birmingham and Derby, the Midland Counties; and on the Eastern the difference in favour of the farmer is still greater; for while limestone, sand, and clay are to pay a penny, and all other manures three-halfpence, coals are to pay twopence, sugar, &c. fourpence, and manufactured goods sixpence per mile.

Saltpetre is, perhaps, the most ancient of all the saline manures, and its introduction is not, as is commonly believed, a modern improvement. It is commended by Virgil as a steep with olive oil, to make the seed-grain swell. To this knowledge of the fertilizing powers of

saltpetre the early cultivators of the earth were probably assisted from noticing that those soils which naturally produce saltpetre are ever found to be of the most fertile description, and that all those rich eastern fields which are so celebrated in Palestine for their fertility, abound in this salt. Three centuries since, according to Googe, it was employed by the German farmers. "Some saie coleworts prospereth best in salt gronde, and therefore they use to cast upon the gronde saltpetre or ashes." In 1676, Evelyn, in his *Discourse on Earth*, tells us, "rains and dews, cold and dry winters, with store of snow, which I reckon equal to the richest manures, impregnated as they are with celestial nitre;" which, although an error, yet displays his opinion of the fertilizing power of nitre. "I firmly believe," he adds, "that were saltpetre, I mean fictitious nitre, to be obtained in plenty, we should need but little other composts to meliorate our grounds." Evelyn recommends saltpetre to be used in solution, three pounds of this salt to fifteen gallons of water mixed with earth. And in this way Sir Kenelm Digby made some barley grow very luxuriantly by watering it with a very weak solution.

It would be, perhaps, difficult to name any other substance in the catalogue of modern fertilizers whose powers have been so often disputed as *common salt*. For this controversy many reasons may be assigned. It has been generally employed with little scientific accuracy, has been tried in a manner far too careless for any reliance to be placed upon the majority of the reports which have been furnished to us, and for many years a prohibitory duty rendered it inaccessible to the farmer; an impost which has not very long been removed, and which yet was the occasion of a great variety of blundering trials, miscalled experiments. The duty on salt was indeed one of long continuance. It originated, as a war-tax, in the ninth year of the reign of William the Third, and was not removed until after an arduous debate at the end of that of George the Third. The price of salt, thus raised to more than 20s. a bushel, was in consequence too expensive a fertilizer to be employed by the English farmers. During that long period it was known only in their traditions. Through these they were told that it was formerly used to kill worms and to destroy weeds, that it cleansed fallows, increased the produce of light arable soils, and sweetened grass. These reported advantages were rendered more probable by certain facts that had been forced as it were upon their attention. Every gardener was aware that the brine of the pickling tubs, when poured over his heaps of weeds, not only killed those weeds and their attendant seeds and grubs, but that these heaps were then converted into so many parcels of the most fertilizing manure, whose good effects, especially upon potatoes and carrots, were very decided. It was well known, too, that a single grain of salt, placed upon an earth-worm, speedily destroyed it; that if brine was poured upon a lawn, from that spot all the earth-worms were immediately ejected; and that if it was sprinkled over a portion of the grass, on this salted portion all

the deer, or sheep, or horses of the park constantly repaired, in preference to any other part of the field. Salt evidently therefore destroyed weeds and worms, and rendered grass more palatable to live-stock; and upon consulting the old agricultural writers, it was found that the notices of salt as a manure were many and important, and that salt had been employed in various agricultural operations from a very early period. Thus, it is referred to by St. Luke, chap. xiv. 34; Virgil reprobates a salt soil; Cato recommends it for cattle, hay, straw, &c.; as does Virgil (*Lib. iii. v. 394*). The early German farmers knew of its value for sheep; and for the same purpose, in Spain, it has been employed from the earliest ages. In 1750, Conrad Herebasch commends it as a certain prevention of the "murrain or rotte." In 1653, Sir Hugh Platt speaks of salt as a fertilizer, in his usual visionary manner, and details the result of a very successful experiment on a "*patch of ground*" at Clapham, from which some late writers upon the uses of salt have led their readers into great blunders, by stating this experiment to have been performed upon an *acre* of land.

The use of salt by the cultivator, since the repeal of the duties in 1823, has been considerable, however, in many districts of England, in spite of these blundering instructions, ill-contrived experiments, and ignorant conclusions. If to this be added the natural difficulty of obtaining correct results in any experiments in which vegetable life is concerned, we need no longer be surprised that many contradictory statements have been made with regard not only to salt, but to all other fertilizers.

A mixture of *salt* and *lime* was recommended as a manure by the celebrated German chemist, Glauber, in his "Hints for the Prosperity of Agriculture," more than two centuries since. He at some length described the mode of preparing it, and characterized the compound of soda and chloride of calcium produced as "most fit for dunging lands, and to be used instead of the common beasts' dung." (*Prosperity of Germany*, vol. i. p. 417.) Christopher Packe, who, in 1688, published a huge folio translation of Glauber's works, enforces the value of this fertilizing compound with much earnestness in his preface, describing it "as the cheapest of all mixtures for the enriching of poor and barren land." The want of scientific knowledge amongst farmers, and the hindrance to the use of salt through the duties which were so long imposed upon it, naturally prevented any extensive use of this fertilizer; yet there have been many accidental or occasional notices of its value. Thus, for a great many years, it has been the practice of the farmers of Essex, and other English maritime counties, to steep their seed-wheat in sea-water, strengthened with salt, until it is of a sufficient gravity to float an egg, and then roll the brined seed in lime. This they consider not only prevents smut in the corn, but promotes the general health and vigour of the plant. The Essex farmers have a tradition that this plan was discovered by the accident of a farmer's labourer dropping a sack of seed-wheat from the boat in which he was crossing the mouth of the River

Crouch. It was long, however, the superstitious belief of the district, that the salt-water wetting must be the result of *accident* to produce a good effect. The Cornish farmers have for centuries used the saline calcareous sand of the coasts of Devon, which contains 64 per cent. of lime, fetching it for some miles from the shore, in preference, says Dr. Paris, to the unsalted sand, which they can procure at their own doors. The very mixture of salt and lime was successfully employed in Ayrshire many years since. And George Sinclair, in 1818, very nearly demonstrated at Woburn the value of this application. He unfortunately, however, applied the salt and the lime separately, yet still with considerable benefit. (*C. W. Johnson's Essay on Salt*, p. 40.) The use of salt and lime was noticed in the year 1800, by Mr. Hollingshead, of Chorley, in Lancashire, who observes, "Lime prepared for manure should be slacked with salt springs or salt-water; lime so slacked will have a double effect." In 1804, in the experiments of the late Rev. Edmund Cartwright, upon potatoes, of 25 manures, or mixtures of manures, salt and lime were found superior, in their product of potatoes, to 19 others. And in 1816, Mr. James Manley, of Anderton, in Cheshire, when giving his evidence before a committee of the House of Commons, on the salt duties, mentioned that in getting marl (which is a mixture of carbonate of lime, alumina, and silica), he had found that, by mixing it with brine instead of water, the portion of the field on which the brined marl was used yielded 5 bushels of wheat per acre more than that portion on which the watered marl was employed.

The use of *ashes* as manure may be traced to a very early age. The Roman farmers were well acquainted with paring and burning. Cato recommends the burning of the twigs and branches of trees, and spreading them on the land. Paliadius says, that soils thus treated would not require any other manure for 5 years. They also burnt their stubbles—a practice common amongst the Jews in Palestine. The ancient Britons, according to Pliny, were used to burn their wheat-straw and stubble, and spread the ashes over the soil; and Conrad Herebasch, a German counsellor, in his *Treatise on Husbandry*, published in 1575, which was translated by Googe, tells us (p. 20), "In Lombardie they like so well the use of ashes, as they esteem it far above dung, thinking dung not meete to be used for the unwholesomness thereof."

Gypsum, or sulphate of lime, when employed as it exists in an impure state in ashes, which owe all their virtues to the gypsum they contain, was used by the early Italian farmers. Virgil (*Georg.* i. l. 80) gives the following injunction:

— "Neve

Effatus cinerum immundum jactare per agros."

"Nor hesitate to scatter the dirty ashes over the exhausted soils." And he also recommends, in addition to ashes, two other remedies for sterility of soil, viz. *stercoratio* (or manuring), and *glebarum cum stipulis incensio* (the turning up and burning the stubble). Robert Ainslie, steward of the celebrated John, Earl of Stair, at Culhorn, in Wigtownshire, had

very nearly discovered the agricultural advantages of gypsum in 1728; for in that year the earl sent from London several hogsheads of peat-ashes, which abound in sulphate of lime, with directions for their use, describing them to Ainslie as being much employed in the south of England as an admirable top-dressing for grass, and even tillage lands. These ashes were used, according to his lordship's directions, with great success, on both barley and grass lands. Ainslie, convinced of their fertilizing properties, immediately began to burn turf, moss, and peat, for the use of the farm under his care, in considerable quantities; he, moreover, submitted these ashes to what he very ludicrously calls an analysis, and gravely tells us, that "with a great proportion of earthy substances, they contained many particles of lime or shelly matter." This was most probably the gypsum.

The use of the mineral gypsum as a manure was discovered in 1768, according to Kirwan, by M. Meyer, a German clergyman of great talents; but as in those days the chemical composition of gypsum was totally unknown, he naturally confounded it with other calcareous earths which it resembled in appearance. His merit consisted in discovering the use of a certain mineral substance existing in his own neighbourhood, which was long afterwards shown to be sulphate of lime, but of which fact Meyer was entirely ignorant. Even as early as 1792 gypsum was tried very successfully by Mr. H. Smith, of Highstead, near Sittingbourne, who first noticed, what has since been confirmed by numerous observations, that clover manured with gypsum is always preferred by horses and cattle to all other clover.

Sir Joseph Banks recommended this substance as a fertilizer to Lord Leicester, and, at his suggestion, it was tried at Holkham many years since; but, owing to mismanagement in its application, it did not then appear to answer the intended purpose. Some years afterwards, owing to the warm recommendation of Mr. Grisenthwaite, it was again employed pretty extensively by the same nobleman, and with great success; and so satisfied was this great friend of agriculture with the result, that he presented Mr. Grisenthwaite with a piece of plate for his exertions in its introduction. In a letter with which I was favoured from the Rev. R. Collyer, dated Holkham, October 17th, 1837, that gentleman tells me, "Lord Leicester wishes me to say, in regard to gypsum, that its effects, when applied to clover and sainfoin, have been invariably such as to induce him to speak from his own experience in favourable terms of that fertilizer." It has since been gradually creeping into use in the east and south of England. Mills have been erected for grinding it, and considerable quantities have been brought from the northern counties; but still not one-thousandth part of the quantity is employed in agriculture that would be used if its correct mode of application were more generally known; since, from the small quantity used per acre, and the low price of the article, it constitutes one of the cheapest of the artificial manures.

From this sketch of the history of the chief manures, and of the steady improvement in the mode of applying them, we may safely conclude that, as regards the cultivation of even the most barren soils, the drifting lands of Norfolk, the heath-lands of the north of England and Scotland, and even the shingle of its sea-coast, much will yet be effected by improved modes of applying manures. Let such improvements proceed; let science go hand in hand with practice; let the naturalist discover new cultivatable vegetables, or new varieties of those already known; let the chemist yield his magic aid to demonstrate the best mode of promoting their growth, and increasing the fertility of the soil; and then I fearlessly assert that many more than the present inhabitants of Britain may be amply supported by the produce of the land of our birth. "Nature," said Davy, "amidst all her changes, is continually directing her resources towards the production and multiplication of life; and in the wise and grand economy of the whole system, even the agents that appear injurious to the hopes and destructive to the comforts of man are, in fact, ultimately connected with a more exalted state of his powers and his condition. His industry is awakened, his activity kept alive, even by the defects of climates and seasons. By the accidents which interfere with his efforts he is made to exert his talents to look farther into futurity, and to consider the vegetable kingdom, not as a secure and unalterable inheritance, spontaneously providing for his wants, but as a doubtful and insecure possession, to be preserved only by labour, and extended and perfected by ingenuity." (*Lectures*, p. 267.)

Manure, Law with regard to.—In most English farm-leases there are covenants introduced with regard to manure, which are often worse than useless; encumbering the efforts of the skilful cultivator, and rarely improving the practice of the ignorant, lazy, and unprincipled. Thus, by some leases the farmer is allowed, on certain conditions, to sell his straw and hay, and bring on to the farm in its stead a given weight of manure (commonly 2 tons of stable-dung for a load of straw, and 3 tons for a load of hay); in others he is restrained from selling either; in others, from liming or chalking his land. In most leases he covenants to spread the manure on the farm, and to leave it, in the concluding year of his term, properly laid up in heaps, if it is not already employed on the land.

The mere relation of landlord and tenant is a sufficient consideration for the tenant's promise to manage a farm in a husbandlike manner, and not to carry away any straw, dung, compost, &c.; but to promise to spend 60*l.* worth of manure every year, is not in law an obligation arising out of the bare relation of landlord and tenant. A tenant from year to year, under a notice to quit, cannot remove manure, except according to the custom of the country, and, if necessary, he may be restrained by an injunction. The custom of the country is usually followed with regard to the management and sale of manure; but in case there is a written agreement, no inquiry can be made as to the custom of the country; and when an

express stipulation is made, the custom of the country is excluded entirely. In this case Lord Lyndhurst said, "The outgoing tenant was bound by the custom of the country to leave the manure on the premises, and was entitled to be paid for it by the landlord, or the succeeding tenant; but in this case they did not rely on the custom. The lease contained a covenant that the tenant, on quitting the farm, should not sell or take away the manure which should be in the fold, but should leave it to be expended on the land by the landlord or his succeeding tenant. It is to be left for their use, and there is no provision as to any payment in respect of it. We are of opinion, therefore, that the plaintiff is not entitled to be paid for the manure." But where an agreement is silent as to the question of manures, then the custom of the country is valid in law. If the outgoing tenant has covenanted with his landlord to sell the manure to the incoming tenant at a valuation, and to leave it on the farm, the outgoing tenant has a right of on-stand on the farm; and if the incoming tenant remove the manure before such valuation, he is answerable to the outgoing tenant in an action of trespass. A tenant may sell or assign over manure to an assignee, although he thereby subjects himself to an action of covenant. And it is a reasonable custom for the landlord to pay the outgoing tenant the expense of manuring. If a tenant, during his tenancy, removes a dunghill, and at the same time digs into and removes virgin soil that is beneath it, his landlord may maintain either trespass *de bonis asportatis*, or trover, for the removal of the virgin soil. But if a tenant covenants to sufficiently muck and manure the land, with two sufficient sets of muck, within the last six years of his tenancy, the last mucking to be within the last three years, this covenant is satisfied by the tenant laying on two sets of muck within the last three years of his term, if he shall think fit to do so.

In valuing manure to an incoming tenant, much depends upon the custom of the country, which is usually followed in these cases. Land which has been rendered perfectly clean by a year's fallowing, is denominated a full tillage, and by tillages the valuation is commonly made.

In estimating the value of manure in arable land, it is done by allowing a full tillage after a fallow or crop of turnips fed off; after a white crop, half a tillage; but after two white crops no allowance is made.

For bones one tillage more is valued than for dung, on arable soils; two-thirds of the value of the bones, and labour of procuring and spreading them, being allowed after one white crop, and one-third of the value after two white crops. Soot, rape-cake, oil, sprats, &c., which are quickly exhausted in the soil, are allowed for as one full tillage before a crop grown, or after turnips, &c., eaten off; but if the turnips, &c. have been carried off, then only one-third of the cost of procuring, carrying, and spreading is allowed.

For earthy manures more is allowed in a valuation than for those of a perishable nature. Thus, on pasture land, lime, chalk, or

marl are commonly valued for six years after they have been spread on the land. This includes prime cost, carriage, and labour in spreading in full, when laid on not more than a year; two-thirds of the value if spread within two years; one-half in three years; one-fourth in four years; and one-sixth in five years: but when lime is used on arable lands, it is commonly valued in the same way as farm-yard manure.

When compost is in the heap, it is usually valued in cubic yards, the value of which necessarily varies; it may be estimated, however, commonly as of the same value as half a bushel of wheat. (*Woodfall, by Harrison, p. 529; Bayldon on Rents; Grainger and Kennedy on Tillage.*)

The custom of the incoming tenant paying for the dung varies in different counties. In the following counties he wholly pays for all dung on the farm: viz. Essex, Kent, Northumberland, Nottingham (artificial manure), Rutland, Stafford, Suffolk, Surrey, Sussex, Westmoreland, and the West Riding of York. In the other English counties the dung is usually left free of charge to the incoming tenant. This, in Scotland, is called holding in *steel-bow*. See CUSTOMS OF COUNTIES.

MANURES, ARTIFICIAL. A great many fertilizing compounds are now prepared in large manufacturing establishments specially devoted to the purpose, and these are extensively used upon the various field crops to which they have been found best adapted. The basis of many of these is night-soil, such as poudrette, &c. The virtues of others depend upon various salts of potash and soda. The following list of the leading articles of this kind now prepared and extensively used by the English farmers, with the prices at which they are vended, cannot but be interesting to the American agriculturist. It forms an ordinary advertisement in a London newspaper:

Agricultural Salt, per ton, 30s. to 32s.
 — — fine, per ton, 36s.
 Alexander's Compost, per bushel, 1s. 10d.
 Bleaching Powder, per cwt. 30s.
 Bone-dust and half-inch Bone, per quarter, 18s.
 Brimstone, per ton, 11l.
 Clarke's desiccated Compost, per hhd., 3l. 12s. 6d.
 Daniell's Bristol Manure, according to quantity, per bushel, 10d.
 Guano (foreign), per cwt., 10s. to 12s. 6d.
 — — Potter's English, according to quantity, per cwt., 13s. to 14s.
 Gypsum, according to quantity, per ton, 30s. to 42s.
 Hunt's New Fertilizer, per bushel, 1s. 8d.
 Muriate of Ammonia, per cwt., 24s. to 26s.
 — — Lime, per cwt., 12s.
 Nitrate of Soda, according to quantity, duty paid, per cwt., 17s. 6d. to 18s. 5d.
 Petre Salt, per ton, 3l. 10s. to 5l.
 Phosphate of Ammonia, per lb., 1s. 9d. to 2s. 3d.
 Phosphate of Soda.
 Poittevin's disinfected Manure, per quarter, 13s. 6d.
 — — concentrated Manure, per quarter, 30s.
 Rape-dust, according to quantity, per ton, 7l. 10s.
 Rock Salt, per ton, 4l., in quantity, 3l.
 Saltpetre, per cwt., 25s. 6d.
 Silicate of Potash (pure), per cwt., 65s.
 Soda Ash, per cwt., 14s.
 Sulphate of Ammonia, per cwt., 18s.
 — — of Iron, per ton,
 — — of Soda, per ton, 7l.
 Sulphur, per cwt., 16s.
 Sulphuric Acid, according to strength, per lb., 1½d. to 2½d.
 Trimmer's Composition for Clover, per cwt., 8s.
 — — — for Wheat, with Silicate of Potash, per cwt., 32s.

Trimmer's Compost for Turnips, per cwt., 8s.
 Urate, per ton, 5l.
 Watson's Compost, per cwt., 10s., in quantity, 9l. per ton.

MAPLE (*Acer*, from the Celtic *ac*, a point, the wood having formerly been much sought after for manufacturing into heads of pikes and lances). The maples are for the most part beautiful trees, of considerable size, generally employed in forming avenues or the back of shrubberies. The soil they delight most to grow in is open sandy loam, in which also cuttings will strike freely in the open air; or they may be increased by layers put down in the autumn: but all the best plants are obtained from seed, which should be sown soon after gathering. There are a great many species of maple; but two only, with some varieties, are common to Britain.

1. The greater maple or sycamore (*A. pseudo-platanus*), which grows in hedges and about houses, common, but not truly wild. It is a large, handsome tree, of quick growth, with a smooth ash-coloured bark, and round spreading branches. The wood is white and soft, useful for many purposes, such as making musical instruments, cheese and cider presses, tables, mangles, and some parts of machinery; but is chiefly employed by coopers. The sap is said to yield some portion of sugar, and to be made into wine in the Highlands of Scotland. The sycamore is propagated entirely by seed. The principal cultivated varieties are, the yellow variegated sycamore, or Costurphine plane (*Ac. p. flavo-variegata*, Loudon), the white variegated leaved sycamore (*A. p. variegata*, Loudon), and the purple-leaved variety.

2. The common or field maple (*A. campestre*). This is a common tree in hedges and thickets, but is rather rare in Scotland and the north of England. It is of much more humble growth than the preceding, with more spreading branches; the bark corky and full of fissures; that of the branches smooth. The wood is compact, of a fine grain, sometimes beautifully veined, celebrated among the ancient Romans for tables, though now superseded by mahogany, and even by our native oak.

The Norway maple (*A. platanoides*) has latterly been classed among British forest trees. It is a tree of the first rank, thrives well in England, and attains a height equal to that of the sycamore within a like period of years, it is a decided acquisition to park and woodland scenery, and its wood promises to be of more value, and adapted for a greater variety of purposes, than that of the sycamore, being white, close-grained, firm, susceptible of a fine polish, and frequently exhibiting the beautiful appearance in the direction and disposition of the fibre, for which the bird's-eye maple of America is so highly prized and sought after. The foliage, though not so heavy and massive as that of the sycamore, is umbrageous; the leaves, which in shape bear a striking resemblance to those of the *Platanus occidentalis*, are large, with slender petioles, and, when fully expanded, of a fine, shining light-green; in an early or half-expanded state, they are of a delicate yellowish-green, and in autumn, before they fall, become of a rich, warm yellow.

There are many species of maple found in the North American forests, which are generally lofty and beautiful trees. They are capable of enduring the most intense cold, and therefore form in the north of the new continent, as they do of the old, extensive forests, which, with those of the beech, appear to succeed the spruce, the larch, the pine, and to precede the chestnut and oak. Michaux gives 7 species of maple to Europe, and 7 to America, exclusive of the dwarf red maple of the Northeastern States, and the species found in the Northwestern territories.

The wood of the maples differs so widely in quality in different species, that it becomes difficult to characterize it by general observations. It may be remarked that it speedily decomposes and decays when exposed to the weather, that it is liable to be injured by worms, and that hence it is unfit for building. It possesses properties, however, which compensate in part for these defects, and which render it useful in the arts and domestic economy.

Two of the American maples not only flower but mature their seed during the spring months. These are:—the white maple (*Acer eriocarpum*) and the red-flowering maple (*A. rubrum*). In the other kinds, the fructification is autumnal, namely:—the sugar maple (*A. saccharinum*), black sugar maple (*A. nigrum*), moose wood, or striped maple (*A. striatum*), box elder, or ash-leaved maple (*A. negundo*), mountain maple (*A. montanum*).

Some of the inhabitants of the Western States make sugar by boiling down the sap of the white maple, which, however, like that of the red maple, yields only half the proportion of sugar obtained from the juice of the sugar maple. The sap is in motion even earlier in the white than in the sugar maple, beginning to ascend about the middle of January.

The red-flowering maple is the earliest tree whose bloom announces the return of spring, the beautiful purple blossoms unfolding more than a fortnight before the leaves. It never attains its full size except in swamps where the bottom is composed of fertile soil, and it affords the wood chiefly used in the manufacture of Windsor chairs.

The moose wood maple of the Eastern States was so called by the first settlers, from observing that the moose fed upon its twigs during the latter part of winter and beginning of spring. Although it fills the forests in Nova Scotia and Maine, it becomes rare on approaching the Hudson, to the west and south of which river it is confined to the mountainous tracts of the Alleghanies, on the cold and most shaded sides of which mountains it extends to their termination in Georgia. Where it mostly abounds, its principal advantage to the inhabitants consists in furnishing them, at the close of winter, when their forage is exhausted, a resource for sustaining their cattle, till the advancing season has renewed the herbage. As soon as the buds begin to swell, the famished horses and neat cattle are turned loose into the woods, to browse on the young shoots, which they consume with avidity. Poor as this resource may appear, it is not wholly inadequate, since the twigs are tender, and full of sweet

juice. This species of maple is much admired in European parks and gardens, particularly on account of its variegated trunk. When grafted on the Sycamore, as is commonly the case, the striped maple grows to nearly four times its ordinary size.

The box elder, or ash-leaved maple, is common in the states west of the Alleghanies, and rare to the eastward of these mountains. It is the species which ventures least to the north, not being seen on the Delaware higher than the neighbourhood of Philadelphia. It is chiefly found in low bottoms where the soil is deep, fertile, and constantly wet. Even in such situations it seldom attains more than 50 feet in height, and 20 inches in diameter.

The mountain maple abounds in Canada, Nova Scotia, and along the whole range of the Alleghany mountains, preferring the northern sides, and the moist, coolest, and most shady situations, on the abrupt and rocky banks of torrents and rivers. It seldom is more than 6 or 8 feet high, and is most frequently in the form of a shrub, with a single, straight stock. Like the moose wood, this maple is frequently grafted on the sycamore (*A. pseudo-platanus*), by which means it is increased to nearly twice its natural size. This surprising development proves how great are the advantages which may be derived from this process and from continued cultivation, in improving inferior vegetables.

But by far the most interesting tree of this family to the American is the sugar maple, which in the north begins to appear a little north of lake St. John, in Canada, near the 48° of latitude, which in the intensity of its winter cold corresponds to the 68° in Europe. It is nowhere more abundant than between the 46° and 43°, which comprise Canada, New Brunswick, Nova Scotia, the states of Maine, New Hampshire, and Vermont, where it enters largely into the composition of the wide-extending forests. Farther south, it is common only in Genesee, in the state of New York, and in the northern highlands of Pennsylvania. Dr. Rush estimated that in the northern parts of these two states, there are 10,000,000 of acres which produce these trees in the proportion of 30 to an acre. In some places large masses of woods are formed of them almost exclusively. In Virginia and other Southern States, the tree is comparatively rare, and only to be found in mountainous situations. In those sections of country where the sugar maple most abounds, they distinguish the kinds of soil into what are called *black*, or *soft wood lands*, comprising the pines and spruces covering the low grounds and valleys, and the *hard wood lands*, consisting of leaf-shedding trees, such as the sugar maple, the white and red beech, the birch, and the ash. These last occupy the level grounds. Above the 46° of latitude, the maple and other trees of the hard wood class begin to be rare, and the pines and other resinous trees take their place. Below 43°, the spruce and other soft wood trees are less common, and lose their preponderance in the forests, where they become mingled with the numerous species of oaks and walnut.

Black sugar maple. In the Western States

and in the parts of Pennsylvania which lie between the mountains and the Ohio, this species of maple is called the *black sugar tree*, probably on account of the colour of its leaves being darker than those of the genuine sugar maple. In the Genesee country of New York, both species are indiscriminately called rock maple and sugar maple. The two species have also been confounded by botanists. In the Northern States, the black sugar maple is inferior in size and also more rare than the true sugar maple. A few degrees farther south, it forms a large part of the forests of Genesee, where it is one of the most common and most lofty trees. The wood is much like that of the other species, but coarser grained and less brilliant when polished. It is comparatively but little used, because, wherever it abounds, other trees are found, such as oak, the walnut, cherry, and mulberry, more esteemed for building and cabinet work. It is, however, preferred for the frames of Windsor chairs, and, after hickory, considered the best of fuel. It forms one of the finest shade trees, assuming, when standing alone, a regular and beautiful form. (*Michaux.*)

The sugar maple covers a greater extent of the American soil than any other species of this genus, flourishing most in mountainous places, where the soil, though fertile, is cold and humid. Under such favourable circumstances it is often found 70 or 80 feet high, and proportionably large in diameter. It is one of the most beautiful native trees, and distinguishable by the external whiteness of its bark. The grain of the wood is fine and close, and when polished it has a silky lustre. It is very heavy and strong, but wants the property of durability for which the chestnut and the oak are so highly esteemed. Exposed to moisture it soon decays. The different forms of this wood furnish the most admired undulated or curled maple, and the highly esteemed and still more beautiful spotted variety called bird's eye maple.

The wood of the sugar maple makes good fuel, for which purpose it is extensively used in Boston and other northern cities. The ashes afford a large proportion of the alkaline principles, and, it is asserted, furnish four-fifths of the potash exported in such abundance from Boston and New York to Europe. The extraction of sugar from the maple is a valuable resource in a country where all classes of society daily make use of tea and coffee. The process by which it is obtained is very simple, and everywhere nearly the same. Though not essentially defective, it might be rendered still more perfect and profitable than is commonly the case.

The work of sugar-making commonly begins in the month of February, or early in March, whilst the cold still continues intense and snow covers the ground. Thus the sap begins to move nearly two months before the general revival of vegetation.

In a central situation, lying convenient to the trees from which the sap is drawn, a shed is constructed, called a sugar-camp, which is destined to shelter the boilers and the persons who tend them, from the weather. An auger three-

fourths of an inch in diameter, small troughs to receive the sap, tubes of elder or sumac, 8 or 10 inches long, corresponding in size to the auger, and laid open for a part of their length, buckets for emptying the troughs and conveying the sap to the camp, boilers of 15 or 18 gallons' capacity, moulds to receive the syrup when reduced to a proper consistency for being formed into cakes, and, lastly, axes to cut and split the fuel, are the principal utensils employed in the operation. The trees are perforated in an obliquely ascending direction, 18 or 20 inches from the ground, with two holes 4 or 5 inches apart. Care should be taken that the augers do not enter more than half an inch within the wood, as experience has shown the most abundant flow of sap to take place at this depth. It is also recommended to insert the tubes on the south side of the tree; but this useful hint is not always attended to.

A trough is placed on the ground at the foot of each tree, and the sap is every day collected and temporarily poured into casks, from which it is drawn out to fill the boilers. The evaporation is kept up by a brisk fire, and the scum is carefully taken off during this part of the process. Fresh sap is added from time to time, and the heat is maintained till the liquid is reduced to a syrup, after which it is left to cool, and then strained through a blanket or other woollen stuff, to separate the remaining impurities.

Some persons recommend leaving the syrup twelve hours before boiling it for the last time; others proceed with it immediately. In either case the boilers are only half-filled, and by an active, steady heat, the liquor is rapidly reduced to the proper consistency for being poured into the moulds. The evaporation is known to have proceeded far enough, when, upon rubbing a drop of the syrup between the fingers, it is perceived to be granular. If it is in danger of boiling over, a bit of lard or of butter is thrown into it, which instantly calms the ebullition. The molasses being drained off from the moulds, the sugar is no longer deliquescent, like the raw sugar of the West Indies.

Maple sugar manufactured in this way, is lighter coloured, in proportion to the care with which it is made and the judgment with which the evaporation is conducted. It is superior to the brown sugar of the colonies, at least, to such as is generally used in the United States; its taste is as pleasant, and it is as good for culinary purposes. When refined, it equals in beauty the finest sugar consumed in Europe. It is made use of, however, only in the districts where it is made, and there, only in the country: from prejudice or taste, imported sugar is used in all the small towns, and in the inns.

The sap continues to flow for six weeks; after which, it becomes less abundant, less rich in saccharine matter, and sometimes even incapable of crystallization. In this case, it is consumed in the state of molasses, which is superior to that of the islands. After three or four days' exposure to the sun, maple sap is converted into vinegar, by the acetous fermentation. The amount of sugar manufactured in a year varies from different causes. A cold

and dry winter renders the trees more productive than a changeable and humid season. It is observed, that when a frosty night is followed by a dry and brilliant day, the sap flows abundantly; and 2 or 3 gallons are sometimes yielded by a single tree, in 24 hours. Three persons are found sufficient to tend 250 trees, which give 1000 pounds of sugar, or 4 pounds from each tree. But this product is not uniform, for many farmers on the Ohio do not commonly obtain more than 2 pounds from a tree. Trees which grow in low and moist places afford a greater quantity of sap than those which occupy rising grounds, but it is less rich in the saccharine principle. That of insulated trees, left standing in the middle of fields or by the side of fences, is the best. It is also remarked, that in districts which have been cleared of other trees, and even of the less vigorous sugar maples, the product of the remainder is, proportionally, most considerable. "Having introduced," says a writer, "twenty tubes into a sugar maple, I drew from it the same day, 23 gallons and 3 quarts of sap, which gave 7½ pounds of sugar; 33 pounds have been made this season from the same tree; which supposes 100 gallons of sap. It appears here, that only a little more than 3 gallons was required for a pound, though 4 are commonly allowed.

It has been advanced, and doubtless correctly, that the Northern parts of New York and Pennsylvania contain maples enough to supply the whole consumption of the United States. But the annual produce by no means answers to this patriotic calculation. The trees grow upon excellent lands, which by the influx of emigrants from the older settlements, and by the surprising increase of the population already established, are rapidly clearing; so that in less perhaps than half a century, the maples will be confined to exposures too steep for cultivation, and will afford no resource, except to the proprietor on whose domain they grow. At this period also, the wood will probably produce a greater and more ready profit than the sugar. Wild and domestic animals are inordinately fond of maple juice, and break through their enclosures to sate themselves with it.

MARC. The matter which remains after the pressure of fruit; or any substance which yields oil; or, in fact, any fluid matter for the separation of which the action of the press is required. What remains in the press is the *marc*.

MARCESCENT. In botany, a term applied to leaves, &c., which are permanent, and when withered do not fall off.

MARCHES. The name given to the borders or frontiers of any district, but more especially applied to the boundaries between England and Wales, and England and Scotland.

MARE. The female of the horse. See **HORSE**.

MARE'S-TAIL (*Hippuris vulgaris*). A curious indigenous aquatic, growing in marshy situations, and in ditches, pools, and the borders of slow streams.

MARGARIC ACID. An acid obtained from animal fat. Its derives its name from its resemblance to pearl. Its appearance and pro-

perties very much resemble those of stearic acid, another product of animal fat, the chief difference being in the greater fusibility of the margaric, which melts at 140° Fab. See **ACIDS, ANIMAL**.

MARIGOLD (*Calendula*, named from *calendæ*, the first day of the month; there being flowers almost any month in the year). A genus of showy plants, among which is the old and well-known common marigold (*C. officinalis*). This species was formerly used in soups and broths, but is now little regarded.

There are several varieties of the common marigold, among which are—

1. Single. 2. Common double. 3. Largest very double. 4. Double lemon-coloured. 5. Great Childing. 6. Small Childing.

MARIGOLD, CORN. See **CORN MARIGOLD**.

MARIGOLD, AFRICAN. See **AFRICAN MARIGOLD**.

MARIGOLD, THE MARSH. See **MARSH MARIGOLD**.

MARINE ACID. See **MURIATIC ACID**.

MARINE SALT. Common sea-salt, or muriate of soda.

MARJORAM (*Origanum*, from *oros*, a mountain, and *ganos*, joy; the delight of the mountain, in allusion to the habitation of the plants). A genus of well-known, pungent, and gratefully aromatic herbs. The plants are all of easy cultivation; the shrubby kinds are increased by cuttings or slips; the herbaceous species by dividing at the roots. There are as many as 8 species, besides numerous varieties. The species generally cultivated are the common or pot marjoram (*O. vulgare*), and sweet or summer marjoram (*O. majorana*), and bastard or winter marjoram (*O. heracleoticum*.)

A light, dry, and moderately fertile soil is required for their healthy growth; and if it is one that has not been cropped for a considerable time, it is the more favourable for them. If the soil is wet or rich, they are deficient in their essential qualities, and the perennials are unable to withstand severe weather. The situation cannot be too open. The sweet marjoram is propagated solely by seeds; the 2 perennials by seed, as well as by parting their roots, offsets, and slips of their branches. Sowing may be performed of all the species, from the conclusion of February, if open weather, to the commencement of June; but the early part of April is the usual time for performing it. Portions of the rooted plants, slips, &c., may be planted from February until May, and during September and October.

The sowing is performed either in drills, 6 inches apart, or broadcast; in either case the seed being buried not more than half an inch deep.

The tops and leaves of all the species are gathered when green, in summer and autumn, for use in soups, &c.; and a store of the branches are cut and dried in July or August, just before the flowers open, for winter's supply.

MARK. A term applied to a horse, which is said to *mark* when he shows his age by a black spot, like the eye of a common bean, which appears at about 5½ years old in the cavities of the corner teeth, and is gone when

he is 8 years old. When he ceases to mark, it is said he *has rased*. See AGE OF ANIMALS.

The term is also applied to a common mode of marking hogs, &c., in those parts of the United States where they are allowed to run at large, and where the owner fixes a mark upon his property by cropping more or less of the ears, slitting these into swallow-forks and every other shape of mutilation.

MARKET. In English law the liberty or franchise, whereby a town is enabled to set up and open shops, &c., at a certain place within its limits for buying and selling, and better provision of such victuals as the subject wanteth. The establishment of a market, with the grant of the tolls thereunto belonging, is one of the king's prerogatives, and can only be effected by virtue of the king's grant, or supported on long and immemorial usage and prescription, which presuppose such grant. The general rule of law is, that all sales and contracts of any thing vendible in fairs or markets overt (i. e. open), shall not only be good between the parties, but valid against all claim by others having any right or property in the subject. See FAIRS.

MARL. Marl implies, properly speaking, a natural mixture of chalk, shells, or carbonate of lime, in some of its forms, with clay or sand, or both. Its application to land, as a fertilizer, is of very ancient date, as it was much used by our English forefathers as a manure; and no one can read the account given by Pliny of the agricultural operations of the early Britons, without being struck with the minute discrimination, the evident result of long, attentive practice, which was displayed by them in the application of marl to particular soils; and from a very early period the Cornish farmers have been used to employ extensively the sea sand of Padstow harbour (which contains 64 per cent. of carbonate of lime), for the same purpose, carrying it from the sea-shore either in carts, or even on horses' backs, some miles up the country.

Marl was certainly used by the early Italian cultivators as a valuable addition to the soil of their fields. It is thus spoken of by Columella:—"If, nevertheless, you are provided with no kind of dung, it will be of great advantage to it to do what I remember Marcus Columella, my uncle, a most learned and diligent husbandman, was frequently wont to do, viz., to throw chalk or marl upon such places as abound in gravel, and to lay gravel upon such as are chalky, and too dense and stiff; and thus he not only raised great plenty of excellent corn, but made most beautiful vineyards; for this most skilful husbandman denied that dung ought to be applied to vines, because it would spoil the taste of the wine; and thought that stuff gathered together out of thickets, and from among briars and thorns, or, in a word, any other sort of earth fetched from any other place, and carried to them, was much better for making a plentiful vintage."

The mixture of soils, we find from Theophrastus, was a practice common in his days: they found, it seems, the advantage of uniting the light with the heavy, the fat with the lean,

and, in fact, any that were of a contrary nature. This mixture, he tells us, not only supplies what shallow soils need in depth, but adds to the power of both; so that a worn-out soil, thus treated, begins again to bear crops with renewed energy: thus barren clays, when thus fertilized, again become fruitful; in truth, this mode of cultivation he deemed a complete substitute for manure. The inhabitants of Megara, besides practising this system, were used every 5th or 6th year to trench their land, digging as deep as they imagined the rain to penetrate, and bringing the under soil to the top; for it was an axiom with the Megarian cultivators, that the lighter portions of earth proper for the nourishment of plants are always washed downwards as far as the influence of the surface water extends; so that we see from this that the advantages of deep ploughing, or subsoiling, is not a very modern discovery. (*Col. lib. xi. c. 16; Theop. l. ii. c. 25.*)

The right of sinking marl-pits is mentioned in the *Chartæ Forestæ*, A. D. 1285; and in the *Statum Walliæ*, 12 Edward I., marl-pits are mentioned as being dug close to common roads. "It is one of the duties of the sheriff and coroner," says Daines Barrington, "to inquire *de fossatis et marleris levatis juxta iter publicum*," which shows that this kind of manure was very commonly used. When a marl-pit was sunk in ground that did not belong to the king, but which happened to be in the purlieu or neighbourhood of a forest, prosecutions were instituted in the forest, which imposed heavy fines for the offence, as the pit occasioned both inconvenience and danger to the hunter.

Marl is found in many parts of England; and any earthy substance in which the proportion of calcareous matter is apparent, mixed with sand or clay, is styled, in popular language, a marl. Of this there are 3 principal varieties: 1. Clay marl; 2. Sand marl; 3. Slate or stony marl; 4. Shell marl. Of these the last is commonly the richest in calcareous matter. In some shell marl examined by Sir George Mackenzie, he found—

Lime	-	-	-	-	-	41.45
Carbonic acid	-	-	-	-	-	32
Silex	-	-	-	-	-	14
Argil	-	-	-	-	-	14
Oxide of iron	-	-	-	-	-	2.5
Inflammable matter	-	-	-	-	-	2
Loss	-	-	-	-	-	4.70
						<hr/> 100

Clay marl usually contains from 68 to 80 per cent. of clay, and from 32 to 20 per cent. of calcareous matter. Silicious sand often contains 75 per cent. of sand (*Kirwin on Manures*, p. 13). Thus, M. Thaer found in that of Oldenburgh—

Fine sand	-	-	-	-	-	36
Clay	-	-	-	-	-	44
Mould	-	-	-	-	-	5
Carbonate of lime	-	-	-	-	-	14
Gypsum	-	-	-	-	-	1
						<hr/> 100

The quantity of marl applied per acre necessarily varies with the kind of soil and the quality of the marl; it is usual to employ it

very considerable quantities, and it is often some years before it is sufficiently incorporated with the soil to produce an evident improvement; but then that advantage is almost always, sooner or later, not only decided, but permanent.

The clay marls render light sandy soils more tenacious; the sandy marls materially improve the friability of the heavy clays. In Cheshire, they often apply 128 cubic yards of clay marl per acre to light sandy soils, and about half that quantity to their heavy lands. In many parts of Scotland it is spread on grass lands, and suffered to remain for two or three winters exposed to the frost, before it is ploughed in, in about the same proportions per acre.

"The beginning of all improvements in Germany," says Mr. S. S. Carr, in his Prize Essay, "is, to give a dressing of marl (containing, on an average, 60 per cent. of carbonate of lime), at the rate of 164 cubic feet per acre: by this means land, not worth cultivation previously, yields excellent crops for 8 or 10 years; and if the straw produced during that time is carefully converted into manure, the productiveness does not materially decrease. Should that, however, be the case, the deposits of ponds, and even plots of peat-moss, which not unfrequently occur, are carried upon the fallows in winter, where these substances, when broken down by the frost, prove a valuable alternative to the texture of the soil, especially where the pulse, rape, and clover crops are gypsomed."

On the heathy sands of Norfolk much improvement might be effected by the application of marl. Mr. Kiddle, of Marsham, in that county, made many experiments with marl; he preferred, from long experience, the variety denominated "clayey marl," which he thought the best for sandy lands, even if brought from a considerable distance. "A few years since," said General Vavasour, "I purchased, with other lands, a field of 10 acres; it had been part of a common enclosed about 15 years before, and was tithe-free, the soil sandy, mixed with moory earth. I ploughed and sowed it in divisions with various crops, most of which failed. Having discovered a stratum of rich clay marl, within 400 yards of the field, I carted on 75 cubic yards per acre, at 10*d.* per yard, or 3*l.* per acre." The result was, that the value of the land increased from 6*s.* to 1*l.* 1*s.* per acre.

In Europe, the term marl is applied to various mixtures of calcareous matter with clay, sand, &c., and the common test is to effervesce on the addition of vinegar, or other acid. But, in the United States, those at least on the Atlantic coast, where this fertilizer is met with in great abundance, two kinds of marl are extensively used, one of which has been already described under the head of GREEN SAND. This is often so free from lime, as scarcely to retain a trace, and, consequently, the addition to it of vinegar, or other acid, would not produce that effervescence necessary to constitute it a marl in accordance with the common test. What, in the states of New Jersey, Delaware, Maryland, and Virginia, is usually called green

sand marl, instead of containing lime, abounds in potash. See GREEN SAND.

The calcareous marl found in the states named, generally contains more or less of the green sand; and this combination of lime and potash forms a natural fertilizing mixture, the value of which is scarcely yet appreciated as it deserves to be. Its great weight makes it an expensive application to land, wherever much hauling is required, and consequently it yields to burned lime under such circumstances. The admirable treatise upon the subject of "Calcareous Manures," by E. Ruffin, of Virginia, has been extensively circulated throughout the United States, and may be referred to as containing the most useful body of information upon the subject of marl ever brought together, embracing every detail in relation to lifting, transporting, application, and effects, that can be desired by the farmer or general reader. See MIXTURE OF SOILS, LIME, CHALK, EARTHS, &c.

MARRAM. One of the common names of the sea mat-weed or sea-reed (*Arundo arenaria*). See REED.

MARSH (Sax. *meþrc*, a fen). A flat surface, the soil of which is so far saturated with water throughout the year as to be unfit for culture by the spade or plough; but not so much as to prevent it from producing coarse grasses, and other kinds of herbage. Marshes are generally situated in bottoms, where they are kept moist by the water which descends from the surrounding lands; or along the banks of rivers or lakes, where their humidity arises from their being nearly on the same level with the adjoining water. Where a marsh is situated so as to be occasionally overflowed by the sea, or by a river, up which the tide flows, it is called a salt marsh; and the herbage produced by such lands is found highly conducive to the health of animals which pasture on them for a certain portion of the year, from the alterative effect of its saline properties.

Salt marshes abound along the shores of the bays and inlets of the Atlantic coast of the United States. The natural grasses which grow so luxuriantly are extensively mown, and furnish an inferior, and generally a coarse description of hay, which, however, is much relished by cattle in consequence of its saltness. It furnishes excellent litter, and thus contributes greatly to swell the manure-heap. On the Delaware bay it sells for about \$2 to \$4 per ton.

Salt marshes are often reclaimed by embankments, which keep off the tide-water. The best mode of managing land thus reclaimed, is well worth knowing; and the following directions from Mr. T. F. Lambson, of Salem, New Jersey, contain valuable information, the result of much experience and expense:—"1st. The marsh should be secured from the tide by a permanent bank. 2d. A sluice or sluices of sufficient capacity must be laid to discharge the rain-water and back-waters which proceed from adjacent uplands, so that at no time the water-courses and ditches will be filled to overflowing. The sluices should be laid deep enough to draw the water through them from the lowest part of the marsh: great care should be taken to have the doors made tight, so as to

exclude all the tide-water possible. The water-courses and drains should intersect each other at right angles, and no lot of marsh should contain more than 10 acres. If any rain-water should lay upon the middle of these lots, it will be necessary to cut small drains, to let it pass off freely; these might be covered where the materials are at hand. The mud and earth which come out of water-courses and ditches should be removed into the lowest part of the marsh; by a neglect of this, the rain-water will be confined too long upon the surface, and the most luxuriant growth of timothy or clover may in a short time be converted into a nursery of rushes.

“The best time to sow down in grass, is when the tide is first shut off, and when the mud is soft; a growth of coarse grass will spring up sufficient to protect the fine grass in its tender state; this crop should be mown off, and not suffered to lodge upon the marsh. Timothy and herds-grass require about 1 bushel to sow 4 acres. The former will flourish where the water can be kept $2\frac{1}{2}$ or 3 feet from the surface; where it approaches nearer than this in the ditches, the latter will succeed best: in order to avoid having it sown in rows, it should be sown a second time across the first sowing. It is not advisable to mow longer than 3 years in succession; to mow and pasture alternately is the better plan. If the high marsh becomes bound and unproductive, ploughing will be necessary; and after raising 2 or 3 crops of rye, Indian corn, or broom corn, without the application of any manure, the soil will be quite renovated, and when sown down in grass will be much more productive. When the earthy deposit is several feet in depth, it will not soon become exhausted; when it is not desirable to plough, lime may be used with success. Low marsh, or turf, or, as we term it here, “horse-dung” mud, should not be ploughed; when it becomes unproductive, a covering of clay or loam, to the depth of 2 or 3 inches, will be found the cheapest application.” See BOG, WASTE LAND, PEAT SOILS, GRASS LANDS, IRRIGATION, and MEADOW.

MARSH-LANDERS. A term provincially applied in England to neat cattle of the short-horned breed, or such as are bred on lands of the marsh kind.

MARSH-MALLOW (*Althæa*, derived from *altheo*, to cure; from the medicinal qualities of some of the species). This is a genus of tall, free-flowering plants: the biennial and annual kinds should be sown in the open border in spring, and transplanted when sufficiently strong. The herbaceous kinds may be increased by dividing the roots or by seeds. *A. rosea*, the parent of the many beautiful varieties of holly-hock, yields a blue colouring matter equal to indigo. (*Paxton's Bot. Dic.*)

The common marsh-mallow (*A. officinalis*) is in England an indigenous perennial, growing abundantly in marshes, especially towards the sea. The root is perennial, tap-shaped, rather woody. The herbage of a hoary green, peculiarly soft and downy, with a fine starry pubescence. Stems several, about a yard high, simple, round, leafy, tough, and pliant. Leaves

ovate or heart-shaped at the base, various in breadth, soft and pliable, slightly five-lobed. Flowers (which blow from July to September) in very short, dense, axillary panicles, rarely solitary, of a delicate uniform blush-colour, not inelegant. Bees are very fond of its melliferous flowers. The whole plant, especially the root, yields in decoction a plentiful, tasteless, colourless mucilage, besides a fatty oil, uncrystallizable sugar, starch, and phosphate of lime. It is emollient, and salutary in cases of internal irritation. A syrup made with the root, as well as the decoction, is an officinal preparation of the Pharmacopœias. It is used in the coughs of children. See MALLOW.

MARSH-MARIGOLD (*Caltha*, a synonyme of *kalathos*, a goblet; in allusion to the likeness of the form of the corolla to a golden cup). The species of this genus are showy, and do best in a moist situation, but will grow and flower in a common border. They may be increased by seeds or divisions. The British indigenous species are two in number, viz:—

1. The common marsh-marigold (*C. palustris*), which grows in marshy meadows, and about the margins of ponds, rivers, and brooks, almost everywhere. It is perennial in habit, blowing in March and April. The root is thick and somewhat tuberous, with many simple fibres. Stem 12 or 18 inches high, round, hollow, leafy, branched, furrowed. Leaves variously heart-shaped, rounded. Flowers from 3 to 5, large, bright yellow, on alternate solitary stalks. The flower-buds pickled serve for capers, which they resemble, except in having numerous germens. A double variety is frequent in gardens.

2. Creeping marsh-marigold (*C. radicans*). This species is found by the sides of lakes and rivulets in Scotland, and is scarcely half the size of the common *C. palustris*. A double variety of this is cultivated near London.

MARSH-MUD. This substance, which forms such an excellent manure, is not so well appreciated or so generally employed in the United States as it deserves to be. An intelligent correspondent of the *Farmers' Register* (for July, 1834) states, that he deems it more valuable than barn-yard manure, and that it never failed in any application he had made of it. He even prefers it to marl, because its effects are more quickly manifested, and, when readily accessible, much more improvement can be effected for the same money than by applying marl. He, however, confesses that the permanent advantages of marling are much greater, and thinks that marl and marsh-mud will both be improved by combination. This result may certainly be expected in most cases, but must depend much upon the prevailing constituents of the mud. The alluvial deposits found in marshes, must of course contain more or less of the ingredients of the soils of the neighbouring uplands. When these contain lime, magnesia, silex, iron, &c., so will the marsh-mud. This is clearly shown in the following tabular statements, giving the results of Dr. Dana's chemical examinations of a few specimens of marsh-mud taken from the rocky coast of New England.

Analysis in the dry way by Alkali.

Number.	Locality.	Water of absorption.	Organic matter.	Silica.	Alumina.	Oxide of iron.	Lime.	Magnesia.	Salts soluble in water.	Sulphuretted hydrogen and loss.
135	Newburyport -	3.2	3.3	68.1	14.7	7.4	2.0	0.8	0.2	0.3

Analysis by Dr. Dana's Method.

Number.	Locality.	Soluble Geine.	Insoluble Geine.	Sulphate of lime.	Phosphate of lime.	Granitic sand.	Specific gravity
134	Cambridge - - - -	13.0	7.4	2.3	0.4	67.9	1.92
135	Newburyport - - -	1.5	0.1	3.0	0.5	95.1	2.52
136	Medford - - - - -	7.5	5.6	2.6	0.3	84.0	1.92

"A substance," says Professor Hitchcock, "so rich in geine or salts of lime and soda, or in both, as the above analyses show, cannot but prove a fertilizer of the soil if spread upon it. If a soil be quite poor, those varieties should probably be chosen that contain the most geine; and this can be judged of by their comparative lightness when dry; the lightest abounding most in organic matter. But if the soil already contain a good deal of inactive vegetable matter, the varieties that abound most in salts will probably be most efficacious; though an additional quantity of geine can do no harm, and may do much good. If marsh-mud be applied at random, it is not strange that varieties of it, almost destitute of geine, should be sometimes put upon exhausted soil, and that no good effects should follow. Hence the necessity of some fixed principles to guide the farmer. And since Massachusetts contains so much sea-board, and so much land near the coast that may be benefited by this substance, a correct mode of applying it is of great importance. (*Geological Report.*)

The abundant deposit called marsh-mud found along the extensive marshes which border many of the shores of the bays and rivers of the Middle States, is variously constituted, being sometimes a black, unctuous substance, made up of vegetable and mineral matter, in which sometimes no trace of vegetable fibre can be traced, whilst at others it contains not only a perceptible portion, but consists mainly of the fibres of grass-roots and leaves, in a state of greater or less decay. Professor Booth, who has treated of the subject in his *Geological Survey of Delaware*, says, that the first of these is the most valuable, and may sometimes be directly applied to land without admixture; but it is advisable to adopt a uniform method of using it, which may be done in two ways, by mingling it with lime, better after exposure to the air for some time, or by drawing it into the barn-yard to bring it into an incipient fermentation by contact with stable-manure. In either case it will more than repay its expense; and if lime be employed on the land at the same time, a more powerful and durable influence will be derived from it.

Blue mud. The fertility of those lands of which blue mud forms the upper surface, and its beneficial effects in the few instances in which it has been employed on the upland, are a warrant of its fertilizing powers, but it is a matter of some doubt to what substances its effects are mainly to be attributed. Its basis is a fat clay both lead-coloured and yellowish,

with a quantity of organic matter, which appears to be chiefly in the state of crenic and apocrenic acids, combined with the oxide of iron. There is no doubt that it would be advantageous if applied directly to the soil, but its tenacity is an objection to such a mode of using it, and hence it is more advisable either to draw it into the barn-yard, where it will be broken down and mingled with manure, or to mix it with lime, and expose it for some time to the air, adding, at the same time, the black marsh-soil, which is generally to be obtained in its vicinity.

The blue mud is wholly unlike a peaty soil, but being deposited on the river-marshes, it soon becomes a marshy soil, and many of the creek and western marsh deposits are far from being peaty, although they contain much organic matter. Its value, as a manure, rests not on a mere theoretic assertion, but it has received the test and sanction of experience, and such experience, both in Delaware and elsewhere, as may not be contradicted. As it would be a matter of nicety to discriminate between such varieties as are not sufficiently decomposed, and require some preparation prior to their application, and those which might be directly employed, it would be better to adopt a general rule relative to the mode of using it, viz., either to draw it into the barn-yard, or to form a compost with lime, or with ashes. In either case it will form an excellent manure, and with lime or ashes a durable one.

MARSH-THISTLE, or **RED THISTLE** (*Carduus palustris*). See **THISTLE**.

MARSH-TREFOIL. See **BUCK-BEAN**.

MARUM. Bitter. In botany, the term is used to signify an herb with a strong smell.

MASH. A soft sort of diet occasionally given to horses. It is prepared by pouring boiling water upon a small quantity of ground malt, bran, or other similar substance, in a pail, so as just to wet it well. After this has been done, it should be well stirred about, till it is thoroughly mixed and sweetish to the taste, when, after becoming lukewarm, it is in a proper state to be given to the animal. It is frequently used after purges to increase their operation, as well as after hard labour, and in the time of disease. Mashies are very useful for restoring animals in these circumstances.

MAST. The nuts or seeds of the beech, oak, and chestnut-trees, which are the food of hogs, squirrels, &c.

MASTICATION. The process of grinding or chewing the solid parts of food between the teeth, by the united motion of the jaws, tongue,

and lips, in consequence of which it is broken into small pieces, mixed with the saliva, and thus adapted for deglutition as well as more easy digestion; although it is, perhaps, not more essential for the latter purpose than water. Leuchs and Schwan, two German physiologists, have, however, proved that saliva has the property of changing starch into sugar; and it is a well-known fact that the process of digestion in the stomach converts starch into gum, and gradually into sugar. Mastication, in the animal economy, is so essential to the prosperity of the individual, that old horses, &c., whose teeth are impaired, always require to have their food broken, chopped, or crushed for them. See RUMINATION.

MAT-GRASS, or HEATH MAT-WEED (*Nardus stricta*). An insignificant species of grass growing on barren, sandy, moist heaths and moors, in many parts of Britain. The root consists of numerous very strong, downy fibres. Stems and leaves furrowed, roughish with minute bristles, rigid, four or five inches high, remaining bleached through the winter. Spikes solitary, purplish, bristle-shaped, straight, of many slender flowers. Schrank celebrates this deep-rooted grass as a safe support to the hands of the Alpine botanist, in precipitous situations, though it renders his path very slippery. The hard and wiry foliage of the mat-grass is eaten by horses and goats, but disliked by cattle and sheep. This species is often a troublesome weed on arable lands and pastures, where it affords but coarse food to cattle. As it, however, forms large and thick tufts, which resist the action of the scythe, it may be usefully transplanted to loose, sandy lands, where its spreading, horizontal roots will tend to consolidate the soil, and increase the stratum of vegetable mould, for the reception of more useful plants.

MATH. An old term for crop; hence *lat-termath* is the last mown crop of grass.

MATRIX. The womb, or place where any thing is generated or formed. In mineralogy, it implies the earth or stone in which the mineral is imbedded.

MATWEED, THE SEA. One of the names of the sea-reed (*Arundo arenaria*). See REED.

MAUDLIN-WORT. See OX-EYE DAISY.

MAUL. A provincial word, variously applied to a beetle, a mallet, and the mallow, in different localities.

MAW-SKIN. A word used in some places to signify the stomach of the calf prepared for cheese-making. See RENNET.

MAY-APPLE. An American plant, so called from its flowers being very abundant in the month of May. Its botanical name is *Podophyllum peltatum*, and it has also the common names of Wild Mandrake, and Hog Apple; the last name must be regarded as inappropriate, since hogs seldom, if ever, eat them. The plant grows very abundantly in all moist and shaded places in woods, almost from one end of the Union to the other. It has usually a simple stem, terminating in a single broad leaf, 4 to 6 inches in diameter, and deeply divided into 5 or 7 lobes. The root of the plant is biennial, and is frequently used as a medicine, being active both as an emetic and cathartic, when

taken in powder, in small quantities. The fruit consists of a single large, long, and flat-tish apple, yellow when mature, and varying in size from 1 to 3 or 4 inches long by 1 or 2 broad. The soft pulp contained within the rind has a very peculiar musky taste, which is relished by many persons. The fruit is by no means unwholesome, and has been introduced with the dessert, in which case the pulp may be squeezed into a wine-glass, and, with the addition of a little old Madeira and sugar, is said to be equal to the luscious golden grana-dilla of the tropics, a fruit which it greatly resembles in appearance. (*Am. Farm.* vol. 14.)

MAY-DAY. The first day of May.

MAY TREE. See HAWTHORN.

MAY-WEED, THE SCENTLESS. See CORN FEVERFEW.

MAY-WEED, THE STINKING, or MATH-ER. Called in Pennsylvania, Stinking Chamomile, Dog's Fennel, &c. (Pl. 10, v.) It is frequent in the farm-yards, lanes, &c., in the Middle States, and is a disagreeable foreign weed, now extensively naturalized. It is readily distinguished from the preceding by its fetid odor,—as well as by its botanical characters,—on which it has been generically separated from Anthemis, by Cassini, Lessing, &c. There are no native species in the United States.

MEAD (Dutch, *meede*). An agreeable vinous liquor made from honey. The use of this substance as one of the ingredients in drink is of very ancient date. When fermented, honey-water obtains the name of mead, which is, in fact, honey-wine: indeed the Germans call it by that name (*Honig-wein*). Mead is said to have been the principal beverage of the Britons before the use of malt liquor among them; and long after the introduction of the latter beverage, mead was a favourite drink. Under the name of metheglin, it was frequently alluded to by old writers. Mead formed the ancient, and for centuries the favourite beverage of the northern nations. It is frequently mentioned in Ossian. Dryden has a couplet:—

“T’ allay the strength and hardness of the wine,
Let with old Bacchus new Metheglin join.”

Queen Elizabeth was so fond of mead, as to have had it made every year for her. Her receipt for it has been preserved, and is given by Dr. Bevan, in his interesting little volume on the Honey Bee:—Take of sweet-briar leaves and thyme each one bushel, rosemary half a bushel, bay leaves one peck. Seethe these ingredients in a furnace full of water (containing probably not less than 120 gallons). boil for half an hour: pour the whole into a vat, and when cooled to a proper temperature (about 75° Fahr.), strain. Add to every six gallons of the strained liquor a gallon of fine honey, and work the mixture together for half an hour. Repeat the stirring occasionally for two days; then boil the liquor afresh, skim it till it becomes clear, and return it to the vat to cool: when reduced to a proper temperature, pour it into a vessel from which fresh ale or beer has just been emptied; work it for three days and turn. When fit to be stopped down, tie up a bag of beaten cloves and mace (about half an ounce of each), and suspend it in the liquor from the bung-hole. When it has stood

for half a year, it will be fit for use. Such was the receipt.

In Wales, in ancient times, mead was held in very high repute; as appears from an ancient law, which has been given by Dr. Bevan, that—"There are three things in court which must be communicated to the king before they are made known to any other person: 1st, every sentence of the judge; 2d, every new song; 3d, every cask of mead." The mead-maker was the eleventh person in dignity at court, and took precedence of the physician. Besides the preparation of mead, our forefathers were accustomed to flavour their usual grape wines with honey and other ingredients. There were two kinds of spiced wines in use in England in the thirteenth century, called Hippocras and Clary. The first consisted either of white or red wine, and the latter of claret, both mingled with honey and spices. Dr. Henderson, in his *History of Wines*, speaks of a receipt still existing, which gives directions how "to make yprocrasse for lords with gynger, synamon, and graynes, sugour, and turesoll; and for comyn pepull, gynger, canell, longe peper, and claryffied honey." Mead formed the nectar of the Scandinavian nations, and was celebrated by their bards: it was the drink which they expected to quaff in heaven out of the skulls of their enemies; and was, as might be expected, liberally patronized on earth. The Scandinavian mead is flavoured with primrose blossoms. (*Penny Magazine*.)

MEADOW. A field under grass cultivation, generally situated on the banks of a river or lake; but so far above the surface of the water as to be considerably drier than marsh land, and, consequently, producing grass and herbage of a superior quality. The soil of meadow lands is generally alluvial, and more or less mixed with sand; and it is kept in a state of fertility by the depositions made on its surface, in consequence of being occasionally overflowed by the adjoining waters. The produce of meadows is generally made into hay, which, though not equal in quality to that produced on drier grass lands, is yet superior to what is obtained from marshes. See GRASS, HAY, IRRIGATION, and MARSH.

In England some meadows of great extent, belonging to a community or district in which every inhabitant has a right to send his cattle to graze under certain regulations, are never mown. When the number of those who have a right of common pasture is not very great, they frequently agree among themselves to abstain from depasturing the meadows in spring, and, dividing them into portions, each makes hay of his share; after which the cattle are admitted in common for the remainder of the season. Thus a common meadow is converted into a *Lammis meadow*, that is, a meadow which becomes a common meadow after the 1st of August, this being the time when it is supposed that all the hay has been made and secured.

Low alluvial land, or that which can be irrigated at pleasure, is usually left for the scythe, either from its productiveness from the rich deposits which are periodically laid upon it, or from its being too wet for cattle to graze on it in winter without poaching the

surface. In a proper rotation system, upland is also occasionally devoted to the production of grass for the scythe. In upland situations meadows are either alternately mown and pastured, or broken up for oats or wheat, after they have yielded a crop of hay, and been grazed during the preceding year. The practice of leaving young leys in pasture one year after the first mowing, and then ploughing them up, is very general in England and Ireland. Grass land kept constantly for meadow, ought never to be depastured except in dry weather, as the breaking of the surface by the feet of the cattle, not only injures the grasses of the sward, but, by causing the stagnation of the water in holes, promotes the growth of rushes and other coarse aquatic plants, besides killing the finer grasses, and rendering the surface uneven for the scythe. A dressing of sand, even of the worst kind, and the use of calcareous manures, or salt, will be found excellent for coarse, rushy meadows, by tending to render the texture of the grasses finer; but as the rankness and inferiority of the herbage proceeds from a superabundance of water, draining will be found the most certain remedy, and effectual means of improvement. The meadows which are to be mown should be shut up early in spring, and those which are soft and wet should have nothing larger than a sheep admitted into them from November till after hay-making time the next year.

Of late years the practice of soiling has been extensively adopted. By this means all the advantages of mowing for hay are obtained, besides an abundant supply of rich manure, which can be applied to the land in a liquid and diluted state, when its effect is powerful and certain. So much more fodder is produced from the land by the system of soiling, that arable fields are converted into artificial and temporary meadows, in which the different species of grasses are sown, in order to be cut green or made into hay; and when, from the nature of the soil, the herbage degenerates, the field is ploughed up again, greatly improved by this change of cultivation.

When a natural meadow has been neglected, and the grass is of an inferior quality, and mixed with rank weeds and moss, it requires much care to restore it to its original fertility. In most cases (says a writer in the *Penny Cyclopaedia*), the shortest method and the best is to plough it up, clean and manure it during a course of tillage, without taking very exhausting crops from it, and then to lay it down again, in a clean and enriched state, by sowing the best sort of grass-seeds; or, which is preferable, by inoculating or planting in it small tufts of grass from some rich meadow, which will soon increase, and produce a new and improved sward. But when the soil is a very stiff clay, with only a small depth of good mould over it, there is some danger in breaking the old sward, for it will take a long time and much manure to reproduce a proper covering of sward. In this case it is a preferable practice to scarify the meadow, by means of instruments which do not go deep, but only tear up the surface. If this is done in early spring, when the ground is moist, and the whole surface is

brought to resemble a fallow field, good grass-seed may be immediately sown. If rich manure, mixed with lime or chalk, is then evenly spread over the land, and the whole well harrowed and rolled, the old and young grass will spring up together, and show a wonderful improvement in a very few months. Great Britain and Ireland are reputed to possess the most verdant pastures and the finest natural grasses in the vegetable creation.

In extent of meadow and pasture-land, as well as in flocks, Great Britain and Ireland (says a French statistical account) are the most favoured countries in Europe. They contain 5572 square leagues (more than two-thirds of their territory), in meadow and pasture-land. Germany comes next, having one-quarter of its surface in this description of land. Prussia, Holland, and Belgium have a fifth; Austria and Switzerland a sixth. France does not reckon in this respect more than a seventh part, namely, 4000 square leagues. Italy, Naples, Sicily, and Portugal have only a tenth.

MEADOW FOXTAIL. See **ALOPECURUS** and **GRASS**.

MEADOW-GRASS. See **POA**, **COUCH**, **HOLCUS**, and **GRASSES**.

MEADOW OAT-GRASS. See **AVENA**.

MEADOW-SAFFRON (*Colchicum*). An ornamental genus of bulbs, growing best in a light loamy soil, and increased by offsets, or from seeds. One species only is indigenous. See **COLCHICUM**.

MEADOW-SWEET, or **QUEEN OF THE MEADOWS** (*Spiraea ulmaria*). In England an indigenous perennial plant, growing in moist meadows, and about the banks of rivers and ditches; flowering in June and July. The root is fibrous, without knobs; the stems are herbaceous, 3 or 4 feet high, leafy, branched, furrowed, angular, smooth. Leaves interruptedly pinnate; downy beneath; the terminal leaflets largest, and lobed. Flowers extremely numerous, cream-coloured, with a sweet but oppressive, hawthorn-like scent, in dense, compound, cymose panicles, with many styles. The taste of the herbage, like the scent of the flowers, is aromatic, not unlike the flavour of orange-flower water. The distilled water is said to be used by wine merchants to improve the flavour of made wines. Hogs devour the roots with avidity; goats and sheep also relish the herb; but horses and cattle refuse it.

MEAL (Dutch, *meel*). The edible part of wheat, oats, rye, barley, and pulse of different kinds, ground into a species of coarse flour. See **FLOUR**.

MEASURES. See **WEIGHTS AND MEASURES**.

MEAT (Sax. *mæte*, food). A general appellation for the flesh of animals when prepared for human food. See **BEEF**, **BACON**, **CATTLE**, **MUTTON**, **PORK**, **SHEEP**, **SWINE**, &c.

"In whatever manner meat is cooked," observes Mr. Donovan, "there is a considerable diminution of substance, the loss consisting chiefly of water, juices, soluble matter, and fat. In an economical point of view, a comparison of the loss incurred in the two most usually employed processes, roasting and boiling, is interesting, yet it has not occupied the attention of the public so much as the importance of the

subject seems to demand. Professor Wallace, of Edinburgh, has given us the results of some experiments made to determine the loss which meat undergoes in cooking. It is to be regretted that it is not more in detail, and that the weight of the bone in each joint was not ascertained; but still it is of great value. The results, reduced to 100 pounds of meat, are as follows:—

	Lbs.
100 lbs. of beef lost in boiling - - - - -	26½
100 lbs. of beef lost in roasting - - - - -	32
100 lbs. of beef lost in baking - - - - -	30
100 lbs. of legs of mutton, averaging about 9½ lbs. each, lost in boiling - - - - -	21½
100 lbs. of shoulders of mutton, averaging 10 lbs. each, lost in roasting - - - - -	31½
100 lbs. of loins of mutton, averaging 8 lbs. 12 oz. each, lost in roasting - - - - -	35½
100 lbs. of necks of mutton, averaging 10 lbs. each, lost in roasting - - - - -	23½

Thus, the loss in boiling beef or mutton was less than in roasting. And it appears that meat loses by the cooking about one-fifth to one-third. A few years since, I undertook the superintendence of some experiments of the same tendency, with the view of inserting the results in this volume. These trials were made on several parts of the different animals, with as much attention to accuracy as the nature of the subject permitted. They were made on different qualities of the same kind of meat, at various seasons, both in England and Ireland. Such experiments are exceedingly troublesome, and occasion no small inconvenience; it is, therefore, the less surprising that the subject has been so little investigated; and the following results, in the absence of any others so particularly detailed, will, perhaps, prove interesting. Allowance must be made for the nature of such processes, as the difficulty of fixing an average price of meat, fish, and poultry, owing to variations occasioned by the supply and the season, the want of uniformity in the prices of the city, and by the exorbitant demands of some vendors of these articles. The degree of fatness was in all cases brought to a standard by cutting off all excess, and leaving the meat in a proper state for housekeepers' use. The meat was in all cases cooked as nearly as possible to the same degree, and the weights were determined with exactness; avoirdupois weight throughout is intended. The bones were entirely stripped of their meat previously to their being weighed. The only cost taken into account is that of meat, leaving out fuel, &c.

"*Experiment 1.*—A piece of beef, roasted. It consisted of four of the largest ribs, and was not remarkably fat: its weight was $11\frac{1}{8}$ lbs. During the process of roasting it lost 2 lbs 6 oz., of which 10 oz. were fat, and 23 oz. were water dissipated by evaporation. When the meat was dissected off with the utmost care, the bones weighed 16 oz. Hence, the weight of meat, properly roasted and fit for the table, was but 7 lbs. 11 oz., out of $11\frac{1}{8}$ lbs. originally submitted to experiment. This beef would cost in London $8\frac{1}{2}d.$ per lb. The roasted beef cost, therefore, $12\frac{1}{2}d.$ per pound. In another trial, a piece of beef of the same description, the tops of the ribs having been rejected with their meat, was submitted to the same mode of trial; the weight of bone in $10\frac{3}{4}$ lbs. was 16 oz., and

the fat 11 oz., which agrees with the former estimate."

Other parts of mutton, submitted to similar tests, gave the following results.

"*Experiment 17.*—A leg of mutton, weighing 9½ lbs., when boiled gave 1 lb. of bone, shank included; it lost in the boiling 1 lb. 2 oz.: the meat weighed 7 lbs. 2 oz. If the butcher's price was 8*d.* per lb., the meat cost about 10¼*d.* per lb.

"*Experiment 18.*—A similar leg, weighing 9 lbs. 6 oz., afforded 15 oz. of bone, and lost 12 oz. in the boiling: the meat weighed 7 lbs. 11 oz. At 8*d.* per lb. butcher's price, the boiled meat would cost 9¾*d.* per lb.

"*Experiment 19.*—A leg of small Scotch mutton, weighing 6 lbs., afforded 10½ oz. of bone, lost 5½ oz. in the boiling, and the meat weighed 5 lbs.: cost 9¾*d.* per lb., if butcher's price be 8*d.*"

The following are miscellaneous:—

"*Experiment 28.*—A fore-quarter of lamb, weighing 9 lbs., afforded, when roasted, 20 oz. of bone, and lost 1¾ lb. in the roasting: the meat weighed 6 lbs. If the butcher's price be 8½*d.* per lb., the roasted lamb costs 12¾*d.* per lb.

"*Experiment 31.*—A hand of salt pork weighing 4 lbs. 5 oz., lost in boiling 11 oz. The bone weighed 9 oz.: the meat was 8 lbs. 1 oz. If the first cost of the pork was 7½*d.* per lb., the meat, when duly boiled, cost 10¼*d.* per lb.

"*Experiment 34.*—A knuckle of veal weighing 6 lbs., when duly boiled, lost half a pound. Its bones, perfectly cleared of meat, weighed 2 lbs. 6 oz.; the meat weighed 3 lbs. 2 oz. Hence, if the butcher's price was 5½*d.*, the boiled meat cost 10½*d.* per lb.

"*Experiment 35.*—A goose properly trussed, weighed 4½ lbs.: in this state it was roasted, and, when sufficiently done, was found to have lost 18 oz. The skeleton weighed 12 oz.: the meat weighed 3 lbs. This goose would cost, in London, 4*s.* 6*d.* Hence the roasted meat amounted to 1*s.* 8½*d.* per lb.

"*Experiment 41.*—A turkey, with its liver and gizzard, weighing 4 lbs. 14 oz., was boiled: it lost 12 oz. The skeleton weighed 13½ oz.; the meat, 3 lbs. 4½ oz. If this turkey cost 3*s.* 6*d.*, the boiled meat amounted to 1*s.* 1*d.* per lb.

"*Experiment 43.*—A young duck, weighing 20 oz., lost 5¼ oz. in roasting. Its bones weighed 2⅞ oz.: the meat was 12¼ oz. It cost 2*s.* 6*d.*: hence the flesh amounted to 3*s.* 3½*d.* per lb.

"*Experiment 46.*—A fowl, with its liver and gizzard, weighing 1½ lb., was roasted. It lost 3 oz.: the skeleton weighed 4½ oz., and the flesh 16½ oz. If such a fowl cost 2*s.* 6*d.*, its meat, when roasted, would cost 2*s.* 4¾*d.* per lb.

"*Experiment 47.*—A chicken, weighing 1 lb. 4½ oz., when roasted lost 3½ oz. The bones weighed 3 oz., the flesh, 13½ oz. If the chicken cost 2*s.* 4*d.*, the meat, roasted, was worth 2*s.* 3*d.* per lb.

"*Experiment 56.*—A fine mackerel, when trimmed, and ready for boiling, weighed 23¼ oz. (including the weight of the roe, 2½ oz.) It cost 10*d.* It lost 1¾ oz. in the boiling. The skeleton, carefully collected, along with gills, fins, and tail, weighed 4¼ oz. Hence, the cost of the eatable parts of the boiled fish was 9¾*d.* per lb."

It will now be necessary to collect the results

of all these experiments into a kind of conspectus, for the sake of more easy comparison: and it is to be understood, that, in the following estimates, when the butcher's price is mentioned, it of course comprises meat and bone in the usual manner. But, when the ultimate cost of the cooked meat is specified, it refers to the price cost of the meat only, the bone being considered valueless: and it is supposed that the fatness of the meat was such as good meat is expected to have, without any redundancy being left on it. From an average of five experiments, it appears that, when the butcher's price of ribs of beef is 8½*d.* per lb., the cost of the meat, when duly roasted and fit for the table, is 11½*d.* per lb., and that the average loss of weight arising from the liquefaction of the fat, and the evaporation of water from the juices, is 18 per cent. From an average of six experiments, it appears that, when the butcher's price of sirloins of beef is 8½*d.* per lb., the cost of the meat, when duly roasted and fit for the table, is 1*s.* 1⅞*d.* per lb., and that the average weight lost during the roasting is 20⅓ per cent. From an average of other experiments, it appears that when the butcher's price of salted briskets of beef is 6*d.* per lb., the cost of the meat, when duly boiled and fit for the table, is 8½*d.* per lb., and the loss incurred in boiling, arising from the extraction of fat and juices, is 18 per cent. From an average of two experiments, it appears that when the butcher's price of salted flanks of beef is 6*d.* per lb., the cost of the meat, when duly boiled, is 7¼*d.* per lb., and the loss in boiling is 13¼ per cent. From another experiment, it appears that, when the butcher's price of salted tail ends of beef is 7*d.* per lb., the cost of the meat, when duly boiled, is 8½*d.* per lb., and the loss in boiling is 13⅞ per cent. From an average of experiments 17, 18, 19, and 2 others, it appears that, when the butcher's price of legs of mutton is 8*d.* per lb., the cost of the meat, when duly boiled and fit for the table, is 10*d.* per lb., and that the average weight lost during the boiling is 10 per cent. From an average of two experiments it appears that, when the butcher's price of legs of mutton is 8*d.* per lb., the cost of the meat, when duly roasted, is 1*s.* per lb., and the loss incurred by roasting is 27⅞ per cent. From an average of two experiments, it appears that, when the butcher's price of shoulders of mutton is 7*d.* per lb., the cost of the meat, duly roasted, is 11*d.* per lb., and the loss incurred by roasting is 28 per cent. From an average of experiments it appears that, when the butcher's price of the fore-quarter of lamb is 8½*d.* per lb., the cost of the meat, duly roasted, is 1*s.* 1¼*d.* per lb., and the loss by roasting is 22¼ per cent. From experiment 30, it appears that, if the first cost of hams be 10*d.* per lb., the meat, duly boiled, skinned, and browned, will amount to 1*s.* 1½*d.* per lb., and the loss by boiling is 12½ per cent. From experiments 31 and 32, it appears that, when the hand and leg of salt pork average 8*d.* per lb., the boiled meat amounts to 10⅓*d.* per lb., and the loss in boiling is 13⅓ per cent. From an experiment it appears that, if the first cost of bacon is 8*d.* per lb., the meat, when duly boiled, skinned, and browned, amounts to 10½*d.* per lb., the loss

in boiling alone being $6\frac{1}{4}$ per cent. From experiment 34, it appears that, when the butcher's price of knuckle of veal is $5\frac{1}{2}d.$ per lb., the meat, duly boiled, costs $10\frac{1}{2}d.$ per lb., the loss in boiling being $8\frac{1}{2}$ per cent. From an average of experiments 35, 36, 37, it appears that, at the prices of geese quoted, which average $12\frac{1}{2}d.$ per lb. for the raw flesh, the cost of the roasted flesh is $1s. 7d.$ per lb., and the loss per cent $19\frac{1}{2}$. From an average of three experiments, it appears that, at the prices of turkeys quoted, which average $10d.$ per lb., the cost of the roasted flesh is $1s. 2\frac{1}{2}d.$ per lb., and the loss per cent is $20\frac{1}{2}$. From an average of experiments 41 and 42, it appears that, when turkeys are sold at the last-mentioned price, the cost of the boiled flesh is $1s. 1\frac{1}{6}d.$ per lb., and the loss per cent is 16. It appears also, that the roasted flesh of turkeys sometimes amounts to $4s. 2d.$ per lb. From experiments 43, 44, and 45, it appears that, at the prices of ducks quoted, which average $1s. 1\frac{1}{2}d.$ per lb. in the raw state, the cost of the roasted flesh is $2s. 8d.$ per lb., and the loss per cent. is $27\frac{1}{6}$. From experiments 46, 47, and 48, it appears that, at the prices of chickens quoted, which average $1s. 6\frac{1}{2}d.$ per lb. in the raw state, the roasted flesh amounts to $2s. 7d.$ per lb., and the loss per cent. is $14\frac{3}{8}$. From an average of six experiments, it appears that, at the prices of chickens last quoted, the average cost of the boiled flesh is $2s. 8d.$ per lb. and the average loss is $13\frac{1}{2}$ per cent. From an experiment it appears, that, when turbot in the raw state is sold at $9\frac{1}{2}d.$ per lb., the boiled fish costs $11\frac{1}{2}d.$ per lb.; the loss in boiling is $5\frac{5}{9}$ per cent. From experiment 56, it appears that, when mackerel sells in the raw state at $6\frac{3}{4}d.$ per lb., the boiled fish costs $9\frac{1}{2}d.$ per lb., the loss in boiling being $7\frac{1}{2}$ per cent. From an experiment, it appears that the roasted flesh of a woodcock sometimes costs $16s.$ per lb., and sometimes $2s.$ But the flesh of the quail is still more expensive. This bird, when fattened, is sold at the enormous price of $3s.$; and, when allowance is made for the loss in cooking

and the bones, the meat may be estimated at 2 oz., which brings the cost of the cooked flesh to 1l. 4s. per lb.! Those to whom such morsels are necessary are not to be envied. A haunch of venison, weighing 26 lbs., will cost $3\frac{1}{2}$ guineas. The meat of this, when roasted and detached from the bone, will amount to about $3s. 10d.$ per lb.; and if the animal was more than usually fat, to 4s. The foregoing table gives the results in a still more abstract form; but the prices apply to London only. The articles are arranged in the order of their costliness in the London market.

It appears from the experiments, that

The loss per cent. on roasting beef, viz. sirloins and ribs together, is	- - - - -	19 $\frac{1}{6}$
Do. on roasting mutton, viz. legs and shoulders together, is	- - - - -	24 $\frac{1}{5}$
Do. on roasting lamb, viz. the fore-quarter, is	- - - - -	22 $\frac{1}{2}$
Do. on roasting geese, is	- - - - -	19 $\frac{1}{2}$
Do. on roasting turkeys, is	- - - - -	20 $\frac{1}{2}$
Do. on roasting ducks, is	- - - - -	27 $\frac{1}{8}$
Do. on roasting chickens, is	- - - - -	14 $\frac{3}{5}$

Thus, the loss on roasting varies from $14\frac{3}{5}$ to nearly double that rate. The average loss on roasting butchers' meat is 22 per cent., and on roasting domestic poultry is $20\frac{1}{2}$.

The loss per cent. on boiling mutton, viz. legs, is	- 10
Do. on boiling hams, is	- 12 $\frac{1}{2}$
Do. on boiling salt beef, is	- 15
Do. on boiling salt pork, is	- 13 $\frac{1}{2}$
Do. on boiling bacon, is	- 6 $\frac{1}{2}$
Do. on boiling knuckles of veal, is	- 8 $\frac{1}{2}$
Do. on boiling turkeys, is	- 16
Do. on boiling chickens, is	- 13 $\frac{1}{2}$

Thus, the loss on boiling varies from $6\frac{1}{2}$ to 16. The average loss on boiling butchers' meat, pork, hams, and bacon, is 12, and on boiling domestic poultry is $14\frac{3}{4}$. These estimates of butchers' meat do not agree with those of Professor Wallace. I shall select for contrast all those cases that can be compared.

	Wallace.	My trial.
100 lbs. of beef lost in boiling	- 26 $\frac{1}{2}$	15
Do. in roasting	- 32	19 $\frac{1}{6}$
100 lbs. of legs of mutton lost in boiling	- 21 $\frac{1}{2}$	10
100 lbs. of shoulders of mutton lost in roasting	- 31 $\frac{1}{2}$	28

The average loss in boiling and roasting together is, according to Professor Wallace, 28 per cent.; according to my trials, it is but 18. I know not how to reconcile these results otherwise than by supposing a difference in the meat, or its fatness, or in the duration of the heat. I used meat of sufficient, but not unprofitable fatness, such as is preferred in families; the meat was in all cases a little rare at its centre, and the results were determined with the utmost care. In great public institutions, where economy is studied, and every thing is regulated by weight and measure, tables of this kind do not afford a guide that is to be implicitly relied on. It is obvious that another element must be taken into the calculation, to insure true results; the ratio in which each article of food satisfies the appetite, which varies with almost every individual.

Butchers' meat, taking one kind with another, averages 35 per cent. of real nutritive matter; at least, such was the estimate presented by MM. Vauquelin and Percy to the French minister of the interior. Adopting this determination, we are prepared to appreciate the

Names of the Articles of Food estimated.	Cost per lb. raw.	Cost per lb. cooked.	Loss per cent. in cooking.
Salted flank of beef, boiled	6	7 $\frac{3}{4}$	13 1-5
Salted tail-end of beef, do.	6	8 $\frac{1}{2}$	13 7-10
Salted brisket of beef, do	6	8 $\frac{1}{2}$	18
Mackerel, do.	6 $\frac{3}{4}$	9 $\frac{1}{2}$	7 $\frac{1}{2}$
Legs of mutton, do.	8	10	10
Bacon, best part, do	8	10 $\frac{1}{2}$	6 $\frac{1}{2}$
Head and leg of salt pork, do.	8	10 $\frac{1}{2}$	13 $\frac{1}{3}$
Knuckle of veal, do.	5 $\frac{1}{2}$	10 $\frac{1}{2}$	8 $\frac{1}{3}$

Quails, fattened	-	288	-

quantity of real nutritive matter received into the stomach, when a meal of plain meat and vegetables has been eaten: it is not practicable to come to any conclusion when made dishes are used. It is a subject of interest, and particularly so to the inhabitants of the British Isles, who are said by foreigners to make use of more animal food than is necessary or wholesome.

In order, then, to equalize the animal and vegetable matter, and to increase the total quantity, the ratio should be $8\frac{1}{2}$ oz. of boiled mutton, 10 oz. of potato, and the same of turnip; the total amount of food swallowed will be $28\frac{1}{2}$ oz., but the quantity of real nutriment will be but 6 oz., half being animal and half vegetable matter. This is certainly a sufficient meal for most persons who have but little laborious occupation; for, if a pint of liquid be drunk at the same time, the load on the stomach will weigh 3 lb.; and this will be increased to $4\frac{1}{4}$ lb. if a pint of wine be swallowed. Now, the difference between $8\frac{1}{2}$ oz. of boiled meat and 10 oz. appears very trivial; but, if the greater of the two quantities be persevered in regularly every day for the term of a man's adult life of half a century, it may excite a little surprise in the person who practises it, to learn that he will have consumed a flock of sheep, consisting of about fifty-three head, in excess above what he ought to have made use of. In a life of sixty-five years, allowing $8\frac{1}{2}$ oz. per day for fifty years, two-thirds of that quantity for ten years, and 3 oz. a day for three years of childhood, the total animal food amounts to 350 sheep. If to this be added the excess above mentioned, the number of sheep, the cooked meat of which is devoured by one man during a life of sixty-five years, is about 400; along with 5 tons of potatoes, about the same of turnips or other vegetables, 9 tons' weight of common drink, and 6 tons' weight of wine, at 1 pint per day for three years only: thus, for dinner alone, above 30 tons' weight of solids and liquids must have passed through the stomach. Inordinate work will wear out any machinery before its time, especially if the work performed be of a peculiar wearing character. Whether it is advisable to add the fifty-three unnecessary sheep to one's dinner, is a question which every reader will answer to himself as he thinks proper. The food of old Parr, who died at 153 years of age, consisted of cheese, coarse bread, milk, and small beer. Would it have made no difference in the duration of his life if he had swallowed 1050 sheep! for about this number would have been his share at the usual rate, along with his twenty tons of wine. It may assist in drawing a conclusion, to recollect that when he was brought to London, and lived in splendour, "fed high, and drank plentifully of the best wines," he soon died: and his death was generally attributed to that cause, for he had vigour of body "to have lived a good while longer," as the reporter says. (*Lardner's Ency.*)

1. *Selection of Cattle and Beef.*—In the selection of cattle to be sent alive to market, they should invariably possess fine symmetry and small bone, carrying the greatest weight of beef on the most valuable points, such as

rumps, loins, and crops; the back well covered, the buttocks and flanks well filled up, and the whole carcass exhibiting a fulness of flesh, excepting the necks and coarser parts. They should handle hard and firm, in order to stand well the voyage, and handle and look well in the market. Firm handlers, whether heifers or oxen, always cut well up. A good coat of hair, too, is of great use in a sea-voyage on deck, and also in enabling cattle to stand the vicissitudes of weather in the markets, and it enables them to be turned out in safety, in case they should not be disposed of on the first market-day. Thin-coated cattle always look tender, and are, in fact, so under any circumstances. Cattle only possessing these requisite properties should be sent to Smithfield market, and any others will assuredly incur loss to the shipper. An ox or heifer of these properties, weighing 80 stones per Smithfield stone of 8 lbs., will actually realize more money than a coarse ox or heifer weighing 100 stones. Heavy cattle, however, do not take readily in Smithfield, except for a month about Christmas, unless they are remarkably handsome; nor do very light cattle, under 40 stones, for two or three months in summer, unless they are really neatly shaped, and thick on the backs and best points. The most saleable weights are from 50 stones to 55 stones. Of the Scottish breeds, the Galloway and West Highlanders fetch generally the top price; fine Angus and Aberdeenshires, of fine points and thick backs, take well; and handsome, well-bred short horns also take readily, but do not realize so much money as Galloways or West Highlanders. Fine crosses are also very saleable.

The meat intended to be sent to the carcass market in London should be taken from such cattle as we have described. It is not large quantities of lean and fat that are wanted there, but both well mixed. Ox and heifer beef of equal quality command the same prices. Rumps, loins, crops, and other fine parts fited for roasting and steaks, are more in demand than the boiling pieces, and realize comparatively higher prices, and therefore they alone should be sent. Coarse beef always fetches low prices in London, and therefore should be purchased (to use a sporting phrase) at a low figure in the country to return any profit, for the best buyers look more to quality than quantity; and as this quality of beef is rather cheaper in London than in Scotland, shippers should be cautious in sending any such thither.

2. *Selection of Sheep and Mutton.*—Ripe, compact sheep, of light weights, carrying a large proportion of lean on the back, loins, and shoulder, with a full round leg and handsome carcass, are admirably suited for Smithfield. Such, from 14 lb. to 20 lb. per quarter, will take readily; but they are most valuable from 16 lb. to 18 lb. The nearer the form and quality approach those of South Downs, the more likely are they to command the top prices; for the Downs have long been unrivalled favourites in Smithfield. True bred Cheviots and the black-faced Linton breed approach nearly to the qualities of the South Downs, and com

mand as high a price. Half-breeds from Leicester rams and Cheviot and black-faced ewes, which resemble the true breeds in form and quality, form saleable sheep in London. The old black-faced breed are too thin in the leg and back, and are in London termed "goaty." There are by far too many of this kind sent from Scotland, and they are generally, besides, only half-meated, or half-fat, and of course only fetch middling prices. They, however, generally please the consumer for flavour. Pure bred Leicesters are too fat, unless they are sent young, and do not exceed 20 lb. per quarter; when above that weight they fetch inferior prices. A fine South Down or Scotch sheep, of 18 lb. per quarter, will fetch 7*d.* per lb. by the carcass, whereas a heavy Leicester, Gloucester, Lincoln, or Kent, of 24 lb. a quarter and upwards, will realize no more than 6*d.*

The carcasses of mutton to be sent to London should, of course, be those of sheep such as are here recommended to be sent alive. Large quantities of fat are not so desirable as a proportionable mixture of fat with the lean. In using the loins and other parts of very fat mutton for chops, much of it has to be pared away, and sold for the price of raw fat, perhaps 4*d.* a pound; whereas well-mixed chops may be sold for 7*d.* or 8*d.* a pound. This shows the nature of the mistake committed in sending fat heavy mutton to London. The great point is, to select ripe mutton and sheep; for the latter will stand the voyage better than half-fat, and will not lose half the quantity of flesh in three days as the latter. No overgrown animals, having masses of fat on one place and not on another, would therefore command the top price: but those having plump carcasses, well mixed with fat and lean, firmly and equally laid on, with fine symmetry and valuable points, will always command the top price, both at Smithfield and the carcass markets.

3. *Selection of Lambs.*—Lambs are a favourite stock to send to London, and they are always sent alive. Leicester lambs are admirably adapted for the London market. They are handsome, compact, thick on all the points, and although they might become too fat when grown to sheep, they cannot be too fat as lambs. Their flesh is white, a property much admired in London, and every joint of them looks well on the table. The lambs of the cross between the Leicester and the Cheviot and black-faced ewes are next best for fat and lean, and cut well into joints, although they have not the handsome figures of the pure Leicester. True Cheviot and black-faced lambs, unless very fat, do not take so well in Smithfield, not being so compact, taking longer time to come to maturity, not cutting up so thick, and presenting small joints on the table; but they make very delicate and high-flavoured chops. No lambs should be sent to Smithfield until they are at least three months old, and have obtained the weight of 9 lb. or 10 lb. a quarter; and if they are not fat enough, and have not attained that weight at that age, they should be kept on. Shippers may calculate on a loss of 1 lb. a quarter on the voyage: unless, therefore, lambs are from 9 lb. to 10 lb. a quarter, they would be

too small after that loss, and they then become unsaleable except at low prices. Ewe lambs are preferred, being more delicate than wethers, which are next in value, for ram lambs are very unsaleable. All wether lambs, therefore, intended for Smithfield, should be castrated when a few days old, and their tails cut short, leaving not more than three inches. The docking gives them a very compact form, and it causes the flesh to grow up towards the back, long tails giving a contrary tendency.

4. *Selection of Pigs and Pork.*—Much caution is requisite on the part of the shipper of pigs for London. A very mistaken notion prevails among many shippers, and the notion has been contracted in ignorance of the nature of the London market, that pigs must be fat to suit the English taste. The fact is quite the reverse, for the larger the pig is fattened, the less money per pound it fetches. Pigs are worth the most money when their weight ranges from 35 lb. to 40 lb.; and from this weight up to 60 lb. or 70 lb., they are termed *dairy-fed porkers*. If at the former weight, they are of good symmetry, fine quality, delicate and white in the flesh, and not more than 1 inch or 1½ inch thick of fat on the back, they will fetch the top price of the day. Pigs of the average weight of 60 lb. will give about 7*d.* per lb.; from 70 lb. to 100 lb., averaging 85 lb., and 2 inches thick of fat, 6*d.* per lb.; from 100 lb. to 150 lb., averaging 130 lb., and about 2½ inches of fat, 5*d.* to 5¼*d.* per lb.; from 150 lb. to 200 lb., averaging about 170 lb., and about 3 inches of fat, 4*d.* to 4½*d.* per lb.; and all above the last weight and thickness of fat, only about 3½*d.* per lb. Besides the large-sized, a very small fat pig is not relished in London. Indeed, we need not be surprised at this preference, when we consider that only the small lean and fat porkers are used for roasting, chops, and pickled pork, and the large fat pigs are chopped down for sausages. No pigs, therefore, should be sent to London exceeding 100 lb., exclusive of head and feet, but which are only moderately fat and of fine quality; all other qualities should be cured as fitch, bacon, and hams. Pigs, if possible, should be sent alive to London. Occasionally they arrive in pretty good order in carcass; but in carcass, in thick weather, the flesh becomes very soft, and the skin dry; and in dry weather the skin becomes quite hard and brown coloured. Of equal qualities, the live pig will draw from a halfpenny to a penny a pound more than in carcass. Feeders of pigs should be careful on what they feed their pigs, especially fish. The retail butchers are such nice judges of pork, that on buying a carcass at Newgate or Leadenhall market, and cutting a slice, they can detect the least peculiarity in taste, which, if they do, they will return it again, and cause the carcass to be resold for what it will bring, rather than send any such pork to their customers.

Cutting up Meat.—The mode of cutting up meat is more diversified even than the slaughtering, almost every town having its own. But as London is the great emporium of the export meat trade of Scotland, the method of cutting up meat in the metropolis should constitute the particular study of the shippers of meat. To

acquire this necessary information, the shippers should have a few of the most expert butchers in London to slaughter and cut up the carcasses of the various sorts of animals. They should never consider themselves above acquiring such information, when their own interest will be benefited by its adoption. Whether the London method of cutting up meat is really the best of any, and we think it is, it must be admitted that the London butchers must have the most extensive and varied experience; and any one has only to witness the operation performed by expert London butchers to be satisfied that they display great skill in their art, and execute their work with the utmost precision. Indeed, the precision with which they divide the different qualities of meat from the same carcass shows their thorough knowledge of the qualities of meat; and the variety of prices which different parts of the same carcass fetch, shows with what accuracy they can gratify the tastes of the various grades of their customers.

In practising this precision, they not only make the best use of the carcass, but realize the highest value for it, and at the same time gratify the taste of the greatest number of cus-

tomers. In the carcass of any animal, an ox, for instance, there are different qualities of meat, and these qualities are situated in different parts of the carcass. All the best parts are in London used for roasting and steaks, and the inferior for boiling, either in pieces, or making stock for soups, or minced meat, in the various forms of pies, sausages, &c.

The carcass of an ox is cut up into the following pieces, as may be seen on referring to the numbers on the annexed cut, *fig. 1*.

The relative value of these different cuts of an ox may be stated at their current value, viz., when the rumps, loins, and fore-ribs of a fine ox fetch 8*d.* a pound, the thick flank, buttock, and middle rib will fetch 6*d.*; the itch or adze-bone, thin flank, chuck rib, brisket, and leg of mutton piece, 5*d.*; the clod and sticking, and neck, 3*d.*; and the legs and shins, 2*d.* a pound. Such is the difference in value of the different cuts of an ox in the meat markets in London.

As an object of comparison, we shall also give a figure of an ox cut up in the Edinburgh method, as in *fig. 2*, and the great difference between both methods may be seen at a glance. See cuts.

It is therefore obvious that, of the two methods of cutting up beef, the London affords much more of roasting and steak, that is, the more valuable pieces, out of the same carcass; and, of course, more money would thereby be realized from it.

Much of what we have said on the management requisite in sending beef to the London market will apply equally to sending mutton, veal, or lamb to the same market. The best pieces only should be sent to London, and the remainder kept for the home market: and were this recommendation attended to, the expense of exportation would be diminished on what was sent; for the best pieces would pack well together in a comparatively small space, whereas whole carcasses of mutton, by the roundness of the rib, occupy much unnecessary room, for which freight must be paid.

Mutton is also cut up differently in London and Scotland, as may be seen on referring to the figures at the top of next page, of which the first represents the London method.

In the fore-quarter, No. 1 is the shoulder, 2 and 2 the neck, after the shoulder has been taken off, and 3 the breast; and in the hind-quarter, 4 is the loin, which, when cut double, that is, partly from both sides of the carcass, is called a chine or saddle, and 5 is the leg. A leg of mutton in London is cut short; a haunch is cut long, taking in the hook-bone, similar to a haunch of venison. The flap of the loin is left attached to that part of the fore quarter called the breast. The Scotch mode of cutting up mutton is represented by *fig. 2*, in which, in the hind quarter, No. 1 is the gigot, and 2 the

Fig. 1.

Fig. 2.

loin; and in the fore, 3 the back ribs, and 4 the breast and shoulders. The gigot is cut about half-way between the leg and haunch of the London method; and the fore-quarter is cut right through the shoulders in two places, called back-ribs and breast. Shoulders of mutton are never cut off in Scotland before being cooked, except by keepers of eating-houses; but the London plan of cutting mutton is decidedly the best, the shoulder forming an excellent roast, and the best end of the neck-piece being admirably suited for chops.

The different joints of mutton vary almost as much in price in London as pieces of beef. The leg is sometimes sold as high as 10*d.* a pound, whilst the breast of the same sheep will only fetch 4*d.* or 5*d.*; and if, in the wholesale market, the whole carcass is sold at 6*d.* a pound, the hind-quarter will be worth 7*d.* and the fore only 5*d.* From these facts it is obvious, that it is the interest of the shipper only to send hind-quarters of mutton to London, for which 7*d.* a pound may be easily obtained, and a ready market for them in the west-end butchers, who seldom deal in fore-quarters. The fore-quarters could be sold at home; hence realizing as much for them as they could fetch in London, besides saving on them the freight, commission, and wharfage. They form excellent joints for tradesmen's families, and are, in fact, generally preferred by them to the hind-quarters, which are considered dry eating, and certainly do not make so good broth as the fore-quarter. Besides the saving of room in packing the hind-quarters, they would run no risk of being stained when sent by themselves, as the staining generally arises from blood oozing out of the veins in the fore-quarter.

Lamb is cut up in London in much the same manner as mutton, excepting that the neck and breast, when the shoulder is taken off, is roasted whole, and the piece is called *ribs of lamb*. In Scotland lamb is cut up exactly as mutton.

Veal is cut up in London in a different way from any other meat. The knife is drawn between the buttock and itch-bone, and through the pope's eye, taking a sloping direction through the coarse end of the buttock, leaving a flap. The piece thus cut out is called a *fillet*

of veal. It is like a round of beef with a part of the thin flank left to be skewered around it. The round bone is taken out, and stuffing put into its place. When the itch-bone and hook-bone are cut from the loin, the piece is called a *chump* of veal. The hind-quarter of veal thus consists of fillet, chump, loin, and leg. The fore-quarter is cut in the same manner as mutton, having shoulder, breast, and neck. In Scotland, veal is cut very much like mutton.

The London mode of cutting up pork is the same as the Scotch mode of cutting up mutton, so *fig. 2* will illustrate the mode; in which, in the hind-quarter, No. 1 is the leg, and 2 is the loin; in the fore, 3, back-rib, chine, or hand; and 4, breast and shoulders, spring or belly. The spring is used for pickling, and the hand for roasting, and for chops, or sausages. In Scotland, the hind-quarter consists of leg and loin, and the fore of back-ribs and breast. For pickling or roasting, pork is cut in the hind-quarter like that of English mutton, and in the fore like that of Scotch. In both countries, the ham is cut out alike. (*Donovan's Dom. Econ.; Quart. Jour. of Agr.* vol. iii. p. 241—281.) See CATTLE and SALTING.

MEDICK (*Medicago*). An extensive genus of herbaceous, mostly procumbent, plants. The perennial herbaceous species are sometimes cultivated for ornament; they will grow in any common garden soil, and are increased by dividing the roots of the plants in spring. The shrubby kinds grow in a similar soil, and are readily increased by cuttings. The seeds of the annual species require to be sown in the open border in spring. There are six indigenous species.

1. Purple medick, or lucern (*M. sativa*). See LUCERN.

2. Yellow sickle medick, or button-jags (*M. falcata*). This perennial species grows on dry, gravelly banks and old walls. The root is long and woody. In habit it very closely resembles lucern, but the numerous stems are procumbent, spreading every way, hairy. The flowers, which blow in June and July, are generally pale-yellow, but occasionally violet, and more frequently green, evidently from a combination of these two colours. The legumes are black, downy, sickle-shaped, not twisted in a screw, as in lucern. This species is, perhaps, as good fodder as lucern, though less succulent, and, from its position, less accessible to the scythe. It withstands severe winters better than lucern, and is eaten eagerly by cattle and horses, though its stalks are hard and woody.

3. Black trefoil medick, or nonsuch (*M. lupulina*). This annual species is, in England, very common in meadow pastures and cultivated fields, where it flowers from May till August. The black medick has the habit of some of the procumbent yellow trefoils, and has such general resemblance to the proper trefoils or clovers, that it is often mistaken for some of the smaller species. The form and colour of the seed-pods afford a ready distinction. The root is tapering, and somewhat fibrous. Flowers small, yellow, from 30 to 40 and upwards in each spike, which is at first roundish, afterwards ovate. Legumes kidney-

shaped, rugged and veiny, single-seeded, turning black when ripe. Sir J. E. Smith speaks of this as "one of the most valuable of artificial grasses, affording excellent fodder for sheep;" but this good opinion is hardly borne out by experience, for, though Arthur Young makes favourable mention of it, Sinclair, in his more recent experiments on the grasses, observes that it is only fit for light soils, and these must be deep, as the root penetrates to a considerable depth. It does not appear to be fit for separate cultivation, nor even to be employed in any large proportion in a mixture of other seeds; and the root being annual, its use is, therefore, confined to the alternate husbandry.

4. Spotted medick (*M. maculata*). This is another annual species, growing on a gravelly soil in the southern parts of England. The root is fibrous, beset with little fleshy knobs. Stems prostrate, various in length. Leaflets inversely heart-shaped, spotted. Stipules dilated, sharply toothed. Flowers yellow, rather small, two or three together. Legumes spiral, depressed, fringed with long spreading bristles; when ripe, brown, not black. This has been mentioned, but not much recommended as a fodder for cattle.

5. Flat-toothed medick (*M. muricata*). This is a doubtful native, growing on the sea-coast. It is an annual, and flowers in June and July.

6. Little bur medick (*M. minima*). This is a little prostrate annual species, growing in sandy fields, but rare, clothed in every part with fine, soft, rather silky hairs.

MEDLAR (*Mespilus*). A genus of large-growing fruit trees, which are very ornamental, and therefore worth a place in every shrubbery. Any common soil suits them, and they are readily increased by budding or grafting on the common hawthorn, or they may be increased by seeds, which do not vegetate till the second year.

The common medlar (*M. Germanica*) is indigenous, growing wild in hedges. The branches of this tree are spreading, and thorny in a wild state; but the thorns disappear by culture, and are not to be seen in gardens. Leaves deciduous, lanceolate, 4 or 5 inches long, a little downy. Flowers solitary, nearly sessile, terminal, large, with white undulated petals, inodorous. Styles 5. Fruit depressed, concave at the top, somewhat hairy; austere, not eatable till it is mellowed by keeping. Cultivation has produced many varieties, differing in size and flavour. The Dutch medlar is the finest as to size, and the Nottingham the most delicate in flavour.

The wood, being hard and tough, resembling that of the pear tree, is useful for various domestic vessels, as well as for the smaller implements of husbandry.

MEDULLA, or MEDULLIN (Lat.) Marrow. In botany that tissue which constitutes the pith of certain plants, as the pith of the sunflower. *Medullary rays* are the vertical plates of cellular tissue, which radiate from the centre of the stem of exogenous plants, through the wood to the bark. They cause that appearance in timber which carpenters call silver grain, or flower of the wood. The *medullary sheath* is a thin layer of vessels, which surround the

pulp of exogenous plants, and thence extend into the leaves and parts of fructification.

MELIC-GRASS (*Melica*, from *mel*, honey; the Italian name of the great millet). A genus of perennial harsh grasses, with slender, oblong panicles of elegant, often drooping, flowers, greatly varied in the different species. There are, in England, three indigenous species. 1. Wood melic-grass (*M. uniflora*). 2. Mountain melic-grass (*M. nutans*), found in the mountains of England and Scotland. 3. Purple melic-grass (*M. cærulea*).

For the purpose of pasture or hay, these grasses are comparatively of no value. The country people make of the tough straws a neat kind of besoms, which they sell to the neighbouring inhabitants as a cheap, and no despicable substitute, for hair brooms: they are even made into baskets where better materials are rare. Mr. George Sinclair made some experiments on an exotic species, the fringed or ciliated melic-grass (*M. ciliata*), which grows wild in Germany on hilly grounds, downs, and by the margins of woods; but the result of his observations only went to prove that it was one of the inferior grasses with respect to produce, nutritive qualities, and reproductive powers.

MELILOT, COMMON, Melilot 'Trefoil, King's clover, Hart's clover. Pl. 10, b. (*Trifolium officinale*.) This plant is very nearly allied to the long-rooted clover: the tapering root, however, appears to be strictly annual. The lower leaves are oblong, wedge-shaped; the upper ones elliptical: they are more serrate, and smaller in every respect than those of the long-rooted clover. The flowers are smaller and more drooping. The legume contains often more than two seeds, which is seldom or never the case in the long-rooted clover.

In England the common melilot grows wild in thickets, hedges, and the borders of fields, sometimes among corn. Stem 2 or 3 feet high, erect. Clusters unilateral, 2 inches or more in length, on long axillary footstalks. Flowers numerous, all drooping towards one side, of a full yellow, veiny. Stipules awl-shaped. Legumes prominent, acute, transversely wrinkled, hairy.

All the species of live-stock are said to eat this clover. The whole plant in drying acquires a scent like new hay, but far stronger. The seeds, when mixed with bread-corn, give it a nauseous flavour. This plant, or a variety of it, is used in making the Swiss cheese called *schabzieger*. It is ground in a mill, and mixed with the curd into a kind of paste, which is put into conical moulds, and there dried. See *SCHABZIEGER*.

From the experience of Sinclair and others, this plant appears to be very much inferior to the long-rooted clover, and cannot be put to any use for which that species is not equally good or superior: it grows chiefly in clayey soils. In very exposed situations it attains only to a small size; while in such as are sheltered it sometimes reaches to the height of six feet. It ripens an abundance of seed, and flowers in the third or last week of June. Melilot is out of use in medicine, though it served too long to give a green colour and an

odious scent to a sort of blister plaster, called by its name, of no use whatever.

MELILOTUS (Lat. *mel*, honey, and *lotus*, a leguminous plant). The plants are similar to the lotus, and are the favourite haunt of bees. These are, for the most part, honey-scented plants, with upright stems, and long erect racemes of small yellow or white flowers, resembling those of clover, of which they were formerly considered distinct species. In some parts of Europe two or three varieties are cultivated as annual fodder plants.

The *Melilotus leucantha major* is the celebrated *Bokhara Tree Clover*, a plant which Mr. Robert Arthur, of Edinburgh, says, "claims a place in every flower-garden, for its beauty. It is an herbaceous plant of very striking appearance, 10 or 12 feet in height, covered with spikes of white pea-blossoms, which also shed a sweet perfume. Hence it is sometimes called Sweet Flowering Clover.

"I esteem its value in agriculture of greater importance. The objections to its cultivation are, that cattle give a preference to other green food, and that the stem contains too much woody fibre. The plant, however, is new to Britain, and we know that man and animals frequently require successive trials of new food before taste is acquired for it. As a proof of this, I understand that some cattle are getting very fond of this clover; and we know that the tissue of plants in general is changed more and more into woody fibre as they progress towards maturity. Nature increases the woody fibre of this clover for support as it elongates its gigantic stem. If, however, it is cut for cattle, when about 2 feet in height, it will be found nearly as succulent as the common red clover.

"I exhibited plants of it at the Highland Society's show, last September, 9 feet in height, being the second crop of it that season, from poor sandy land. I know no plant whatever that will produce so much weight of vegetable matter in equal time and space; and were it only for the production of vegetable manure, it is a boon to the agricultural world. In my experiments with it last summer, as a manure, for new varieties of Alsike (?) Clover, I found it the very best and cheapest manure.

"In the economical formation of manure, it might be liberally supplied, with other food, throughout the summer, to young cattle and pigs, in an open straw-yard profusely bedded over with layers of turf, peat-earth, whins, broom, brushwood, ferns, straw, weeds, &c., and thus save much outlay on the purchase of foreign manures.

"The Bokhara Clover may be sown at any time throughout the growing season; but the most profitable time to sow it is immediately after a crop of early potatoes, or even after grass, barley, wheat, &c. The land being well manured, ploughed over, and harrowed smooth, it may be sown in shallow drills 18 inches apart; being cut once in autumn, it will produce a much earlier spring crop than tares, Italian rye-grass, &c. It should always be cut very close to the ground, as the shoots produced from beneath the surface are the most luxuriant, and it will thus stand a severe win-

ter much better than when its vitality is exposed on long stubble. Treated in this way with me, it stood two successive winters, and acquired all the characteristics of a perennial root. I have no doubt of its continuing perennial and more vigorous with the age of the plants, if only cut close in autumn, and top-dressed with rich compost."

Mr. James Gowen, who resides at Moun Airy, near Philadelphia, has been much in the practice of keeping up a considerable stock of uncommonly fine cattle, and soiling them in summer upon lucern, rye, and red clover. He has raised patches of the melilotus, and from his observation says, "there is no grass or plant I have yet seen that affords to me such promise as the Sweet-scented or Bokhara Clover." (*Cultivator*, Nov. 1842.)

MELON, THE COMMON, or MUSK (*Cucumis melo*). An herbaceous, succulent, climbing, or trailing annual, cultivated for its fruit in hot eastern countries from time immemorial. The varieties of the melon are numerous; yet few of them comparatively are worthy of cultivation in England. The larger varieties especially are deficient in flavour and richness. Mr. Knight says, that whoever is acquainted with the green-fleshed, and Salonica, or white-fleshed, will cultivate no other.

The cantaleups are varieties characterized by their rinds being universally covered with reticulations. With the exception of the green, or oblong-ribbed, these bear round fruit, more or less approaching a flattened spheroid. Their common name is derived from that of one of the country-seats of the pope, where they are much cultivated.

MELON CULTURE. The warm summers of the Southern and most of the Middle States, are highly favourable to the culture of melons of every description, which in some places constitute a very profitable crop. The following communication relative to the culture of the musk melon or cantaleup, addressed to the Editor of the *Cultivator*, by T. G. Bergen, a person well versed in the business, will show how this is managed on Long Island, for the New York market:

The kind which we at present cultivate, says Mr. Bergen, and with which the New York market is principally supplied, is known among us by the name of Skillman melons. They average about 6 inches in diameter, are nearly round, have a rough skin, and their flesh is of a green colour. This is the sixth variety which has been in vogue during my recollection, and the finest of them all. The seed from which all these varieties originated, I believe to have been imported from the coasts of the Mediterranean. They soon degenerate unless care is taken in the selection of the seed. We prefer for melons a rich sandy soil, and on this they flourish better than on any other, and are not so liable to speck in rainy weather. When planted on a red clover sod I have seldom failed having a good crop; but when this is not to be had, we prefer preparing the ground by sowing with rye in August or September of the preceding year, as described in my former communication on the cultivation of cucumbers: the ground is also pre-

pared in a similar manner in the spring, except that the hills are furrowed 5 feet apart, and the same kind and quantity of manure made use of.

We generally commence planting about a week later than we do cucumbers, but occasionally at the same time, dropping from 20 to 30 seeds into a hill, and covering them about an inch deep with fine soil. Eight or 10 days after putting in the first seed we commence planting over, which we seldom perform the second time, unless by examination we find the first seed about to fail. The seed of melons is not so liable to rot as that of cucumbers, but long storms are very apt to destroy the young plants, and they will even produce great injury when the plants have vined from off the hills. In 1837, a succession of wet weather caused the ends of the principal part of the melon-vines in our vicinity to die as late as the 8th of July; but mine fortunately did not suffer as much as those of my neighbours. We cultivate the plants in the same manner as cucumbers, except that in hoeing it is generally necessary to remove a small portion of the soil from between them, in consequence of their being too short to admit of the young weeds being covered without injury to the plants. We gradually thin them down to 4 in a hill, standing from 5 to 6 inches apart. The plants are liable to the depredations of the same species of insects which prey upon cucumbers, and they are destroyed in the same manner.

Melon vines are in bearing from 5 to 6 weeks; whenever a drought occurs, this period is much less, for that of 1838 finished mine in 4 weeks. They often bear a second crop, which answers for pickling, but I have known this crop to come to perfection.

When the fruit is ripe, it requires to be gathered every day, otherwise there would be large quantities lost in consequence of becoming too ripe and soft. When ripe, they have a yellowish colour; but such as are cracked around the stem and come off easily from the vines, we always gather, for they will be fit for eating by the next day, when sold in the markets.

To insure good crops, melons should not be planted two years in succession on the same ground; they require a rotation. Marshall, an English writer, recommends the carrying of cucumber and melon seeds a week or two in the breeches pockets previous to planting, to dry away some of the more watery particles: were we believers of this doctrine, it would be a difficult matter, and require large pockets or a regiment of small ones to carry it into practice, since some of us, to secure our crops, plant from 3 to 4 bushels of seed in a season.

The following is the number of hills planted, produce (large quantities of unsaleable ones fed to the hogs excepted), and amount of sales for the preceding 4 years: viz.

Year.	Hills planted.	Bushels sold.	Amount received
1835	- 6,664	1,133	\$939 10
1836	- 7,850	561	590 57
1837	- 8,011	990	913 56
1838	- 7,590	823	713 96

MELON PUMPKIN, or SQUASH (*Cucurbita melopepo*). See SQUASH.

MELON, WATER (*Cucumis citrullus*). A plant well known in the United States for its delicious and refreshing fruit. To acquire the greatest perfection it demands a warm and sandy soil, and this it finds in New Jersey, and more Southern States, where the water-melon is extensively cultivated. There are several varieties, such as the long and striped Carolina, the more round and dark-skinned Spanish, &c. In some parts of southern Russia, a kind of beer is brewed from their very abundant and cheap water-melons, with the addition of hops: they also prepare a conserve or marmalade from this fruit, which is a good substitute for syrup or molasses.

MENDING. A country term used to signify the improving the quality or texture of land by the application of manure.

MERCURY (*Mercurialis*). These are regarded as mere weeds, possessing narcotic, fetid, and dangerous qualities.

MERINO SHEEP. See SHEEP.

MESLIN. A term applied in New England to the crop of peas and oats when sown together

MESLIN-CORN. A term applied to wheat and rye produced in a state of moisture.

METEOROLOGY. The science of meteors, or the science which explains the various phenomena which have their origin in the atmosphere. Under the term meteorology, it is now usual to include not merely the observation of the accidental phenomena to which the name of meteor is applied, but every terrestrial as well as atmospherical phenomenon, whether accidental or permanent, depending on the action of heat, light, electricity, and magnetism. In this extended signification, meteorology comprehends climatology, and the greater part of physical geography; and its object is to determine the diversified and incessantly changing influences of the four great agents of nature now named, on land, in the sea, and in the atmosphere. It is the object of meteorology to investigate and discover the modes of operation, and the causes instrumental, as well as final, of the multitude of interesting phenomena which exercise an influence on the animal and vegetable kingdoms. To this science belongs the examination of the force of radiation from the sun, or the temperature directly produced by his beams; the inquiry into the constitution, mechanical as well as chemical, of that intimate intermixture of gaseous bodies which is the subject of what are called *atmospheric* changes; the scrutiny of the laws governing the variations of *climate*; that also of those which regulate the diminution of heat in the atmosphere, in proportion to the altitude; the development of the principles determining the quantity and state of the aqueous portion of the atmosphere; and the acquirement of knowledge, in short, on every subject of science presented by the atmosphere itself, or by its modes of relation to the aqueous and mineral kingdoms, and the general laws of its influence on organized matter. This branch of natural history also comprehends the examination of two great series of phenomena, not strictly comprised by the foregoing enumeration; by which, on the one side, its boundaries are

united with those of physical geography, and on the other side with those of astronomy. The temperature of the interior of the earth itself, and that of the ocean, as well at the surface as at every accessible depth—subjects of the greatest interest, with respect not only to the present state of the earth, but also to its former physical condition—are so intimately connected with the temperature and other affections of the atmosphere, that the study of them becomes, in fact, a department of meteorology. And the various kinds of luminous and igneous meteors which *appear* within the atmosphere, though some of them *originate*, in all probability, in distant regions of the solar system,—such as the zodiacal light, the polar lights, or aurora borealis and australis; the meteors called shooting stars, and the stupendous masses of matter in combustion called *fire-balls*, which cast down upon earth immense blocks of red-hot iron, or showers of heated stones,—constitute another wide field of meteorological inquiry. This interesting branch of science must ever command the especial consideration of the shepherd, the farmer, and the cultivator of the soil in general.

METEORS. A name given to any phenomena of a transitory nature originating in the atmosphere. Meteors are of various kinds: some are produced simply by a disturbance of the equilibrium of the atmospheric fluid, and are called *aërial meteors*; such are **WINDS**, **WHIRLWINDS**, &c. A second class arise from the deposition of the aqueous particles which the atmosphere holds in solution, and which are precipitated in consequence of a diminution of pressure or temperature, sometimes in a fluid and sometimes in a concrete form. These are called *aqueous meteors*, as **DEW**, **FOGS**, **HAIL**, **RAIN**, **SNOW**, **VAPOUR**, &c. A third class of meteors or atmospheric phenomena are caused by the action of the aqueous particles dispersed in the atmosphere, or the rays of light. These are called *luminous meteors*, and comprise fata morgana, halo, mirage, parhelia, the rainbow, &c. A fourth class are the *igneous meteors*, comprehending those which present the phenomena distinctive of combustion. See **AEROLITE**, **NORTHERN LIGHTS**, **LIGHTNING**, **SHOOTING STARS**, &c.

METHEGLIN (Germ. *meth*, mead). A beverage made of honey and water, fermented by the addition of yeast. See **MEAD**.

MEZEREON, or **SPURGE OLIVE** (*Daphne mezereum*). This is a pretty shrub, indigenous to England, where it grows wild in woods, but is not common. The stem is bushy, 4 or 5 feet high, with upright, alternate, smooth, tough, and pliant branches; leafy while young. The flowers are pale garnet-coloured, highly, and to many persons too powerfully fragrant, seated in little tufts on the smaller branches. The scarlet berries, which are the favourite food of some species of finch (*Loxia*) are poisonous to many animals. There are varieties with pink and white flowers; and the berries also vary to a yellow or orange hue. The bark of the root is employed in medicine. It is excitant and sudorific. The active principle is a fixed acrid aloe resin. See **SPURGE LAUREL**.

MICA. A well-known mineral, with a pearly, metallic lustre, consisting of extremely thin, elastic plates or layers somewhat resembling glass. The largest sheets are brought from Siberia, and used instead of glass, especially to enclose fire where it is desirable to see the flame, as in stoves, &c. Mica enters into the composition of granite. Its specific gravity is 2.65. When analyzed it is shown to contain potash, magnesia, silica, oxide of iron, with other ingredients of well-known fertilizing properties. (See **GEOLOGY**.) Hence, where any of these are deficient in soils, the application of mica must be advantageous.

MICE (*Mus*). A very destructive sort of vermin to many of the cultivator's growing and housed crops, and which should, therefore, be destroyed as soon as possible. Cats, dogs, owls, snakes, and hedge-hogs are the natural enemies of rats and mice, and should, therefore, be encouraged about the farm.

To destroy Rats and Mice in Corn Stacks.—The following method was adopted by the late Mr. John Gibson, of Millbeck Hall, Keswick, and is still continued by his son, Mr. Joseph Gibson, of the same place, with never-failing success. It is accomplished by simply driving in a few hedge-stakes, at about 4 feet distance, round the stack intended to be housed, and having a woollen or linen web, of about 6-4ths or 7-4ths wide, upon the stakes, so as to be perfectly close at the bottom, of which particular care must be taken, in order that none of the vermin may creep under the folds. It is certain that none will attempt to climb over the top, and it matters not whether there are fifty or a hundred within the enclosed area, they will be quite safe. An active lad and a dog may easily destroy any number, and he must be a clumsy fellow if he lose one in a hundred. A few neighbours, by subscribing about 2s. 6d. each, might get an article at 10d. a yard that would serve them all for about 20 years. If the above simple method were generally adopted for a short time, those destructive enemies to the stack-yard would soon be considerably reduced. A correspondent of the *Mark Lane Express* suggests the following plan for the destruction of these obnoxious vermin. Feed with flour and a few sweet almonds bruised and mixed together with a small quantity of treacle, to form a paste (add a few drops of oil of aniseed), for 5 or 6 nights, until they take it freely, never laying more of the mixture than they will eat up clean; then add a teaspoonful of carbonate of barytes to about a pound of the paste. I prefer the barytes to arsenic, it being free from the sour taste of the arsenic, which the rats will never take a second time. By using the above composition, I have kept my premises clear, without employing a rat-catcher, at the expense of a few shillings a year.

MID-RIB. In botany, the middle vein of a leaf, which passes from the petiole to the apex.

MIGNONETTE (*Reseda*, to calm or appease; the Latins considered its application useful in external bruises). The sweet mignonette (*R. odorata*) is an old and universal favourite, on account of the very pleasant odour emitted by the flowers. Though usually annual, by care in a green-house and constantly

pruning, the cultivated mignonette may be rendered perennial, and even shrubby.

MILDEW, or RUST. Of all the many diseases which attack our cultivated plants, not one is so destructive as the mildew. It is the "plague" of our wheat crops; and as that fatal distemper is always lurking in some district of climes warmer than our own, so the mildew is always in our fields, waiting for circumstances favourable to its outspread, and ready to destroy the expected harvest of the husbandman. So constantly present is this destructive disorder, that in the fairest fields of wheat grown in the richest corn districts of England, and in the most genial years, I never saw a single acre entirely uninfected. Every year the farmer is more or less injured by this disease, for the produce of each acre of wheat is unquestionably reduced annually several bushels. Yet those who suffer most by the loss, the farmers themselves, are almost universally ignorant of the fact; and their attention is rarely arrested by it till a year occurs in which their crop of wheat is nearly annihilated.

Its prevailing injurious nature was well known in an age as distant as that of the Hebrews; and it had not spared the Greeks and Romans. Even the poets, as Horace in his Odes, speak of it as the "sterile Rubigo" (*Carmin.* lib. 3, ode 23); and warning voices have not been since wanting to speak loudly of its ravages. Mr. Marshall says, "a certain preventive of the mildew would be a discovery worth millions to this country;" and many others have coincided in this estimate of its injuries.

This disease is known to be the effect produced by a minute fungus belonging to a genus closely allied to that which causes the smut. The roots of this fungus penetrate the vessels of the plant, and are nourished by the sap intended for perfecting its seed; consequently, if the fungi are so numerous in each stem as to make it a marked "mildew year," the grain is either partially or totally shrivelled, owing to the roots of these parasites intercepting the sap in its upward passage.

The ignorance relative to this disease is not a consequence of its novelty, since it has been known and dreaded in the earliest ages to which our knowledge extends. Thus, when God held out as a warning to the Israelites the afflictions he would bring on them if disobedient, he enumerated the pestilence and the sword to destroy their persons, "with blasting and with mildew;" to lay waste their fields (*Deut.* xxviii. 22; *1 Kings* viii. 37; *2 Chron.* vi. 28); and when the same Almighty Being had punished that rebellious people, he reminded them by his prophet; "I have smitten you with blasting and mildew; when your gardens and your vineyards, and your fig trees, and your olive trees increased, the palmer-worm destroyed them." (*Amos* iv. 9.) "I smote you with blasting, and with mildew, and with hail, in all the labours of your hands." (*Haggai* ii. 17.) The Hebrews called it *yarcoon*, implying a yellow pallidness arising from moisture. To the Greeks it was known as *erubise*, ερουβίση; and Theophrastus, who wrote his *History of Plants* about 320 years before the Christian era, observes (*lib.* viii. c. 10) that it occurs more

frequently to corn than to pulse; that in the climate of Greece barley was more subject to it than wheat, and particularly a variety then known as *achillum* barley. Experience had taught them, that the crops on high lying lands were seldom attacked by this disease; but that the hollows surrounded by hills, where winds could not get at the crops they bore, were most frequently infected. It is chiefly generated, concludes Theophrastus, during the full moon.

By the Romans, the mildew was denominated "*rubigo*." Pliny informs us, in his *History of Plants* (*lib.* vii. c. 28 and 29), that it was the prevailing opinion that this disease arises from certain dews settling upon the corn, and obtaining a caustic or burning quality from the intense heat of the sun. This naturalist himself thought, on the contrary, that the disease arises from cold, considering that infection first occurs during the sun, and always about the new or full moon. Pliny, and the still later writers of the *Geoponica* (for this work is composed of fragments of Roman writers living after the removal of the seat of empire to Constantino-ple, though written in the Greek language), considered that the best remedies were stinking pungent smokes; hence they recommended fish, horns, goat's dung, &c., to be burned on such side of the field as would enable the wind to diffuse the smoke over and throughout the crop. They evidently had the same prejudice as is now entertained by our own farmers, that the mists which frequently prevail during midday in the hottest periods of summer are the cause of the mildew; for they direct those fumigations to be performed at such time as it is seen in the atmosphere. They also thought that if branches of the laurel were fixed among their corn, the mildew would pass from the crops to those branches. (*Geopon.* lib. v. c. 33; *Plinii Hist. Plant.* lib. xvii. c. 17, &c.) One of their practices recommended is much more rational, namely, to bruise the leaves or roots of the colocynth, to macerate these in water, and, before the sun has risen, to sprinkle the infected crop with the liquor thus obtained. It is possible that the juice of the colocynth, which is a violent purgative to the human system, may be destructive to the fungus constituting the disease. It approaches to that which, in modern times, has been found the only effectual curative treatment; and the direction that the application should be performed in the morning evinces that it was a direction suggested and confirmed by experience. Columella (*lib.* ii. c. 12) says, that hoeing corn during wet weather is apt to induce mildew.

Some modern writers have considered that the rubigo of the Romans is the disease known to us as the smut; but, independent of the name, which evidently referred to the red or rusty hue of the disease, and which is not a characteristic of the last-named disorder, we have the direct testimony of Virgil (*Geor.* L. 150), that the rubigo was a disease of the straw; his words are, "Mox et frumentis labor additus; ut mala culmos esset rubigo, &c."

Horace (*Carminum*, lib. iii. ode xxiii.) and Ovid (*Fast.* iv. 907) speak of the same vegetable epidemic. The Greeks and Romans were as conscious as the Hebrews of the destruction

it would inflict on their crops. They considered it as the instrument of vengeance directed by a particular deity, to whom they applied the same appellation as to the disease itself. (*Schneider's Scriptorum Rei Rusticæ*, vol. i. pt. ii. p. 246.) To propitiate this presiding deity, a festival entitled *Rubigalia*, was instituted by Numa in the eleventh year of his reign, that is, 704 years before the birth of Christ. It was celebrated annually on the 25th of April, in the neighbourhood of a grove, at the fifth milestone, on the Claudian Way, and comprised sacrifices, races, and obscenities. Reddish-coloured bitches (*rufæ canes*) were sacrificed, because the lesser dog-star was then in the heavens, and was considered unpropitious to corn. (*Plinii Hist. Plant.* lib. xviii. c. 29; *Varii Flacci Facti*, p. 63.)

Ovid, who enters fully into the religious performances of the festival, says, that the limbs of a sheep and the entrails of a dog were offered as a sacrifice on the occasion; and that the priest informed him that he knew of no reason for the latter animal being sacrificed, but that its name coincided with that of the constellation which at that season was apparent in the sky. The prayer addressed by the priest to the presiding deity marks so strongly their knowledge of the extent and inducements of the disease, that I shall give a nearly literal translation of a part:—

“O, blighting Rubigo, spare the corn-plants.
And let the ear wave gently o'er the surface of the earth:
Suffer the crops which have been nourished by the propitious
Stars of heaven, to grow until they become fit for the sickle.
Thine is no small power; the crops thou hast marked
The dispirited cultivator reckons as lost.
Neither winds, nor showers, so much injure the corn;
Neither when bitten by the frost does it acquire a hue
so pallid,
As if the sun fervently heats the moist stalks;
Then, O! dread goddess, is the opportunity for thy wrath;—
Be merciful, I pray, and withhold your rusting hands
from the crops;
Nor harm the cultivated land: it is sufficient to be able
to do harm.”

The misty weather, mistaken by the Roman cultivators as actually a cloud of mildew, is only one of many numerous instances which might be quoted where causes of the disease have been considered to be the disease itself. To enumerate these would form a long catalogue of mistakes; yet these I should not hesitate to detail, because the refutation would incidentally introduce much useful information, but that they will for the most part be noticed among the circumstances which promote the occurrence and aid the progress of this epidemic.

The first person, I believe, who correctly pointed out the nature of mildew, was Felice Fontana, who, in the year 1767, published at Lucca a very particular description of the fungus occasioning it, in a work entitled “*Osservazione sopra la Ruggine del Grano.*” Since then it has engaged the attention of many botanists, and the results of their researches have been to establish it as a distinct species of fungus, though they differ as to the genus to which they attach it. It is the *Puccinia graminis* of

Persoon (*Disp.* t. 3, f. 3); and it is the *Uredo frumenti* of *Sowerby*.

In Plate 2 there is a representation of this fungi, in which

l, is a portion of wheat-straw affected with rust, magnified, to show the parasitic plant or fungus, giving rise to the disease called rust, blight, and mildew.

m, Another portion of a diseased stem in a green state, and before the fungus is quite ripe.

n, The small portion marked *l* (*l*), still more strongly magnified.

o, p, q, r, s, t, u, Very highly magnified representations of the fungus parasite in different stages of growth and maturity.

o, Shows it in the young state; *p*, full-grown; *q*, two plants bursting and shedding their seeds when under water in the microscope; *r*, two plants bursting in a dry place; *s*, apparently abortive; *t*, seeds in a dry state; *u*, a small part of the bottom of a pore, with some of the parasitic fungi growing upon it.

Rust grows on the leaves and stems of wheat, &c., appears in dense diffuse tufts, often confluent, forming long, parallel lines on the culms; at first brownish-yellow, but changing to black. Sporidia elongated, clavate, very slightly constricted at the septum; upper cell the shortest; stipes filiform. It must not be confounded with another parasitical fungus, which is common upon the wheat-leaves and culms, but which is not so injurious, namely, the *Uredo rubigo*, of *Decandolle* (*Flora Franca*, vol. vi. p. 83). Characterized by spots yellow; heaps oval, scattered, generally epiguous; epidermis at length bursting longitudinally; sporidia sub-globose, red-brown, easily dispersed. If the straw of wheat be examined with the assistance of a magnifying glass, its striped surface will be seen to arise from longitudinal partitions of the outer bark or epidermis. The depressed partitions are furnished throughout their length with 1 or 2 rows of pores or orifices, which seem capable of emitting or imbibing moisture as the wants of the plant may require. Similar pores, though varying in form and arrangement, pervade the leaves and chaff, or glumes; and it is in these pores that the seeds of the parasitical *Puccinia* obtain admission, and, vegetating in the cavities to which they lead, doubtless thrust their minute roots into the cellular texture beneath the bark, and intercept for their own nourishment that sap which should proceed to the grain for its development and completion. The corn necessarily becomes shrivelled, proportionally as the fungi are more or less numerous on the plant: and as it is the nutriment that would have perfected the interior of the grain, which is chiefly extracted by the fungi, for the exterior form is nearly completed before the mildew occurs, the proportion of flour to bran is always much reduced. Sir J. Banks observed, in 1804, which was a “mildew year,” that some of the wheat would not yield from a sack so much as a stone of flour.

Sir Humphry, then Mr. Davy, placed the loss caused by this fungus beyond a doubt, by chemical analysis. He found that 1000 parts of

	Flour.	Bran.
Thin-skinned Sicilian wheat afforded of -	Gluten, 239 } Starch, 722 }	961 39
Middlesex wheat, average crop -	Gluten, 190 } Starch, 765 }	955 45
Spring wheat, -	Gluten, 240 } Starch, 700 }	940 60
Mildewed wheat of 1804	Gluten, 130 } Starch, 520 }	650 350
Mildewed wheat of 1806	Gluten, 32 } Starch, 178 }	210 790

Showing, in one instance, a loss of 31 per cent. of flour in the mildewed when compared with the average English wheat, and in the other of nearly 74 per cent. (*Elem. of Agr. Chem.* p. 150.) Mr. W. Jones of Wilmington, Somerset, found that wheat, partially mildewed, produced one-fifth less of flour than that not affected.

I have almost always been able to detect the *Puccinia* upon the lower part of the culms, generally on the shoot-blade (*folia vaganans*), early in June; but it is not till the following month that the season determines whether the ravages of this fungus will be more than ordinarily extensive. Throughout July the English farmer should scrupulously, and almost daily, examine his wheat crop, especially that which appears strongest and most luxuriant; and if he detects any considerable number of tufts of the fungus upon the stems, must lose no time in using those curative measures which will be detailed in the close of this article. If July is hot and dry, it may be concluded, without much fear of disappointment, that there will be but little injury incurred by the mildew. The reason of this is very apparent; for in such a season no fungus will vegetate vigorously. This order of plants invariably delights and flourishes in a moist atmosphere, and in a subdued light, accompanied by gentle warmth. A *muggy* season is the most expressive term to describe that wherein the mildew vegetates most rapidly. In such seasons likewise, it unfortunately happens that the wheat plants remain longest succulent, their pores expanded, and their fibres relaxed; circumstances peculiarly favourable to the admission of the seeds of the fungus, to their vegetation, and to the penetration of their roots. That it is in such seasons the *Puccinia* vegetates most rapidly and extensively, is supported by the observations of others; for, although they consider such a season as the actual cause of the mildew, their testimony is equally valuable, though from it they have drawn erroneous conclusions. Thus, M. Duhamel says, that the mildew is caused by mild, hazy, or gloomy weather, while the corn is at the height of its vegetation; that is, about the time of its blooming. When a hot sun has succeeded such weather, he observed the wheat crops mildewed in a few days. He always observed wet springs very productive of this disease; but it rarely occurs in clear, dry, hot years. One or two writers have given most incomprehensible theories of the cause of mildew.

Mr. R. Somerville concluded that the mildew originates from the attacks of insects introduced with the manure; but he evidently intended by his descriptions the minute acarus (a species of louse), which is almost always to be found upon decaying vegetable matter; and in the cases of mildews, this insect is the follower, not the introducer, of the disease.

The Abbé Rozier, in his "Dictionary," observes that it is "caused by the drops of fog or dew, dissipated by a hot sun;" an opinion which is the echo of Ovid's verses forming part of the Flamen's prayer for the preservation of the Roman crops from this disease—

"Quantum, si culmos Titan incalfact udon;
Tunc locus est iræ Diva tremenda tuæ."

And such a season, as I have before observed, has a damp atmosphere, which, above all other states of the air, is favourable to the vegetation of this *Puccinia*. There is no doubt, also, that in such seasons vegetables are more than ordinarily weak and prone to disease, in which condition they are likely to become the prey of parasitic plants. "The application of cold water to the plant," says Mr. Knight, "on which the sun is shining strongly, is very injurious to its health, and therefore likely to give increased activity to any disease to which the plant is subject." This observation follows the detail of an experiment, in which he found that sprinkling wheat plants growing on ground very dry, with cold water, in the afternoon of a warm, bright day, caused them to be extensively mildewed. "A considerable absorption, therefore, probably took place; and to this absorption," says he, "and the effects of a sudden change of temperature, as secondary causes, I am disposed to attribute the appearance of the disease; but whether the seeds of the mildew were carried into the pores of the plants by the water, or existed there before, is a question which I shall not attempt to solve." (*Banks, On the Blight in Corn*, p. 30.) There is no difficulty in accounting whence the seeds of the fungi came: for Mr. Knight records, in the previous page, that other wheat plants close by were extensively mildewed.

The observations of Mr. Marshall, which were the results of long experience in many counties in England, coincide with the preceding opinions. "In a dry, warm summer," he remarks, "which is well known to be favourable to the health, vigour, and productiveness of the wheat crop, the seeds of the fungi are harmless, so long as the fine weather continues. On the contrary, in a cold, wet season, which gives languor and weakness to the wheat plants, few crops escape entirely. A succession of cold rains, while the grain is forming, is very inducive." Mr. Marshall previously concludes that "The fungi are an effect, not the cause of the disease;" an error which is at once refuted by the fact, that if all the fungi are removed from a plant, it is speedily cured.

Of other circumstances favourable or unfavourable to the occurrence or exasperation of mildew, little need be said, because they have comparatively little influence upon its occurrence. All soils and situations are liable to its incursions; for it is, in the fullest sense of the term, epidemic. The soil on which it appears the most rarely is a tenacious clay; and that on which, when it does occur, its ravages are the most extensive and destructive, is the light, calcareous, and rich. "As far as my observations extend," says Mr. Egremont, "the soils wherein clay predominates have yielded crops the least affected by the mildew. The soils most liable to have their crops injured,

particularly that of wheat, are the following, and in the order stated:—Peat or moor, calcareous, calcareous loams, sand, sandy loams, and another kind not found in any great breadth, but in patches, chiefly but not exclusively in clayey soils. The practical farmer calls it *gray earth*." (*Egremont's Obs. on the Mildew*, p. 93.)

The slightly superior power of clayey soils to protect the crop growing upon them from being the most severely affected by the mildew, probably arises from the temperature of such soils being less liable than lighter ones to sudden vicissitudes of temperature. Dr. Hales found, in the month of August, when the temperature of the air and of the surface of the soil were 88°, that the temperature of the soil 16 inches below the surface was 70°. In October, when the air and surface were at 35°, the temperature at 16 inches beneath was 48°, and at 24 inches 50°. This statement led me to make a few experiments upon the comparative rapidity of cooling, or, in other words, the power of conducting heat of various soils; and I invariably found, that the mercury in a thermometer, whose bulb was buried equally deep in a silicious, as those of others were in a calcareous and in an aluminous soil, rose most rapidly, and that in the last-named most slowly. Their rapidity of cooling followed the same order. Some experiments substantiating the same fact will be found in Sir H. Davy's *Agricultural Chemistry*, p. 179. Every gardener knows the injury his plants sustain from sudden vicissitudes of temperature. "Whatever has a tendency to check a quick and great loss of heat in the substances which surround such vegetables, particularly their roots, will be best calculated to save them from that injury, and from vegetable death; consequently, those earths which are the worst conductors of heat, or, in other words, are the longest in heating or cooling, will be most favourable in resisting any sudden alteration, and the vegetables growing on them will be the least injured when so assailed." (*Egremont's Observations on the Mildew*, p. 30.)

Situation appears to have rather more tutelary power than the soil, since I have invariably found the wheat growing in fields lying in closely enclosed valleys more frequently and more seriously injured by mildew than those upon elevated exposures. "A Lincolnshire Farmer," Mr. Lambreth and other writers in the forty-fourth vol. of the *Annals of Agriculture*, agree in this observation, and it is no more than might be anticipated from our knowledge of the habits of the fungus tribe; such situations being always more damp, and subject to a moist, foggy atmosphere.

All varieties of wheat are liable to the disease, but the *white* is always the earliest affected, and the bearded or rivet the last. This may arise from the latter variety having a firmer epidermis, arising from its containing a little more silex, and thence having its pores less easily acted upon by atmospheric changes, and consequently less liable to the entrance of the seeds of this fungus. Moreover, the hardness of the epidermis checks their rapid outspread

when vegetating. Mr. Sirs considered *spring* sown wheat not liable to this disease of *the* mildew, and that is the general opinion in South Holland. Other authorities *deem* that spring-wheat is exempted from it; and to this opinion I incline, in the absence of any thing like decisive knowledge on the point.

Early sowing is advisable, because the wheat plants, by this means, have a chance of passing the time of blooming before they are extensively attacked; and the more advanced the growth of the seed, the more it is out of the power of this parasite to check its perfection. Another reason suggested by Mr. W. Jones, of Wilmington, Somerset, is, that when sown late the plants are green and sappy in July, and even at the commencement of August, the season in which the cold and frosts occur that are so inducive of the disease; and this green state necessarily renders them more than ordinarily liable to suffer by such a reduction of temperature. On this account it is that in super-luxuriant crops, and plants growing upon dunghills, the former are liable to, the later almost always are infected by, mildew. Yet the time for sowing is no unfailing preventive, for in "mildew years" all crops are attacked; and instances have occurred where, in fields sown in September, October, and November, the first and the last have been most injured.

The *berberry* has been anathematized as a source of this vegetable pest; but I have never yet met with any facts which establish the charge. It is true that Rolesbury, in Norfolk, is locally known as "mildew Rolesbury," and that the berberry abounds in the neighbourhood of that village; but I know many low-lying arable districts, proverbially liable to the mildew, having no berberries in their vicinity. It is true that a band of mildew has been traced across a field of wheat from a berberry bush growing in one of its hedge-rows; but then I have seen a similar track of the disease commencing from an oak. It is also true that Mr. Knight, the late excellent president of the London Horticultural society, found wheat, sprinkled with water, in which berberry branches had been washed, speedily became infected with the mildew; but he also ascertained that wheat sprinkled with clear water, became similarly diseased. I have tried many experiments, with a view to ascertain the truth or error of this supposition, but have not succeeded. However, I am convinced that the parasite which affects the berberry is not the *Puccinia graminis*: the sporidia are dissimilar, and the colour totally unlike; but it may be, and certainly much resembles, the *Uredo rubigo*. It is no objection to say that the identity is unlikely, because the plants attacked are so widely distant; for, as already noticed, these parasites will vegetate on very various and even dead vegetable matters. The parasite which infects the leaves of the berberry is the *Æcidium berberidis*: it is a beautiful minute gastro mycus, and there is no resemblance between it and the rust of wheat, except in colour. It is a vulgar error to suppose that an *Æcidium* on the berberry could produce a *Puccinia* on wheat." See BERBERRY.

The age of the seeds, the thickness of sowing it, and previous or subsequent cultivation, appear to have no preservative influence; therefore, it now only remains to consider whence the seeds of the fungi come to the crop, which will lead to a consideration of the modes of prevention; and, lastly, whether there is any practicable cure. There seems to me little doubt that the fungus is communicated from the soil to the crop. It is certainly not conveyed thither with the seed-corn, for no washing, no cleansing, nor pickling of this has ever been observed to have any effect. In "mildew years," all fields of any infected districts are affected; and when it is only partial, one end, or a breadth across the middle of a field, of which the seed has all been treated alike, will be grievously injured, whilst the other parts suffer little more than ordinarily; for I have previously noticed, every year, and in all fields, the mildew is partially present. There is little difficulty in accounting for this. Every *Puccinia* sheds some hundreds of seeds, more minute and lighter even than those of the puff-ball; and as every wheat crop annually produces some, these are wafted over neighbouring closes by every wind during their seeding-time, which is chiefly in the months between May and October. In the soil upon which those seeds alight, they attach themselves to the stubble or other matters, and vegetate, reproducing seeds, or remaining without germination until the following spring. This fungus has also the characteristic of spreading by stooling, or throwing out offsets. This may be seen if its progress is watched upon any culm which it affects. I once placed in a paper box some pieces of straw that were more completely mildewed than any I had before observed; this was left during the whole winter in a closet, which at this season is unusually damp. Upon opening the box in the spring following, I found the *Puccinia* had grown, and spread in various rectilinear forms, upon one of its sides, and upon the bottom, a fact which I remember to have seen confirmed in one of the volumes of the *Quarterly Journal of Science*. The fungus, then, though its natural habitat is the culm of the wheat, will vegetate upon other vegetable bodies; and this satisfactorily explains the mode in which it may, after being preserved through the winter, be conveyed to the succeeding year's crop,—to say nothing of those seeds which may be attached to the straw of the preceding year, and be conveyed to the next year's crop by various modes.

These facts demonstrate that *prevention* is impossible; for however careful a farmer may be to avoid every source whence the seeds of the *Puccinia* may arrive, yet every summer wind may waft them to his crops from other, even far-distant lands. To prevent the communication to the wheat from the soil by the stooling, or spreading power of the fungus, it will be well to sprinkle the surface with salt, immediately after sowing, at the rate of 5 or 6 bushels to the acre; and in the spring, early in May, to apply, in a similar manner, about the same quantity of caustic fresh-slacked lime,

applications of which are not only destructive of the *Puccinia*, but also of slugs, and promote the general health of the crop.

For testimonies to the power of common salt to prevent, in some instances, the occurrence of mildew, I would refer the reader to my brother's *Essay on the Uses of Salt*, p. 50—60, where will be found the concurrent testimony of Sir John Sinclair, Mr. Siekler, Rev. R. Hoblyn, Mr. S. Robinson, Mr. Wood, and Dr. Paris. Mr. Prevost, quoted by Sir John Sinclair, states that the sulphate of copper, if dissolved in water at the rate of $3\frac{1}{4}$ oz. to the gallon, forms a solution which will prevent the attack of mildew upon the wheat plants arising from seed which has been steeped in it. I am afraid it has no such power.

Salt, if not a complete preventive, is an effectual cure of the mildew. Mr. Chatterton, a Lincolnshire farmer, says, in the 44th vol. of the *Annals of Agric.*, that "on the sea-side the wheat is little damaged by the mildew, yet within 3 miles inland the crops are as much affected as those still further from the sea." This fact can be supported by the experience of most farmers whose fields skirt our native shores; and unquestionably it is owing, not only to the soil containing a greater proportion of common salt than is found in more inland soils, but because the sea-haze, which rises almost nightly in the summer season, bathes, as it were, the crops in the immediate vicinity of the coast; and this haze holds in solution a portion of salt.

The following well-attested communication from the late Rev. Edmund Cartwright, of Hollenden House, near Tunbridge, is conclusive on this subject, and gives full directions to the farmer how to apply, and at what expense, a practical remedy.

"It gives me great pleasure to have it in my power to furnish you with some information respecting the application of salt, which, perhaps, you are not aware of. I, and a neighbour of mine, have applied it as a remedy for the mildew in wheat, with the most unequivocal success. I first made the discovery 2 years ago; my experiments at that time were upon a very limited scale; they have this year extended only over an acre and a half, but under circumstances that leave not a shadow of doubt of salt being an absolute specific for mildew, in the most aggravated stages of the disorder; of this I will state to you a convincing proof. In the year 1818 I found a few ears of wheat, which I conceived to be a new and improved variety; from these ears I raised as much wheat as last year planted a land 4 feet wide and 100 yards in length: the produce I had promised to Mr. Coke; and, to augment that produce, I had the ground, previously to planting, highly manured; and as soon as the wheat came up I gave it a good dressing with soot, and this dressing was repeated once or twice, in consequence of this superabundant dressing, the wheat, as might indeed have been expected, was as rank as the wheat you may observe growing accidentally upon a dunghill, which never fails to rot upon the ground, without bringing a single grain to maturity. The mil-

dew made its appearance on this particular part of my field, while the straw was quite green, and the grain in a milky state; notwithstanding the danger that might be apprehended to the wheat itself, from its being thus succulent, I ventured to give it a dressing with salt and water; as a heavy shower of rain fell a few hours afterwards, the dressing was repeated the next morning. The proportion of salt to the water, 1 pound in a gallon, laid on with a plasterer's brush, the operator bearing a pail of the mixture in one hand, and the brush in the other, making his casts as when sowing corn, or else with a common watering-pot, which, being swung with great force, throws the water very rapidly; 2 men will get over about 4 acres a day—the one to spread, the other to supply the mixture. The result was, that the mildew was completely subdued, and the wheat went forward to maturity; and although the sample was not so bold as it might have been, it was sound and marketable. In other parts of the field where the mildew showed itself, not under the aggravated circumstances described above, but as it usually appears, the wheat was not in the least injured by it after the salt and water was applied; it was, indeed, as fine a sample as could be grown. Both mine and my neighbour's wheat was examined by many practical farmers, who are so decidedly convinced of the efficacy of my remedy, that they intend never to be without a reserve of salt ready to meet the enemy the moment he appears. The effect of the salt upon the mildew, to those who do not consider the manner of its operation, is truly astonishing; I believe it to be *instant death to the fungus*; this, however, is certain, in less than 48 hours the straw nearly recovers its original colour and brightness. The certainty and celerity of its operation I account for thus: the mildew, it is now well ascertained, is a parasitical plant of the fungus tribe, the principal constituent of which tribe is water; when salt, therefore, is applied to them, the aqueous particles are immediately absorbed, and their vitality destroyed. The action of salt upon mushrooms, as in making mushroom catsup, confirms this theory." (*Johnson's Essay on Salt*, 3d ed. p. 52—54.)

I can afford decided testimony to the efficacy of the cure recommended by Mr. Cartwright; but I would add these precautions. The safest quantity of salt per gallon is 8 oz., and then the application may be rendered more effectual by frequent repetition, without any danger of injury to the plants. If the application is not made during a clouded day, it is best to defer it until the evening. Some have recommended a rope, held at its extremities by two men, to be drawn up and down each ridge of the infected crop to remove the fungus; and there is no doubt that this treatment is partially effectual, for the parasite is removed whenever it comes in contact with the rope, but the points of contact necessarily are limited.

Professor Henslow endeavours to prove (by strengthening with additional evidence his previously expressed opinions) the specific identity of the fungi producing rust and mildew. See RUST, ERGOT, DRY ROT, &c.

Mr. John Baker of Leeds, in commenting upon my brother's essay, is of opinion that the berberry has a considerable influence in the communication of the mildew to wheat, and gives several instances which seem to support his view of the case. But the distinction between the parasite of the berberry has already been mentioned, and it is scarcely necessary to repeat that the one cannot produce the other.

MILE (Lat. *Mille pasuum*, a thousand paces).

The following table, given on the authority of *Kelly's Cambist*, shows the length of the modern mile, and also the league, of various countries, and their relation to the English statute mile.

	Yards.	Stat. mile.
Modern Roman mile	1628	·925
English statute mile	1760	1·000
Tuscan mile	1808	1·027
Ancient Scotch mile	1984	1·127
Irish mile	2240	1·273
French posting league	4263	2·422
Spanish judicial league	4635	2·634
Portugal league	6760	3·841
German short mile	6859	3·897
Flanders league	6864	3·900
Spanish common league	7416	4·214
Prussian mile	8237	4·680
Danish mile	8244	4·684
Dantzic mile	8475	4·815
Hungarian mile	9113	5·178
Swiss mile	9153	5·201
German long mile	10,126	5·753
Hanoverian mile	11,559	6·568
Swedish mile	11,700	6·648

According to the same authority, the Arabian mile is 2148 yards, the Persian parasang 6086 yards, the Russian werst 1167 yards, and the Turkish berri 1826 yards. The English geographical mile is 1-60th of a degree of latitude, or about 2025 yards; the geographical league of England and France is 3 such miles, or 6075 yards; and the German geographical mile is equal to 4 English geographical miles, or 8100 yards.

MILFOIL, THE WOOLLY YELLOW. See YARROW.

MILIARY. In botany, a term signifying granulated; resembling many seeds.

MILK (Germ. *Milch*). A well-known fluid, secreted by animals for the nourishment of their young. See LACTOMETER, BUTTER, CHEESE, DAIRY, CATTLE, &c.

Cow's milk is that principally used by Europeans; that of the goat, and even of the sheep, is used in some parts of Britain; that of the mare is a favourite beverage in Tartary when it is fermented. If milk be left at rest, the fatty globules separate, rise to the surface, and form cream; if it be long agitated, they attract oxygen, coalesce, and form butter.

Milk owes its whiteness and opacity to an emulsion composed of the caseous matter and butter, with sugar of milk, extractive matters, salts, and free lactic acid; the latter of which causes fresh milk to redden litmus paper. Milk, in general, contains from 10 to 12 per cent. of solid matter, on being evaporated to dryness by a steam heat. The mean specific gravity of cows' milk is 1·030, but it is less if the milk be rich in cream. The specific gravity of the skimmed milk is 1·035; and of the cream is 1·0244. 100 parts of cream milk contain:—

Caseous matter, containing some butter	2 600
Sugar of milk	3 500
Alcoholic extract, lactic acid, and lactates	0 600
Salts; muriate and phosphate of potash, and phosphate of lime	0 420
Water	92 675
	<hr/>
	99,995
Cream consists of—Butter separated by churning	4 5
Caseous matter precipitated by the coagulation of the milk of the butter	3 5
Buttermilk	92 0
	<hr/>
	100 0

When milk contained in wire-corked bottles is heated to the boiling point in a water-bath, the oxygen of the included small portion of air under the cork seems to be carbonated, and the milk will afterwards keep fresh, it is said, for a year or two; as green gooseberries and peas do by the same treatment.

The number of cows kept in London and its environs for the supply of milk is estimated by Mr. Macculloch to amount to 9000, and their annual produce of milk to be equal to 78,800,000 quarts. For this purpose the Yorkshire cow is preferred to all others. The daily average of milk yielded by one of this breed is estimated, according to Mr. Youatt, at 22 or 24 quarts.

The quantity and quality of the milk produced by a cow is materially influenced by the food and distance from calving. Some interesting experiments to determine this were made by MM. Boussingault and Le Bel. They observe, "In the observations, of which the following table presents the abstract, it will be seen that the quantity of milk given by the cows progressively diminished. This diminution cannot be attributed to the regimen to which the cows were subjected, since, in

again putting them on the food on which they had previously fed, the same quantity of milk was not obtained as at first; the diminution continued. The distance from the period at which the cow has calved seems to be the principal cause of the decrease of the milk. This cause is so strongly marked, that it may even prevent the influence that the nature of the food exercises over it from being seen. Indeed, this result permits us to state, that the nature of the food consumed does not exert so very sensible an influence on the quantity and chemical composition of milk (we do not say on its quality), if the cows receive equal nutrition from the different kinds of food. It is very evident, that if the weight of the feeds were not calculated according to that of the equivalents, great variations would be observed in the products of milk; but then those variations would be principally caused by the augmentation or diminution of the nutritive matter. We know, for example, that cows which, during winter, are reduced to simple feeding on chopped straw, cease almost entirely to produce milk, and with difficulty recover their ordinary rate of production; in cognisance of such a fact, we are led to ascribe the return and abundance of milk exclusively to the properties of the green food in spring, whilst that effect is in a great part produced by a real increase in the feeds.

"In establishments where a regular rotation is followed, healthy and abundant nourishment to cattle in winter is in a manner assured, the difference, if any exist, betwixt the feeding in winter and summer, being in all cases much less considerable. These are the results of experiments made during a year on eight cows constantly fed together on a great variety of food."

There is a paper on the adulteration of milk, by M. Barruel (*Quar. Jour. of Agr.* vol. ii. p. 304), in which he states that the substances used to adulterate milk in London and Paris are usually flour, sugar-candy, potash, and sometimes iodine, to give it its bluish colour.

In Stephens's "*Book of the Farm*," we find the following interesting details relative to the subject of milk, milch-cows, and their treatment in Scotland, and more especially in the city of Edinburgh.

Cows are kept on every species of farm.

though for very different purposes. On *carse* and *pastoral* farms they are merely useful in supplying milk to the farmer and his servants. On *dairy* farms, they afford butter and cheese for sale. On some *farms near large towns*, they chiefly supply milk for sale. And on *farms of mixed husbandry*, they are kept for the purpose of breeding young stock.

On *carse* and *pastoral* farms, cows receive only a few turnips in winter, when they are dry, and are kept on from year to year; but where the farmer supplies milk to his work-people, as a part of wages, they are disposed of in the yeld state, and others in milk, or at the calving, bought in to supply their place, and these receive a large allowance of turnips, with perhaps a little hay. On these farms, little regard is paid to the breed of the cow, the fact of being a good milker being the only criterion of excellence.

On true *dairy* farms, the winter season is not a favourable one for making butter and cheese for sale; for, do what you like to neutralize the effect of the usual rooted green crops on these products, and especially butter, they remain unpalatable to the taste. The cows are therefore in calf during this season, and receive the treatment described above until the period of calving in spring.

In and near large towns, the *dairy-man* must always have milk to supply his customers, and it is his interest to render the milk as palatable as possible. For the purpose of maintaining the supply, he buys cows at all seasons, just calved or about to calve. He disposes of the calves, without attempting to fatten them; and to render the milk he sells palatable, he cooks all the food partaken of by the cows. When the cows run dry, they are fattened for the butcher, and not allowed to breed again.

The cows in the public dairies in Edinburgh are supported in winter on a variety of substances, namely, turnips, brewers' and distillers' grains, called *druff*, *dreg*, malt-comins, barley, oats, hay-seeds, chaff, cut hay. One or more of these substances, with turnips, are cooked together, and the usual process in doing this, and administering the cooked food, is as follows:—Turnips, deprived of tops and tails, and washed clean, are put into the bottom of a boiler, and covered near to its top with a quantity of malt comins, cut hay, hay-seeds, chaff, or barley, or more than one of these, as the articles can be procured. Water is then poured into the boiler sufficient to boil them, and a lid placed upon it. After being thoroughly boiled and simmered, the mess is put into tubs, when a little pounded rock-salt is strewed over it, and chopped into a mash with a spade. As much *dreg* is then poured upon the hot mash as to make it lukewarm, and of such a consistence as a cow may drink up. From 1 to 1½ stable-pailfuls of this mixture,—from 40 to 60 pints imperial,—according to the known appetite of the cow, is then poured into the trough belonging to each. The trough is afterwards removed and cleaned, and the manger is ready for the reception of fodder—hay or straw. This mess is given 3 times a day, *after* the cows have been milked, for *dairy-men* understand that animals should not be disturbed while eating

their food. The times of milking are 6 A. M., 12 noon, and 7 P. M. The sweet milk and cream obtained by these means, and received direct from the dairy, are pretty good. The former sells in Edinburgh at 1*d.*, and the latter at 1*s.* the imperial pint. Dr. Cleland states the price of sweet milk in Glasgow at 1½*d.* the imperial pint.

It will be observed that none of the articles usually given to cows are so expensive as oil-cake, cabbages, kohlrabi, or cole-seed. These products were employed by the late Mr. Curwen in his experiments to ascertain the cost of raising milk for supplying the poor, and the results show they left him very little profit. (*Curwen's Agricultural Hints*, p. 47—52.)

Cattle are fed on other substances than turnips, either with themselves or in conjunction with turnips. Oil-cake and potatoes are the most common substances used for this purpose. Linseed oil and linseed have been recommended, and many are fed at distilleries on *druff* and *dreg*, as the refuse of distillation are termed; and these are also sold to the farmers for the purpose of feeding. Oats, barley-meal, and bean-meal, have also been pressed into the service of feeding cattle.

The potatoes used in feeding cattle are either the common kinds known in human food, or others raised on purpose, such as the yam and ox-noble; and they are given either alternately with turnips, or together. In feeding cattle with potatoes of any kind, and in any way, there is considerable risk of flatulency and choking. To prevent the latter, the potatoes should be smashed with a hammer, or with an instrument like a pavier's rammer, and though juice should come out in the operation, no loss is incurred, as it is considered of no service in feeding. To prevent flatulence from potatoes is no easy matter; but a friend of mine used a plan which completely answered the purpose, which was, mixing cut straw with the broken potatoes. The straw obliging the cattle to chew every mouthful before being swallowed, may prevent such a large quantity of gas being generated in the paunch as bruised potatoes alone would do, and it is this gas which occasions that distressing complaint called *hoven*. A farm-steward, who had considerable experience in feeding cattle on potatoes on a led-farm, always placed as many potatoes, whole, before cattle as they could consume, and they never swelled on eating them, because, as he conjectured, and perhaps rightly, they do not eat them so greedily when in their power to take them at will, as when doled out in small quantities. This fact confirms the propriety of mixing cut straw amongst potatoes that are given in small quantities, in order to satisfying the appetite, and filling the paunch with unfermentable matter. The only precaution required in giving a full supply of potatoes, is to give only a few and frequently at first, and gradually to increase the quantity.

Oil-cake has been long and much employed in England for the feeding of cattle, and it is making its way in that respect into Scotland. It consists of the compressed husks of linseed, after the oil has been expressed from it, and is formed into thin oblong cakes. The cakes are

broken into pieces by a machine. Cattle are never entirely fed on oil-cake, but in conjunction with other substances, as turnips, potatoes, cut hay, or cut straw. When given with cut hay or straw, an ox will eat from 7 to 9 lb. of cake a day, and the hay or straw induces rumination, which the cake itself is not likely to do. When given with other substances, as turnips or potatoes, 3 lb. or 4 lb. a day will suffice. A mixture of oil-cake and cut meadow-hay forms a very palatable and nutritious food for oxen, and is a favourite one in England. Oil-cake costs from 7*l.* to 10*l.* a ton.

Statement of the comparative quality of Milk from 8 Alderney and 8 Kerry (Irish) Cows, upon the Farm at Oakley Park, in May, June, July, and August, 1840, by Mr. R. White, tested from a Lactometer holding 1 Pint of Milk, and divided into 100 parts by Index.

Cows.	Portion of Cream in 100.	Difference.	Observations.
May.			
Alderneys	25	15	In favour of Alderney.
Kerrys -	10		
June.			
Alderneys	20	10	Ditto.
Kerrys -	10		
July.			
Alderneys	23	13	Ditto.
Kerrys -	10		
August -			
Alderneys	16	3	Ditto.
Kerrys -	13		

Butter churned from 3 pints of cream from each :—

Alderneys - 1 lb. 8½ oz. }
Kerrys - 1 lb. 4¼ oz. } 16 oz. to the pound.

This was taken in August, when the Alderneys' produce of cream was at the lowest.

MILK-FEVER. Cows in high condition are most subject to puerperal fever. This inflammatory disease sometimes appears as early as two hours after parturition; if 4 or 5 days have elapsed, the animal may generally be considered safe. On the appearance of this fever, from 6 to 10 quarts of blood should be taken, according to the age and size of the animal. The bowels must be opened, or the disease will run its course; and purging once established in an early stage, the fever will, in the majority of instances, rapidly subside, leaving the strength of the constitution untouched. (*Youatt on Cattle*, p. 547, 548.)

MILK-HOUSES AND CELLARS. The milk-houses in Holland and elsewhere, and the spring-houses of Pennsylvania, have been referred to and described under the head of **DAIRY**. Of late, cellars under houses, properly arranged, are coming to be preferred for the purpose of keeping milk to either milk-houses, milk-vaults, or even spring-houses. Among the advantages claimed for cellars are, being at hand everywhere at a small cost; and keeping drier, thus less disposing to must.

Mr. Miller, of Delaware, a correspondent of the *Farmers' Cabinet* (July, 1843), speaking of the cellars used in the vicinity of Wilmington, says :—It is found sufficient, if the cellar be

sunk a few feet below the surface of the earth, with a wide and shallow window on each side, the bottom of it level with the ground outside; well protected with a wire guard to keep out vermin, large flies, &c., and provided with a close glazed sash, which can be opened and closed at pleasure, by lifting it up to the ceiling, which ought to be no higher than the top of the windows; so that the air of the cellar can be ventilated by opening the windows of the two opposite sides, according to the way the wind sets at the time, shutting them quickly when necessary; for in cold, windy, or damp weather, the sooner the windows are again closed, the better. Indeed, to the management of the cellar in this particular, much of the success of dairying is to be attributed; cold and damp air being unfriendly to the formation of cream and its proper and entire separation from the milk. Hence, therefore, it is a bad practice to set the pans on the brick floor of the cellar; they ought always to be placed around on shelves, about three feet in height, and these, after being well washed with hot water, should be wiped quite dry, that no mouldy evaporation might take place to spoil the butter. The air near the floor of a dairy is always impure, being loaded with acid vapours and putrid exhalations, the density of which confines it to the lowest part of the room; hence it is, that the doors of some dairies are made with lattice work, that the air near the floor, as well as that near the ceiling, might be ventilated at the same time; these lattices being furnished with sliding panels, may be kept close in bad weather. The milk-cellar ought always to have a northern aspect, and be well shaded by trees, not growing too near the windows, so as to impede a dry current of air, or to create a moist atmosphere; this consideration being of more importance than would readily be imagined.

Cellars thus constructed and carefully attended, will, no doubt, supersede the use of spring-houses generally, before many years have passed away; by which the business of the dairy will be rendered more agreeable, less laborious, and far less inimical to the health of those, particularly of females, whose occupation it is to attend to its never-ceasing duties. In the Wilmington market, "cellar-butter" usually commands an extra price.

MILKING. In the operation of milking, the great rules to observe are, regularity, gentleness, and cleanliness. The following observations are taken from an American periodical: "When you go to milk, take a vessel of cold water and sponge. Wash the udder and teats clean, dashing on the cold water. This will prevent the teats from becoming sore, and the udder hot and feverish, besides rendering the process of milking much neater. Milk with clean hands. The whole business of milking is frequently conducted in such a slovenly manner that the milk is entirely unfit for food. The cow should be milked while eating her fodder at morning and evening. She should always be milked and fed at the same time in the day, and uniformly by the same person. Milk without interruption. Be sure to milk the cow as dry as possible. To be milked by different hands, at different times in the day, in

a slow, interrupted, gossiping manner, and leaving part of the milk in the udder, will ruin the best cow in the world." If the cow has sore teats, foment them before milking with warm water, and after milking, dress them with the following salve: Melt together 1 oz. of yellow wax, and 3 oz. of lard, and as these begin to get cool, rub in a $\frac{1}{2}$ of an oz. of sugar of lead, and a drachm of finely pounded aloes. (*Youatt on Cattle*, p. 552.)

MILK-PARSLEY (*Selinum*, from *selinor*, the Greek name for parsley; applied to this genus on account of the resemblance in the leaves). This is a hardy genus of plants of no interest. The only species indigenous to England is the marsh milk-parsley (*S. palustre*), which is perennial, or, as some have it, biennial, growing in wet and boggy meadows, with flowers white, numerous, uniform. The root serves the Russians for ginger; and the whole herb abounds with a white, bitter, fetid juice, of the consistence of cream, which soon dries to a brownish acrid resin.

MILK SICKNESS. This name, together with "Trembles," has been applied to a peculiar and most malignant disease occurring in some localities of the Western United States, and affecting certain kinds of farm-stock, and persons who make use of the meat or dairy products of infected cattle. Bishop Hennipin, a French missionary, who ascended the western waters early in the last century, mentions the existence of this singular disease affecting animals. Although the cause and precise nature of so frightful a malady are still enveloped in great obscurity, and the treatment is far from being so generally successful as could be desired, it may be interesting to be acquainted with some facts connected with its existence. Dr. George B. Graff, a highly intelligent physician of Edgar county, Illinois, has a communication upon the subject in the *American Journal of the Medical Sciences* (April, 1841), from which we draw the following details:—

The milk sickness is a disease peculiar to the United States, occurring seldom, if ever, to the eastward of the Alleghany mountains. It is in a greater or less degree met with in all the Western States, as far south as Mississippi, and extends north to the boundary. The states of Indiana and Illinois are most subject to its occurrence, whilst its existence in the bordering states is comparatively rare. Among the early settlers it committed dreadful ravages, and in the formation of our Western settlements, its prevalence often served as a cause to disband a community, and compel the inhabitants to seek a location which enjoyed immunity from its occurrence. Many of the otherwise most desirable portions of that country remained long exempted from settlement, and even now the inhabitants of these localities have, as a condition of their residence, entirely to abstain from the use of milk, its preparations, and the flesh of their cattle.

Its occurrence or prevalence is confined to no season or description of weather, existing in a like degree in the heat of summer or cold of winter, and with like virulence and frequency during a dry or wet season. An opinion is entertained by some, that it is more

frequently met with in the spring and fall months, whilst others have expressed a belief of its more common occurrence during the heat of summer. However this may be, we know of no season during which it does not occur.

The animals in which it has been observed are the beef-cattle, horses, sheep, and goats, which seem to acquire it with their food or drink.

We will first speak of the *symptoms* manifested in cattle affected with it, as it is only through them that we have yet found the disease communicated to man. They may be affected to such a degree as that their flesh and milk will produce the disease, and yet they themselves manifest no unhealthy symptoms whatever. This latent condition of the disease may be discovered by subjecting the suspected animal to a violent degree of exercise, when, according to the intensity of the existing cause, it will be seized with tremors, spasms, convulsions, or even death. This is a precaution practised by butchers in these countries always before slaughtering an animal in anywise suspected of the poisonous contamination. An ordinary degree of exertion will not develop these phenomena unless it produce the symptoms usually preceding a fatal termination. When, for instance, a cow is sufficiently deeply affected, nothing peculiar is observed until immediately preceding the outbreak of the fatal symptoms. She is then observed to walk about, without any apparent object in view; all food is refused, and there is evidence of impaired vision. The eye is first of a fiery appearance, increasing to a deepened red colour, until the animal is observed to stagger and fall, when, if she rises, the trembling of the whole muscular system will prevent the maintenance of the standing position. The animal usually dies after repeated convulsions, never lingering beyond a few hours. Often it falls suddenly, as if it received a blow from a heavy body on the head, and death is produced in a few minutes.

From the tremulous motion imparted to the muscles, the affection has received the common name of the "Trembles" in cattle. A case which was characterized by the great violence of its symptoms, I had an opportunity to examine very shortly after death. The brain I found suffused with a large quantity of fluid blood, which, from the amount contained within the cranium, must have made great pressure on every part.

In man the symptoms differ from these, and are varied. The length of time found to elapse from the reception of the cause to the appearance of the disease, is dependent on a multiplicity of circumstances, as the age, sex, or condition of the patient, and violence of the poison. It may be developed early as the third, or deferred until the tenth day. As a premonitory symptom, a peculiar and indescribable fetor from the lungs is the most prominent; and so universally have I found it present and to precede the disease, that in almost every instance where I have been brought in proximity to a person predisposed or attacked, have I been able to foretell its approach, and pro-

nounce on the character of the disease. This fetor can no more be mistaken by a person accustomed to it, than that which is so universally attendant on variola; and it may in fact be safely stated to be pathognomonic of the forming and early stage of milk sickness. This halitus from the lungs, which I have never found entirely wanting even some days previous to an attack, increases in intensity until the disease is fully developed, when it gradually disappears with the specific symptoms, and at the termination of 4 or 5 days cannot be detected. A person labouring under the peculiar effluvia from the air passages, in many cases complains of no illness, and appears entirely unconscious of his situation, unless advised of it by his friends or attendants. His appetite may be, and usually is, destroyed; and after the lapse of a few days he is taken down with pain and excessive irritability of the stomach, obstinate constipation of the bowels, a cessation of all biliary secretion, general febrile action, sometimes an intense burning sensation in the epigastric region, with early and obstinate coldness of the extremities. Often the symptoms are observed to differ widely from these. Besides the peculiar smell emitted, there is a premonition of the attack; for some days previous to its development, the patient experiences a restlessness and uneasiness which he cannot describe, with a dread of some impending calamity, confusion of ideas, and other indications of irritation of the brain and nervous system. Vomiting announces the onset of an attack. This continues at short intervals for many days, the matters thrown off the stomach consisting of the fluids swallowed, mixed with a glairy mucus, and not unfrequently tinged with blood. Some days frequently elapse before pain in the stomach is complained of, but during the time the suffering is intolerable, consisting of a sensation of deep distress, which, though referred to the præcordia, or abdomen, the sufferer cannot locate in any particular spot. Pain in the limbs is complained of, and is severally referred to each of the extremities, but is more constantly located in the spine, particularly at the nape of the neck. The pulse, during the forming stage, possesses greater force and volume, with slightly increased action. The bowels will remain obstinately constipated, the powers of nature being incompetent to relieve the condition, so that unless it be done by appropriate remedies, at the end of 6 or 8 days an offensive discharge takes place, quickly followed by dissolution, the symptoms being those which would indicate disorganization of the structure of the intestines. The tongue, during the initiatory stage, is slightly furred, but otherwise not much changed in appearance. This coat disappears soon after the occurrence of vomiting, and becomes clean, of a pale-red or pink colour, greatly resembling a piece of raw veal. Next to the fetor mentioned, the change of volume occurring in the tongue may be viewed as the great characteristic of this disease. It rapidly attains an inordinate size, completely filling the mouth, and so flabby and soft in its texture as to retain perfectly the impressions left by the teeth, when extruded.

Often a number of efforts are necessary before it can be forced out, and then it has a tremulous motion. This condition of the tongue changes with the stage of the disease. When the vomiting has been suspended, and free evacuations from the bowels obtained, it is reduced in volume, the surface is for a time smooth and glazed, soon after becomes dark, cracks open in transverse fissures, is hardened, with an obstinately dry and rough surface. Of all the primary symptoms, vomiting is the last to disappear; it ceases very gradually to annoy the patient, and its continued absence is the most certain indication of a state of convalescence. In no disease is there a greater difference or diversity of symptoms than are usually found in different cases to constitute what may be properly termed the secondary stage of milk sickness.

In some cases the patient is affected with drowsiness, low muttering delirium, nervous tremors, and the whole train of symptoms associated in low typhus fever. When recovery takes place after severe attacks, the convalescence is very slow, and years may elapse before a perfect restoration to health. Indeed, it has been a question with many, whether those once severely attacked ever regain a perfect integrity of constitution. In cases which terminate fatally (of which description is a large majority), a length of time of from 1 to 4 weeks is required, proportionate to the intensity of the primary effects, the propriety of the treatment, and the natural powers of the resistance of the constitution, as they often seem to die from a wearing out, or gradual destruction of cerebral and nervous energy. Those cases which occur during the summer months, are most decidedly inflammatory, whilst in the winter there is always observed a disposition to assume a low form. The autumnal cases, in their secondary fever, are liable to assume a remittent aspect, and I have seen them eventuate in a well-marked intermittent. When recovery has taken place, the patient retains not the slightest recollection of any thing which occurred during the progress of the disease, and this forgetfulness often extends as far back as some days previous to the active development of the disease.

Cause.—The cause of this disease in animals is as yet shrouded in mystery and uncertainty. No satisfactory account of its nature has ever yet been given, and it has in turn been supposed to be of vegetable, mineral, and even ærial origin. The limits of its prevalence is not often over a large continuous tract of country, but rather circumscribed, and surrounded by localities never known to produce it. No example is known in which the property of producing the disease has been acquired by any locality which did not previously possess it. The boundaries which were at the first discovery of the country found to separate the infected from healthy districts, remain unchanged. The locality which serves to produce the disease, most commonly extends as a vein of variable breadth, traversing the country for a considerable distance. It can be traced in one instance for nearly a hundred miles, running parallel to the course of the Wabash river, in the state of Indiana.

Again—it will be found to occupy an isolated spot, comprised in an area of 100 acres, whilst, for a considerable distance around, it is not produced. Thus, having the locality perfectly circumscribed, much labour has been expended in order to discover some production peculiar to the locality. The search has been uniformly unsuccessful in the attainment of its object. The general appearance of these infected districts is somewhat peculiar. I have always observed that the situation of the ground is elevated above that of the surrounding country, occupying what is denominated a ridge, and that the quality of the soil is in general of an inferior description. The growth of timber is not observed to be so luxuriant as in situations otherwise similar, but is scrubby, and stunted in its perfect development, in many instances simulating what in the west is denominated "Barrens." Throughout the entire district in which these localities are interspersed, there is observed an absence of the occurrence of stones scattered over the surface, whilst in the infected tracts they are almost universally present. They are of a small size and darkened aspect externally, breaking with a regular and shining fracture, and, upon analysis, imperfectly made, were found to contain a considerable portion of iron, with slight traces of copper. Another more decided and peculiar appearance, which serves to distinguish them from other spots, is the breaking forth of numerous feeble springs, furnishing but a trifling supply of water, but not varying in quantity with the change of seasons. In its appearance, it presents the general evidences of a sulphurous and ferruginous contamination.

Experiments made upon the water collected from these springs, or more properly called oozes from the soil, with the greatest care by the employment of the most delicate chemical re-agents, failed to indicate the presence of any mineral except iron, sulphur, traces of magnesia, and a quantity of copper barely capable of being demonstrated. A belief being entertained by many that the disease is occasioned by arsenic, or some of its salts, I with much care and patience subjected not only the water, but likewise the earth, from these districts to a most rigid examination, and by no test was I furnished with the slightest evidence of its presence.

An intelligent medical friend expressed to me his belief that it was produced by the inhalation of some noxious gases generated during the night; in proof, he stated that he had observed cattle, which were regularly housed each evening, escaped its attacks, and that when suffered to remain at large, they were frequently seized with the disease. It is difficult to form this belief of the nature of the cause, as we can hardly conceive the particular action of any combination of circumstances, capable of giving rise to such an emanation only at night, ceasing to act during the day. The most popular belief is in favour of a vegetable origin. The advocates of this method of production having failed to designate the plant which they supposed occasions it, have endeavoured to sustain their views by supposing that the poison exists in some shrub or tree,

which is eaten by the cattle, but confess their inability to designate any such peculiar growth confined to these localities. If certain fields which are known to affect cattle fed upon them, be suffered to grow in grass, and the hay produced be given to them for their continual food, no disease results, which is a strong circumstance, unless it be urged that the active poisonous principle is destroyed by the desiccation. Again, it has frequently appeared with its greatest virulence when the ground has been for weeks previously covered with snow.

Butter and cheese, manufactured from the milk drawn from an infected cow, are supposed to be the most concentrated forms of this poison. They possess no distinguishing appearance, odour, or taste, from the healthy article. A very minute quantity of either will suffice to develop the disease in man. The cream, ordinarily sufficient to be added to the coffee drunk at a single meal, is said to have induced an attack. The butter or cheese eaten at one repast, has frequently been known to prove effective. The property is not contained in any of the elements of the milk exclusively, but distributed throughout the whole of them, being possessed by the buttermilk as well as by the whey. Beef, in the quantity of a very few ounces, will produce the disease, and, it is generally believed, in a more violent and fatal form than when it is produced by milk, or any of its preparations.

In the course of my observations I had an opportunity to experiment with a cow suffering in but a slight degree from the cause. She was affected with tremors when unusually exercised, exhibited a red and suffused eye, with frequent twitches of portions of the muscular system. She was kept confined without an opportunity to exercise, and was fed upon ordinary food. At the end of 8 days, the milk drawn from her possessed as violent poisonous properties as at the time of her incarceration. Her confinement was continued for a week longer, at the end of which period, the milk taken from her was found in an entirely healthy condition, and the eyes were restored to their natural appearance. In this instance it will be seen that the property of imparting the poison to the milk was lost in the space of between 8 and 15 days. We, of course, cannot fix on the precise period, but we would infer that the property is suddenly destroyed rather than gradually dissipated.

My trials with the poisoned flesh were, for the most part, made upon dogs, which I confined, and often watched the effect of the poison when administered at regular intervals. In the space of 48 hours from the commencement of the administration of either the butter, cheese, or flesh, from poisoned animals, I have observed unequivocal appearances of their peculiar action. In a few hours a thirst greater than natural is created; the appetite remains unimpaired until the expiration of the fourth or fifth day, or just before the appearance of fatal symptoms, when the animal will refuse drinks, and the most inviting descriptions of food.

Vomiting does not, as in man, always precede death, but the bowels are constipated throughout, except that, in a single instance

observed copious alvine discharges largely mixed with blood. One ounce of butter or cheese, or 4 ounces of beef, either raw or boiled, administered 3 times a-day, will certainly prove fatal within 6 days, and often earlier. In these cases all exertions and exercise must be prevented, or death will occur much sooner, even as early as the third day. When an animal has been subjected to its influence for only a short time, and is induced to fatigue itself, or is driven a distance at full speed, he suddenly stops and falls, and the severity and duration of the convulsion or spasm is in proportion to the intensity of the action of the poison. Often he will appear to entirely recover from the first attack, but to be repeated upon the renewal of the exercise to a sufficient degree.

There is, however, one animal which, from some peculiarity of organization, is rendered proof against the pernicious effects of this otherwise powerful agent. I allude to the hog. Most industriously did I feed a troublesome sow running at large, administering, daily, 5 or 6 pounds of infected beef. This was persevered in for more than a fortnight, and under the treatment she fattened, when I was compelled to desist from the great quantity necessary to supply her voracious appetite, without enjoying the satisfaction to perceive one muscular twitch as an evidence that it produced the slightest effect. When I last saw her she enjoyed excellent apparent health, and was the mother of a numerous offspring.

From all the experiments I have made, and the reasoning used, I can arrive at no conclusion, so far as relates to the nature of the ultimate cause in man, to whom it can only be communicated through the medium of an animal, and that capability of production can be acquired only by the animals of circumscribed localities. An intelligent medical friend, alike distinguished as a statesman, Dr. John W. Davis, of Indiana, in a late letter to me, expresses a belief that milk is never a cause of the disease. He merely states his belief of the fact, without the evidences or observations which have led him to the denial of a proposition heretofore viewed as settled beyond dispute. My own experience enables me to say that I have seen a peculiar affection, which I feel assured could have been no other than the milk sickness, in a city remote from any of its local causes, attacking every individual who partook of a certain cheese which had been purchased from a wagon arriving from an infected district. In this instance the well-marked symptoms, confined to those only who partook of this cheese, appearing nearly at the same time, with no occurrence of new causes after the removal of this cause, all together afford strong evidence of the nature of the origin.

There is a murderous practice now carried on in certain districts, in which the inhabitants will not themselves consume the butter and cheese manufactured; but, with little solicitude for the lives or health of others, they send it in large quantities, to be sold in the cities of the West, particularly Louisville, Kentucky, and St. Louis, Missouri. Of the truth of this I am well apprized by actual observation, and I am as certain that it has often caused death in those

cities, when the medical attendants viewed it as some anomalous form of disease, not suspecting the means by which poison had been conveyed among them. Physicians of the latter city having been questioned particularly on this subject, have mentioned to me a singular and often fatal disease which appeared in certain families, the cases occurring simultaneously, and all traces of it disappearing suddenly, and which I cannot doubt were the result of poisoned butter or cheese. This recklessness of human life it should be our endeavour to prevent, and the heartless wretches who practise it should be brought to suffer a punishment commensurate with the enormity of their crime. From the wide extent of the country in which it is carried on, we will readily perceive the difficulties to be encountered in the effort to put a stop to the practice. This being the case, our next proper aim should be to investigate the nature of the cause, and established a more proper plan of treatment by which it may be robbed of its terrors, and the present large proportionate mortality diminished.

Nature and Treatment of the Disease.—Much diversity of opinion exists among medical men in regard to the essential nature and most proper mode of treating this fatal disease, from which hundreds of persons throughout the West and Southwest annually perish.

Owing to the want of success which has so uniformly attended the practice of their physicians, many of the inhabitants depend entirely on their domestic remedies. It is in that country emphatically one of the *opprobria medicorum*.

"The primary operation of the poison," says Dr. Graff, "seems to be on the brain and nervous system, and this is indicated by the cerebral irritation which so often precedes, and always accompanies an attack, as well as by autopsic appearances. Without an exception, in the animals poisoned, I always found the brain and meninges phlogosed with a greater or less degree of inflammatory action."

Dr. Graff relates the following circumstance, connected with the occurrence of the disease, which will tend to show its mode of development and characteristics. The entire family of a Mr. Frazier, moving westward, purchased a quantity of fresh beef in Indiana, of which every member of the company partook heartily, daily, until the evening of the fourth day, when they arrived in the Doctor's neighbourhood. On this evening they all retired apparently in their usual health, but during the night he was summoned to attend a female with an attack of milk sickness. Upon a careful examination he discovered the peculiar smell present with every member of the family, and, on inquiry, ascertained about the beef, and the locality in which it was purchased, "which," he says, "at once satisfied him that they were doomed. Before the next morning every member of that company of 6 was attacked in a violent manner, and only one of the number recovered."

The Legislatures of several Western States have offered rewards for the discovery of the origin of the milk sickness, in order to lead to its prevention and cure. The reward offered

in Kentucky is \$1000. A creeping vine has been of late years generally believed to be the occasion of the disease, but this has not been so well established as to enable the person who made the supposed discovery to claim the rewards.

MILK-VETCH (*Astragalus*). This is an extensive genus of herbaceous and shrubby plants; many of the species are very handsome, and well suited for the flower-garden. There are 4 species indigenous to England.

MILKWORT (*Polygala*, from *poly*, much, and *gala*, milk; reputed effects of the plant on cattle that feed upon it.) All the species of this genus are very showy. The annual kinds require sowing in the open ground, preferring a peat soil. Some of the species possess useful medicinal qualities. Decandolle enumerates above 160 species in this genus, but only one is British.

A considerable number of the species are natives of the United States, among which the best known is the *P. senega*, or Seneca snake-root.

MILLET (*Panicum*, from *panicula*, a panicle, or *panis*, bread). A useful genus of grasses, one species of which, called Bengal grass, was some years ago introduced into Pennsylvania as an object of culture, and excited much interest for a time among farmers. It was found, however, not to be so valuable as the usual summer crop of which it occupied the place, and it is now pretty much abandoned. The seed is sown in the early part of May. (*Flora Cestrica*.)

Of the millet there are three distinct genera: the Polish millet (*Digitaria*), cultivated in Poland; the common millet (*Panicum*), or panic grass, cultivated in Germany, and sometimes in England; and the great or Indian millet (*Holcus*), cultivated in India, Italy, and America.

Of the common millet there are 3 species: *Setaria Germanica*, a native of the south of Europe; the *P. miliaceum* (Pl. 3, l), a native of the East Indies; and the *Setaria Italica* (m), also of Indian origin.

The *German Millet* (Fr. *Moha de Hongrie*; *S. Germanica*, Pl. 3, k) rises with a jointed reed-like stalk, about 3 feet high, and about the size of the common reed, with a leaf at each joint, 1½ foot long, and about an inch broad at the base where broadest, ending in an acute point, rough to the touch, embracing the stalk at the base, and turning downwards about half the length. The stalks are terminated by compact spikes, about the thickness of a man's finger at the bottom, growing taper towards the top, 8 or 9 inches long, and closely set with small roundish grain. It is annual, and perishes soon after the seeds are ripe. There are three varieties of it, the yellow, white, and purple grained. It was formerly cultivated for bread in some of the northern countries.

The *Common or Cultivated Millet* (Fr. *Millet commun*; *Panicum miliaceum*), rises with a reed-like channelled stalk, from 3 to 4 feet high; at every joint there is one reed-like leaf, joined on the top of the sheath, which embraces and covers that joint of the stalk below the leaf, and is clothed with soft hairs; the leaf has

none, but has several small longitudinal furrows running parallel to the midrib. The stalk is terminated by a large loose panicle hanging on one side. Of this species there are two varieties, the brown and the yellow; the latter of which was formerly in cultivation, and is now sometimes sown for feeding poultry, and as a substitute for rice.

The *Italian Millet* (*Panis d'Italie*: Fr. *Millet a grappe*; *Setaria Italica*, Pl. 3, m), rises with a reed-like stalk, nearly 4 feet high, and much thicker than that of the preceding; the leaves are also broader. The spikes are a foot long, and twice the thickness of those of the common millet, but not so compact, being composed of several roundish clustered spikes; the grain is also larger. There are two or three varieties of this, differing only in the colour of the grain. It is frequently cultivated in Italy (whence its trivial name), and other warm countries. It is a native of both Indies, and of Cochin China.

The *Polish Millet*, or manna grass of the Germans (*Digitaria sanguinalis*, formerly *Panicum sanguinalis*, Pl. 3, n), is a low, decumbent, annual plant, seldom rising above 9 inches or a foot high, with hairy leaves and slender panicles. It tillers much, and forms a close tuft, spreading and rooting at the joints. It is a native of England, but not common. It grows in abundance in Poland, and is sometimes cultivated, the seeds being used like those of the other millets as a substitute for rice or sago.

The *Great or Indian Millet* (Lat. *Holcus sorghum*, *Sorghum vulgare*, Pl. 3, o; Fr. *Sorgho*, *gros millet d'Italie*; Ger. *Sorgsamem*; It. *Sagina*; Span. *Melaxa*) has a stem which rises 5 or 6 feet high, is strong, reedy, and like those of the maize, but smaller. The leaves are long and broad, having a deep furrow through the centre, where the midrib is depressed in the upper surface, and is very prominent below. The leaves are 2½ feet long, and 2 inches broad in the middle, embracing the stalks with their base. The flowers come out in large panicles at the top of the stalks, resembling, at first appearance, the male spikes of the Turkey wheat (maize); these are succeeded by large, roundish seeds, which are wrapped round with the chaff. This grain is a native of India, where it is much used to feed poultry, and is frequently sent to Europe for the same purpose. It is much cultivated in Arabia, and most parts of Asia Minor; and has been introduced into Italy, Spain, Switzerland, and some parts of Germany, also into China, Cochin China, and the West Indies, where it grows commonly 5 or 6 feet high, or more, and, being esteemed a hearty food for labourers, is called negro Guinea corn. Its long awns or bristles defend it from the birds. In England, the autumns are seldom dry and warm enough to ripen the seed well in the field. In Arabia it is called *dora* or *durra*; the flour is very white, and they make good bread of it, or rather cakes, about 2 inches in thickness. The bread which they make of it in some parts of Italy is dark and coarse. In Tuscany it is used chiefly for feeding poultry and pigeons; sometimes for swine, kine, and horses. Cæsalpinus says, that cattle fed on the green herb are apt to swell and die, but thrive on 't when dried. They make brushes

and brooms of its stalks in Italy, which Ray observed in the shops of Venice, and which are sent to England. Of this species there are two distinct varieties; one distinguished by black, and the other by red, husked seeds, besides subvarieties.

The only sorts of millet which are cultivated with success in England are the German, cultivated, and the Polish sorts. According to Professor Thaer, the cultivated is to be preferred, as having the largest grain.

The soil for the millet should be warm, sandy, rich, and well pulverized to a good depth. In England the seed is sown in May, very thin, and not deeply covered. In the course of its growth, no plant, Professor Thaer observes, is more improved by stirring the soil, after which it grows astonishingly fast, and smothered all weeds.

In harvesting the millet, great care is requisite not to shed the seed; and as it ripens rather unequally, it would be an advantage to cut off the spikes as they ripen. No grain is easier to thrash, or to free from its husk by the mill. It is used instead of rice, and in Germany bears about the same price. It produces a great bulk of straw, which is much esteemed as fodder. (*Loudon's Ency. of Agriculture.*)

The great Indian millet will grow in England to the height of 5 or 6 feet; but will not ripen its seeds, or even flower, if the season is not dry and warm. It would doubtless succeed in the United States.

MILLET-GRASS, *Milica* (Fr. *millet*; Lat. *miliun*, from *mille*, a thousand, in allusion to the immense number of seeds produced by it). These are hardy, annual, and perennial grasses; but in England the climate is seldom warm enough to ripen the seed, or to allow of their being cultivated to advantage. The hardened corolla, forming a coat to the seed, affords a mark of distinction between this genus and *Agrostis*, no less obvious than important, as those most deeply versed in grasses will most readily allow.

There are two English species:—

1. Spreading millet-grass (*M. effusum*). Growing very common in moist, shady places. The root is perennial and fibrous, with several creeping shoots. Stems erect, slender, generally 3 and 4 feet high, with about 4 joints, leafy, smooth. Leaves bright-green, flat, very smooth, thin and weak. Flowers solitary, slightly drooping, ovate, in a loose spreading panicle, without awns; panicles from 4 inches to a foot in length. Mr. Curtis observes, that this is distinguished from the panic grasses, to which it has the greatest affinity, by having a calyx of two valves only. The produce of this grass is very light in proportion to its bulk, and it is but little nutritive. Birds are remarkably fond of the seeds: so much as to render it likely that, for the sake of the seed only, it could be cultivated to advantage on the farm. But in covers where game are preserved there cannot be a better grass encouraged: it will save the corn fields. About the beginning of August is the best season for sowing the seed. The surface of the ground near the roots of the bushes should be lightly stirred, and the seeds scattered over it and raked in; a few of the

decaying leaves that cover the ground should afterwards be thrown over. It flowers in the second week or latter end of June, and the seed is ripe in the middle of July and beginning of August.

2. Panic millet-grass (*M. lanigerum*). This annual species is less common, and grows principally in fields where water has stagnated, especially towards the sea. The stem is branched from the bottom and smooth. Flowers in a dense, spiked, erect panicle, pale-green, bristly; corolla awned.

MILLS (Lat. *mola*). The term mill seems to have signified originally an engine for grinding corn, but it is now used in a general sense to denote a great variety of machines, whose action depends chiefly on circular motion. The particular purpose is usually indicated by a prefix: thus, bark-mill, cotton-mill, flour-mill, oil-mill, saw-mill, spinning-mill, &c.

The machinery by which it is necessary to accomplish the ultimate objects of the mill must obviously vary almost indefinitely. Many voluminous works on this subject have been published, as well as separate accounts of particular structures.

The *Kibbling-mill* is well worthy of notice. It is composed of a small iron cylinder, usually about 8 or 9 inches wide, and 6 inches in diameter, tapering slightly to one end, and fluted on the inside. Within this a barrel of the same form, but a size less, and fluted on the outside, revolves by the turning of a spindle on which it is fixed. The meal is rendered finer or coarser in proportion as the working barrel is set nearer to or farther from the small end. This mill is made entirely of iron and steel, and is usually attached to a post. It is provided with a hopper, and is worked by a crank fixed at one end of the spindle, while a fly-wheel revolves at the other. It is used for beans, peas, and other pulse, for malt and various kinds of grain, and is a very useful and ingenious contrivance, but requires care in its adjustment and general management.

Bean-mill. A mill for grinding beans, constructed by Seaman and Bryant of Melton, in Suffolk, is as simple and effective an implement of the kind as any we have seen. It is placed on a wooden stand, with crank, fly-wheel, and hopper; and consists of a coarsely fluted barrel, working against a front cutting plate; the latter being set at the proper distance from the barrel by means of a screw. It is used chiefly for beans and peas, but may be employed for grinding malt, by exchanging the barrel and cutting-plate for a pair of rollers.

The *Norfolk Crusher* is similar in appearance to the foregoing, and is worked by two rollers of equal dimensions, each being flanged at one end, and reversed so as to prevent the grain from falling off at the side. The rollers are perfectly smooth, and consequently, as its name implies, it crushes the grain instead of cutting it.

The *Suffolk Crusher* is simply a variety of the above, and differs from it in having its hind roller finely grooved, and of half the dimensions of the front one; this has no flange, but works within the flanges of the front roller.

which are attached at both ends. To render these mills effective for crushing oats, the rollers should be left rough as they come from the lathe, to draw in the kernels, as the latter are apt to start back at the moment of entering between the rollers, if they are polished. A grooved or fluted roller has not been found adequate to the perfect bruising or cutting of oats, and a mill that shall effect this object may be considered a desideratum in agricultural mechanics.

MILLSTONE GRIT. A geological term applied to a group of strata which occur between the mountain limestone and the superincumbent coal formations; it is a coarse-grained quartzose sandstone.

MINT (*Mentha*). The poets celebrate Minthe, a daughter of Cocytus, as being transformed into mint by Proserpine in a fit of jealousy. (*Ovid. Metam.* 10, v. 729.) This is an extensive and well-known genus of useful herbs, with the culture and propagation of which every one is familiar. In England there are more than a dozen native species, besides numerous cultivated varieties. The roots are perennial, creeping widely. All the herbage is more or less hairy, but variable in that respect; rarely woolly or finely downy; full of pellucid dots, lodging a copious essential oil, which is pungently aromatic, cordial, and stimulant, and is thence used in medicine as an excitant and stomachic for promoting digestion. The following are the indigenous species. Horse-mint (*M. sylvestris*), round-leaved mint (*M. rotundifolia*), spear or green mint (*M. viridis*), black or peppermint (*M. piperita*), bergamot mint (*M. citrata*), hairy mint (*M. hirsuta*), fragrant sharp-leaved mint (*M. acutifolia*), tall red mint (*M. rubra*), bushy red mint (*M. gentilis*), narrowed-leaved mint (*M. gracilis*), corn-mint (*M. arvensis*), rugged field-mint (*M. agrostis*), and pennyroyal (*M. pulegium*). See **CAT-MINT, HORSE-MINT, PEPPERMINT, PENNY-ROYAL, SPEAR-MINT, &c.**

MISSILTOE (*Viscum*; from *vescus*, birdlime, on account of the sticky nature of the berries). The misseltoe is a well-known parasite, readily propagated by sticking the berries on thorn or apple trees, after a little of the outer bark has been cut off, and tying a shade or net over them, to protect them from the birds. Sheep eagerly devour this plant, which is frequently cut off the trees for them during the severe winters; nay, it is even said to preserve them from the rot. Its branches are much sought after at Christmas to hang up in houses, along with other evergreens. It was one of those plants held sacred to the Druids.

MIST. See **FOG.**

MITE. See **CHEESE-MITE.**

MIXEN. A compost heap.

MIXTURE OF SOILS, in agriculture, is the addition of one soil to another, to improve its fertility.

There is perhaps no agricultural improvement more important in both its immediate and permanent effects than the careful, judicious mixture of soils, and there is no question more likely to repay the cultivator for the care he bestows upon it.

This mode of improving the land was one

which very early engaged the attention of the farmer. Nature herself, in fact, pointed out to him the means of producing the richest of soils by earthy mixtures in very intelligible language. The solid matters brought down from the distant hills by the flood-waters, and deposited in the valleys where the waters rested, evidently formed, by the mixture of different strata, and by their union only, the rich alluvial soils of the old and the new worlds; for that the mere mechanical separation of the earth into a fine state of division is not the sole cause of the increased fertility, is apparent to every farmer.

It is useless, he well knows, to expect the *débris* of the hills to produce fertilizing effects on soil of a similar composition. It is the dissimilarity of the earths which insures a maximum fertile mixture: thus, in the soil of the rich marshes of the banks of the Thames are found the clay of the London basin, the sands of Middlesex, and the chalks of Oxfordshire and Kent; and in a similar manner are formed all rich alluvial lands. This good effect of earthy deposits naturally pointed out to the Italian farmers the use of earthy additions to the soil. Columella expressly notices the use of sand, gravel, marl, and chalk (book ii. c. 16, p. 93); and the people of Megara, according to Theophrastus, had made similar observations upon the importance of mixing together different strata of earth (lib. iii. c. 25); for every fifth or sixth year they trenched the gravel to a depth equal to that they imagined the rain had penetrated. The early inhabitants of Britain employed marl, as the people of Gaul did lime, for spreading over their lands. And that this was done to a very considerable extent, is shown by several facts. Thus, marl-pits are mentioned as early as 1285, in the charter of the forest, and again in the statute of Wales in the 12 Edward 1. And so early as the days of Richard, Duke of Cornwall, the Cornish farmers had a grant by which they were empowered to take the calcareous sand of Padstow harbour, and spread it over their clayey lands. The successful mixture of the farmers' soils, therefore, is not a modern improvement; it has evidently been practised with success in all climates, in different ages, and on every description of cultivatable land.

I have witnessed, however, even in soils to all appearance similar in composition, some very extraordinary results from their mere mixture. Thus, in the gravelly soils of Spring Park, near Croydon, the ground is often excavated to a depth of many feet through strata of barren gravel and red sand, for the purpose of obtaining the white or silver sand which exists beneath them. When this fine sand is removed, the gravel and red sand is thrown back into the pit, the ground merely levelled, and then either let to cottagers for gardens or planted with forest trees; in either case the effect is remarkable: all kinds of either fir or deciduous trees will now vegetate with remarkable luxuriance; and in the cottage-garden thus formed, several species of vegetables, such as beans and potatoes, will produce very excellent crops in the very soils in which they would have perished previous to their mixture.

These instances are remarkable, and well worthy of the careful consideration of the farmer; for the poverty of both the sand and the gravel, which is thus so successfully mingled together, is very great. The appearance of the soil here gave no indications of any good being derived from the union of the two. The black gravel and the red sand were equally sterile; yet their mere mixture yielded a productive soil.

The permanent advantages of mixing soils, too, is not confined to merely those entirely of an earthy composition; earths which contain inert organic matter, such as peat or moss earth, are highly valuable additions to some soils. Thus, peat earth was successfully added to the sandy soils of Merionethshire by Sir Robert Vaughan. The Cheshire farmers add a mixture of moss and calcareous earth to their "tight-bound earth," the effect of which they describe as having "a loosening operation;" that is, it renders the soil of their strong clays less tenacious, and consequently promotes the ready access of the moisture and gases of the atmosphere to the roots of the farmers' crops: their vigour is promoted, their food better supplied. There are certain natural indications with regard to the admixture of soils which are self-evident to every cultivator; and there are others which are well understood in particular districts. The Norfolk farmers consider that marl is not far from the surface when the weed coltsfoot (*Tussilago forfara*) abounds: and that all lands will be much benefited by marling which produce the weeds corn-marigold, or bridle (*Chrysanthemum segetum*), and smartweed, or pale-flowered persicaria (*Polygonum Pennsylvanicum*).

In the transfer of the earths the farmer will find it a profitable practice, especially when the distance is great, to have them previously dug in pits, and dried in the sun. In this way the weight of either chalk, marl, or clay is much more considerably reduced than the cultivator would suppose. I have found that when moist chalk is dried in this way it loses from 20 to 24 per cent. of water. Strong adhesive clay, under similar circumstances, loses from 32 to 41 per cent., and marl from 18 to 26 per cent. of its weight; so that, supposing he carts 100 cubic yards of each of these fertilizers, by merely having them previously dried, he saves in weight of carriage

	Tons.
In the chalk - - - - -	20 to 24
In the clay - - - - -	32 to 42
In the marl - - - - -	18 to 26

As there are only these earths present to any extent in all cultivated soils, and as the proportion which they bear to each other makes the chief difference between fertile and barren lands, I shall confine my attention in this paper to the application of 1. Chalk, 2. Clay, 3. Sand, to land which is naturally deficient in them; and in entering upon the investigation, I shall suppose that the farmer is aware that it is merely the excess of one of these earths which renders a soil unproductive, and that the application of the deficient earths operates so advantageously by tending to render the composition more similar to those of richer soils,

in which the earths are mixed in a more fertile proportion. It is of the first importance, however, that the farmer should be aware of this fact; let him, to this end, contrast the analysis of a barren soil like that of Bagshot Heath, which is composed of

Coarse silicious sand - - -	380
Fine sand - - - - -	9
Iron, clay, and chalk - - -	11
	400

with that of the soil of a Lincolnshire pasture, which contains, in the same weight,

Fine calcareous sand and silicious sand -	160
Soluble matters - - - - -	6
Organic matters - - - - -	40
Chalk - - - - -	32
Oxide of iron - - - - -	8
Alumina (pure clay) - - - - -	25
Silex (earth of flint) - - - - -	65
Water, and loss - - - - -	64
	400

The soil of Bagshot, he will observe, contains nearly twice as much silicious matters, and only one-fifth the proportion of chalk and alumina, that is present in the pasture from Croft in Lincolnshire.

Chalk and marl are both used for the sake of the carbonate of lime they contain, and they may, therefore, be treated of under one head. The proportion in which I have witnessed these applied per acre naturally varied with the expense of the carriage of the material. On the light gravelly soils of the coast of Essex, I have used, in common with my neighbours, about 20 to 25 tons of the chalk of Kent per acre, at a cost of about 6s. per ton; but of marl the quantity applied in the same district is from 50 to 100 tons per acre, which may be commonly procured for the expense of carriage and spreading; and this addition to the soil is a very permanent improvement. Chalking, the Essex farmers say, lasts for 20 years, and marling for a man's life.

Upon analyzing a productive soil, worth 30s. per acre, which had been thus chalked about five years previously, it was found to contain

Stones and gravel, principally silicious - -	27
Vegetable fibres - - - - -	1.5
	28.5
Soluble matters, principally vegetable extract -	3
Carbonates of lime and magnesia - - - - -	18
Oxide of iron - - - - -	4
Animal and vegetable matters - - - - -	1
Alumina - - - - -	4.5
Silica - - - - -	40
Loss - - - - -	1
	100

A portion of the same field (which was an enclosure from a poor common), not chalked, being examined, was found to yield nearly the same proportion of ingredients, but the chalk was almost entirely absent. Now, before the addition of the chalk, the land was too poor to yield any thing except the fern and the furze.

In Dorsetshire, near Weymouth, and on the Coomb Hills, which separate Berks from Hampshire, where chalk is in many places readily obtained by sinking a well, and drawing it up

by a windlass to the surface, the quantity applied per acre is much more considerable. I have seen from 50 to 100, or even 150 tons per acre, spread on the gravel and clay lands with decided success.

The cultivator sometimes deludes himself with the conclusion that applying sand, or marl, or clay, to a poor soil, merely serves to *freshen* it for a time, and that the effects of such applications are only apparent for a limited period. Some comparative experiments, however, which were made 16 years since on some poor, hungry, inert heath-land in Norfolk, have up to this time served to demonstrate the error of such a conclusion. In these experiments the ground was marled with 20 cubic yards only per acre, and the same of compost; it was then planted with a proper mixture of forest trees, and by the side of it a portion of the heath, in a state of nature, was also planted with the same mixture of deciduous and fir trees. Sixteen years have annually served to demonstrate, by the luxuriance of the marled wood, the permanent effect produced by this mixture of soils. The growth of the trees has been there rapid and permanent; but on the adjoining soil, the trees have been stunted in their growth, miserable in appearance, and profitless to their owner. Time has made no alteration; while the marled soil has yielded an annual and luxuriant crop, the land left in its original state has demonstrated by its produce that something was wanting, some earthy ingredient only needed to render it no longer barren, and the adjoining *marled* land has further shown of what that addition was composed.

The expense per acre of this marling, and otherwise preparing the soil, was

	£	s.
20 cubic yards of marl, at 1s. 3d. -	1	5
20 cubic yards of compost, at 5s. -	5	0
Deep ploughing - - - - -	1	10
Trees, carriage, planting - - -	7	10
	<hr/>	<hr/>
	15	10

In this instance the marl had to be carried about a quarter of a mile.

It is difficult to account for the want of that general attention to the use of earthy admixtures which so many successful experiments with them would lead us to anticipate. Mr. Rodwell, of Livermere, in Suffolk, successfully clayed and marled 820 acres of sandy heath not many years since, using about 140,000 tumbril loads, which, at 8½d. per cubic yard, cost him 4958l. He found, from experience, that clay was to be preferred to marl on all his sandy soils. The result was highly satisfactory: 350l. per annum was added to the value of the estate.

This excellent farmer practised also the system of hand-harrowing the clay. "The men make good earnings at 10d. a cubic yard, wheeling it 30 rods; and down to 7d. a yard at shorter distances:" and on the whole, deemed this "the cheapest method of all others, especially on heavier soils." But he did by far the greatest part by tumbrils, the expense of which, by contract carting, and labour, was 8d. per cubic yard. He found also, contrary to the commonly received opinion, that *deep ploughing*

was the best for his marled and clayed lands "I have found," he said, "that the clay and marl works the better, the more soil it has to incorporate with."

One cause of the failures which have sometimes taken place in the attempted improvement of soils by their admixture, arises from the want of a *thorough union* of the heavy clays, added to the light sandy soils. The earths were in these cases never incorporated by the aid of the harrow, on such frosty mornings as are best adapted to the mixture, and, in consequence, the more ponderous lumps of clay or marl were allowed to gradually *sink*, as the farmers say, into the sand; and in some such soils as these, the stratum of clay and marl which was applied 10 years since may now be found in one unbroken seam, at a depth of 12 or 14 inches in the soil. Such erroneous modes of applying the earths are much to be lamented: they decide no controverted question,—they prejudice the unreflecting cultivator,—they add nothing to the common stock of agricultural knowledge.

This error was noted by the late General Vavasour: he told the farmers very correctly, that under a poor sand, a stratum of clay, marl, or other substance peculiarly adapted to give fertility to the soil will generally be found that nature seems to have designed that no land should be unproductive, and if any be unfruitful, the cause is in the ignorance or indolence of man. If clay marl, he thought, could be had at a convenient distance, 75 cubic yards per acre was a good covering; if of a shelly or soapy marl, 20 or 25 yards will be sufficient. The marl, after being spread, should be repeatedly rolled and harrowed, to divide and pulverize it the better.

The application of sand to the farmers' heavy clay soils is a practice which, in several districts of England, is attended with very decided success. Thus, in that part of Suffolk which is bounded on two sides by the rivers Orwell and Stour, there is found a fine red sand abounding with shells, both in their perfect and broken state, which, when applied to the clay soils at the rate of 20 to 30 tons per acre, is productive of very excellent permanent good effects.

In the valley of the Kennett, in Berkshire, in similar proportions I have witnessed the use of the gravelly *débris* of the Bath Road used upon the peaty soils of that district with excellent effect, and with equal success on some stiff clay meadow-land; the result of dressing it with about 30 tons per acre with the same road-sand is equally decided. The land is not only prevented from cracking in the summer months, but the produce of grass is very materially increased.

The employment of sea-sand is a very ancient custom in the west of England; it is one, in fact, to which no one can assign the period of its commencement: many thousand tons per annum are carried away by the farmers who cultivate the lands in the neighbourhood of Padstow Harbour, even on horses' backs, and they think it well worth their while to carry this sand some miles into the interior of the country. In a similar manner the farmers of

Devon dredge for the sand at the mouth of the Tamar, and when they have filled their barges, carry it up the river. They deem the fine-grained sand the most immediate in its effects, but both are very durable, and decided improvements to the soil. The coarse sand, they say, lasts for many years.

The composition of the sands of Padstow Harbour, and of the estuary of the Tamar, are very similar; they contain from 60 to 70 per cent. of carbonate of lime, and are both preferred by the farmers, when they can be obtained, mixed with the sea-water.

Another, but the least commonly practised mode of improving the staple of a soil by earthy additions, is claying; a system of fertilizing, the good effects of which are much less immediately apparent than chalking, and hence one of the chief causes of its disuse. It requires some little time to elapse, and some stirring of the soil, before the clay is so well mixed with a sandy soil as to produce that general increased attraction and retentive power for the atmospheric moisture which ever constitutes the chief good result of claying poor soils. Clay must be, moreover, applied in rather larger proportions to the soil than chalk; for not only is its application rarely required as a direct food for plants, for the mere alumina which it contains, since this earth enters into the composition of plants in very small proportions, but there is also another reason for a more liberal addition of clay being required, which is the impure state in which the alumina exists in what are commonly called clay soils. For instance, chalk usually contains, when perfectly dry, about 98 per cent. of carbonate of lime. Mr. Kirwan found in a specimen of chalk 2 per cent of alumina, or

	Parts.
Lime - - - - -	52

Alumina - - - - -	2
	100

But the heaviest clay soils seldom contain more than 20 per cent. of alumina; in the stiff clays of Sussex and the Weald of Kent are found only about 28 per cent. of this earth: even the adhesive clays employed by the potter yield only about 33 per cent. of alumina, porcelain earth only 47 per cent.

The following is the analysis of a heavy Sussex clay soil:—

	Parts.
Silica - - - - -	54
Alumina - - - - -	28
Carbonate of lime - - - - -	3
Oxide of iron - - - - -	5
Organic matters - - - - -	4
Loss, chiefly moisture - - - - -	3
	100

The farmer, therefore, who applies 50 tons per acre of such a clay to a sandy field, only adds about 14 tons of alumina to the soil; but if he applies 50 tons of chalk, he adds 49 tons of carbonate of lime.

Hence, is the reason why, in all efforts to alter the earthy constituents of a soil, a much smaller quantity of chalk produces more de-

cidated effects than the addition of a much larger proportion of the most tenacious clay. Chalk, too, when merely spread on the surface of the soil, and exposed to the action of frost, speedily crumbles to powder, and becomes intimately combined with the other earths of the soils. The clay, however, is too adhesive to be thus readily, and without some little labour, so intimately mixed with the soil: its effects, however excellent, are much more slowly apparent; but patience and judicious management of clay will do wonders, even on the most unlikely soils; and I could not, perhaps, state any more complete cases of the recovery of an absolutely barren soil by means of clay and chalk, and that, too, at a reasonably profitable rate, than those successful experiments which have recently been made on the shingle of the sea-coast near Eastbourn, in Sussex, consisting entirely of silicious pebbles, varying in size from that of hazel-nuts to hen's eggs, and that extending to a depth of many feet.

In this case the clay was drawn in *hand-carts* by three men, rather better than a quarter of a mile. The cart contained about 880 lb. of clay, or about 13 cubic feet. Eight of these cart-loads, or about 3 $\frac{1}{8}$ tons, were spread on each square rod of 16 $\frac{1}{2}$ feet, which, when first spread loosely and in lumps, made the soil 5 or 6 inches deep, and when it had become settled and solid, about 4 inches; each cart took back a load of shingle to fill up the hole made by the excavation of the clay. The work was laborious, but the men readily earned about 1s. 6d. per day, and were contented. They did their work by contract, receiving 3s. per square rod for the shingle they thus covered, or 24l. per acre; and for this sum they carried 250 tons of clay. The clay is of the ordinary red description, so common in Sussex, and though not particularly adhesive, is yet sufficiently so to form a plate, on which in wet weather the water stands, although this superstructure of clay is resting on a mass of coarse shingle stones, 15 feet in depth. This experiment was made on a small field of about 3 acres in 1839, and promises as well as a similar effort made with the same clay in 1832.

In this instance an acre and a quarter of shingle was covered with the same clay to a similar depth. But the clay being only divided in this case from the shingle by the Eastbourn and Hastings Road, the expense was less; the men digging, carrying, and spreading the clay, for 2s. per rod, or 16l. per acre. This land was let in 1834, for a term of 14 years, at 40s. per acre. The tenant has succeeded in making it produce excellent crops; has added to it a considerable quantity of muck and ditch scrapings; has paid his rent regularly, and is contented with his bargain: it produced, in 1838, an excellent crop of rye, which was cut green for horses; this was followed by a good crop of potatoes, and in 1839, the tares which it produced were a very heavy crop. It is rated to the poor at 21s. 8d. per acre.

It would be hardly possible, I think, to produce a more complete case of the absolute formation of a soil, by means of claying, than these valuable experiments; the soil (if utterly barren boulder stones or large shingle thrown

ap by the sea can be called soil) not affording a single substance of any kind which could, to any extent, be profitably mixed with the clay. The attempt, therefore, was one of much more difficulty than any case which usually presents itself to the notice of the cultivator. It was not a mere claying a poor sand or chalk, or peat, either of which would assist in forming a mould, but the entire soil had to be formed; and this, it will be seen, was accomplished successfully and profitably, and by manual labour only.

Some valuable observations and experiments upon claying a light sand are contained in the prize essay of Mr. Linton. The description of land he improved "was a light barren sand; the substratum a white sand, from 1 to 4 feet deep; the surface of the same texture, but darker in its colour, through the decomposition of vegetable matter upon it. Beneath the bed of sand lay a yellowish kind of clay, about 1 foot thick; under it a rich marl, about 18 feet deep. The land generally being very wet, my first object was to underdrain it thoroughly with tiles; unless this is first done, where necessary, marling is a waste of capital. I cut my drains about 24 inches deep, and 9 yards apart." As to the choice of clay, Mr. Linton tested it with vinegar and water: the description he used "effervesced nearly as tartaric acid and carbonate of soda do when mixed together in water; this was my test, that it contained a quantity of carbonate of lime, which rendered it fit for my purpose, and worthy of the name of marl. I consider, that on the proper testing and selection of the clay or marl chiefly depends the success of marling operations. All clay will do good, there is no doubt, but on the quality used must rest the amount of benefit obtained." In these experiments "the land was made completely level by the plough-harrows, and in some places the spade, after which it was ready for the marl being laid on, which was done at all times of the year;" he prefers, however, doing this when the land is in seeds. The quantity laid on "varied from 100 to 200 cubic yards per acre, the average 150 yards. Where the land was very light and barren (which was mostly the case on elevated parts), a larger quantity was laid on; but where it was a better soil, a much less quantity answered the same purpose, my object being to lay on just as much as would grow wheat after seeds; to do more than this would have been an injury to the land, for eating turnips upon it with sheep, and for the barley crop; when sufficiently clayed to grow wheat after seeds, a point requiring close attention, I always found it effectually done for any other crop.

"The way in which it was done. It was necessary, in the first place, to fix upon the most favourable situation for the pit, keeping three objects in view. 1. The most convenient place for carting to the plot of ground intended to be marled. 2. The best situation for a pond to answer for a permanent watering-place, cutting, if possible, across a fence, so as to water 2 fields, one from each mouth of the pit. 3. Where the clay could be got with the least difficulty. After the place was fixed upon, the work was carried

on by 5 diggers, a driver, 4 horses or beasts, and 2 carts (which are of the Scotch kind, with short bodies, and broad wheels); the pit was dug with a gradual descent, so that 3 horses could draw out about a ton, which was shot out where wanted, the last returning by the time the other was loaded: thus, 3 horses were always ready for the loaded cart: the clay was spread by the diggers, at broken times after being exposed to the action of the air; rain, after either frosty or drouthy weather, would cause it to fall to pieces, sufficiently for harrowing and ploughing in. The expense I paid for digging, filling the carts, and spreading, was from 4*d.* to 5*d.* per cubic yard (full 1 ton), varying according to the quantity of stones imbedded in the clay; the total expense per acre was as follows:—

	£	s.	d.
Digging and spreading 150 yards, at 4½ <i>d.</i> per yard	2	16	3
4 horses 4 days, at 2 <i>s.</i> 6 <i>d.</i> each, 10 <i>s.</i> per day	2	0	0
Driver 4 days, at 2 <i>s.</i> 6 <i>d.</i> per day	0	10	0
Other expenses (wear and tear)	0	3	0
Total expenses in marling 1 acre	5	9	8

Mr. Linton marled 80 acres in this way; but by employing a windlass to draw the carts out of the pit, he reduced the expenses per acre 7*s.* As regards the improvement of the land by marling, the value of the produce in 4 years before marling was

£	s.	d.
14	7	0

In four years after draining:—

When marled upon seeds	24	16	6
When marled upon fallow	22	15	0
Balance in favour of marling upon seeds	2	1	6

"The land," Mr. Linton adds, "is never so productive the first 2 years (or until the clay has got well pulverized and mixed with the sand) as it is afterwards, and it will not grow a good crop or a fine sample of barley for 5 or 6 years after the clay is laid on. I have therefore sown oats instead. If people (he concludes) would improve the land they have, particularly light land, by draining, marling, &c., they would realize a far greater return for the outlay than by purchasing more." (*Journ. Roy. Agr. Soc.* vol. ii. p. 67.)

From these facts the cultivator, I think, will arrive at the conclusion, that the judicious admixture of soils, and other applications of manual labour, for the purpose of increasing their productiveness, can hardly fail, sooner or later, to amply repay him for the labour he thus employs. It is an improvement, let him remember, that, when once accomplished, lasts forever, since the very character of the soil is changed; his organic manures, such as farm-yard compost, oil-cake, and even bones, are gradually dissolved or decomposed, and disappear from the land, are absorbed by his crops, or evolved in the gases of putrefaction; but no such results arise from either deepening the soil or the addition of the earths, they, when once united to the soil, remain there to increase the crops, to lessen the toils, and to add to the profits of succeeding cultivators, even in distant periods. And to effect these important,

these national results, let him, too, remember, that no neighbouring lands are impoverished, no organic matters are drawn from one field to enrich another; the dead, the deep-buried earth is merely brought to the surface, and that which is utterly profitless in the mass diffuses riches and gladness when spread over the farmer's fields.

MOLASSES (Port. *Melasso*). The saccharine principle in the dregs or refuse drainings from the casks, &c., of sugar, and the uncrystallizable part of the juice of the cane separated from the sugar during the process of granulation. It consists of sugar prevented from crystallizing by acids, saline, and other matters. All cattle are fond of sweets, and thrive well upon substances which yield a large proportion of saccharine juice, of which no better proof can be afforded than the condition of the cattle and swine of the West India Islands, which are fed mainly on the tops and refuse of the cane after the juice has been expressed for sugar. Mr. E. Waters (*Com. to Board of Agr.* vol. vi. p. 30) gives the result of a very satisfactory experiment as to the advantage of feeding live-stock with molasses. There can be no doubt that when this substance can be had cheap, its use must prove very beneficial in improving the condition of cattle.

MOLE. A species of the genus *Talpa*, common in England and other parts of Europe. This quadruped exhibits in perfection that modification of structure by which the mammiferous animal is adapted to a subterranean life. Its head is long, conical, and tapering to the snout, which is strengthened by a bone, and by strong gristles worked by powerful muscles. The body is almost cylindrical, thickest behind the head, and gradually diminishes to the tail. There is no outward indication of a neck, that part being enlarged to the size of the chest by the massive muscles which act upon the head and fore-legs. These, which are the principal instruments by which the mole excavates its long and intricate burrows, are the shortest, broadest, and strongest, in proportion to the size of the animal, which are to be met with in the mammiferous class. The food of the mole consists of worms, insects, and the roots of plants; its voracity is great, and it soon perishes if food be scarce or wanting. The sense of sight is very feeble, the eyes being minute and rudimental; but the other faculties of smell and hearing, as being more serviceable in its dark retreat, are extremely acute. The female prepares a nest of moss, dry herbage, roots, and leaves, in a chamber commonly formed by excavating and enlarging the point of intersection of 3 or 4 passages. The young are brought forth to the number of 4 or 5 in April, and sometimes later.

The farmer views the operations of the mole as destructive to his crops, by exposing and destroying their roots, or by overthrowing the plants in the construction of the mole-hills; his burrows, moreover, become the haunts and hiding-places of the field-mouse and other destructive animals. The mole is also accused of piercing the sides of dams and canals, and

letting out the water, and of carrying off quantities of young corn to form its nest. Hence every means are devised to capture and destroy it, and in Europe men gain a livelihood exclusively by this occupation. Some naturalists, however, plead that the injury which it perpetrates is slight, and that it is more than counterbalanced by the benefit which it produces by turning up and lightening the soil, top-dressing pasture-land, and especially by its immense destruction of earth-worms, slugs, grubs, wire-worms, and many other noxious animals and insects which inhabit the superficial layer of the ground, and occasion great injury to the roots of grass, corn, and many other plants. The soundest practical conclusion lies probably in the mean of these opinions; and the enlightened agriculturist, while he takes prompt measures to prevent the undue increase of the mole, would do well to reflect on the disadvantages which might follow its total extermination. The Etrick Shepherd (James Hogg), from a course of 30 years' hard-earned experience and observation, speaks of the pernicious effects of destroying the moles on sheep pasture. He alleges, that besides the inferior pasturage which the soil affords when moles have been exterminated, the pining and the foot-rot, two baneful diseases, come in their place to annihilate the stock.

There can be no question that moles do much injury to gardens, by destroying the neatness of the beds, rooting up onions, tulips, and other tubers; but in the wide-spread surface of the field it is a question whether he does not do more good by his teeth than injury by his snout.

The animal so well known in the United States under the name of mole, belongs to an entirely different genus of quadrupeds from the common mole of Europe. The late Dr. Godman has designated the American, the *shrew-mole*, and given, in his *Rambles of a Naturalist*, a most interesting account of its habits, &c. It is the *scalops aquaticus* of naturalists. Whether the true mole has ever been found in the United States, appears doubtful. Moles live in pairs, and frequent soils of loose textures most abounding in earth-worms and insects. They exhibit great dexterity in skinning the worms, which they always do before they eat them, stripping the skin from end to end, and squeezing out all the contents of the body.

In the United States where professional mole-catchers are not yet to be met with, other means of destroying the pest are resorted to. Dogs are sometimes found very expert in digging out moles. Mole-traps are also used, and for a good design of one see *Ellsworth's Report*. It is found that if fine shreds of fresh lean beef are placed in their furrows, the moles will eat them, if found soon after deposit; and if poison, arsenic or strychnine, is placed on these shreds, they are frequently killed. The trap most recommended is one constructed on the principle of that, a figure of which is given in the *Cultivator*. Wherever the mole shows itself in numbers, it is a pest of no small magnitude. For accurate descriptions, with drawings, of the various animals known in the United

States under the names of moles, or mice, the reader is referred to the 1st volume of the *Natural History of the State of New York*.

MOLE-CRICKET (*Gryllotalpa vulgaris*. *Acheta gryllotalpa*). This destructive insect is known in different localities in England, under the several names of churr-worm, jarr-worm, eve-churr, and earth-crab. The mole-cricket measures 2 inches in length, and 4 lines in breadth. Its colour is dark-brown. The most remarkable feature in the insect is the size and strength of its fore-arms. The power which is requisite to move them is great. The cavity of the main trunk is divided lengthways by a double gristly partition, surmounted by a bony frame, with an inferior condyle, with which the inner part of the base of the clavicle of the arm is hinged; and by this mechanism the arms are moved. The mole-cricket burrows under ground, and devours the roots of plants. The female hollows out a place for herself in the earth, about half a foot from the surface, in the month of June, and lays her eggs in a heap, which often contains from 200 to 300. They are shining yellowish-brown, and of the size and shape of a grain of millet. The young, which are hatched in July or August, greatly resemble black ants, and feed, like the old ones, on the tender roots of grass, corn, and various culinary vegetables. They betray their presence under the earth by the withered yellow patches in the meadows, and by the withering decay of culinary vegetables in the gardens. In October or November they bury themselves deeper in the earth, as a protection from cold, and come again to the surface in the warm days in March. Their presence is discovered by their throwing up the earth like moles. The best method of destroying them is to dig up the young brood; but boiling water or oil of any kind poured over their holes will be found effectual. (*Kollar on Insects*, p. 144.) For a description of the American mole-cricket see **CRICKET**.

MOLE-PLOUGH. See **DRAINING** and **PLOUGHS**.

MOLE-TREE (*Euphorbia lathyris*). Commonly called Caper Spurge, and by the French Epurge: a plant with a biennial root; stem 2 to 3 feet high; found in the United States in gardens and lots. It is a naturalized foreigner, and was originally introduced under a notion that it afforded a protection against the incursions of moles. The same common impression once existed in regard to the Palma Christi; but little faith seems now to be attached to either plant as protectives against moles.

MONADELPHOUS. In botany, having the filaments cohering into a tube, or one bundle.

MONANDROUS. A botanical term applied to plants having only one stamen, or male organ.

MONILIFORM. In botany, formed like a necklace; that is to say, articulated with alternate swellings and contractions resembling a string of beads.

MONK'S HOOD. See **WOLF'S-BANE**.

MONOCOTYLEDONOUS. In botany, having only one seed-leaf or cotyledon.

MOON, INFLUENCE OF. The following

observations upon this subject are taken from a lecture delivered before the Franklin Institute of Pennsylvania, by G. Emerson, M. D., of Philadelphia.

There is, perhaps, no opinion relative to the phenomena of the natural world, more universally maintained, than that the moon exerts a decided influence over the states of the weather. This long-cherished notion has doubtless derived increased strength, since it was shown that the ocean tides depend upon a physical connection subsisting between our planet and her satellite.

I, however, think it capable of conclusive demonstration, that the moon exerts no influence in the production of wet or dry weather.

I assume it as incontrovertibly proven, by the experiments of Mr. Dalton, that the watery vapour from which rain and all the precipitations are formed, owes its elevation and suspension, in an invisible form, entirely to heat, deprived of a due proportion of which, by any refrigerating cause, it is condensed, and falls from the atmosphere in one or other of the forms of aqueous precipitation. *The conditions of wet or dry weather are, consequently, to be regarded as regulated solely by temperature.*

Now, the nicest experiments have failed to show that the presence and light of the moon are attended by the slightest change of temperature. The lunar rays have been concentrated by powerful lenses and the largest reflectors, and thrown upon that most delicate test of heat, the differential thermometer, without any indication of their effect in raising the temperature. Unless, therefore, it can be proved that the moon exerts some perceptible influence upon the temperature of our atmosphere, we shall be warranted in believing that she has no power in determining the conditions of the weather, whether this shall be wet or dry.

I am fully aware of the multitudes of observations which have from time to time been made upon this question, and that most of those reported appear to favour a belief contrary to the position here taken.

It cannot be denied that the power of the moon, so conspicuously manifested in the production of the ocean tides, may also be felt by the atmosphere. The aerial ocean must, weight for weight, be as subservient to the law of attraction subsisting between the earth and her satellite, as any other terrestrial matter; and I have no doubt of the correctness of the results of observations made in Italy and France, by Polina, Flaugergues, and others, which go to prove that the mean height of the barometer is affected by the different positions of the moon in relation to the earth, the greatest mean elevations corresponding with the quarters. But, in thus admitting the existence of lunar influence upon the terrestrial atmosphere, we should not deceive ourselves in regard to the nature of this influence. We must not admit that every cause which operates in producing the rise or depression of the mercurial column, is capable of influencing the hygrometric conditions of the air, &c, in other words, exercising an influence in the production of wet or dry weather. The attraction subsisting between

the earth and moon, causes an accumulation of the liquid and movable materials spread over the terrestrial surface, on that part addressed, towards the moon; hence, the rise observed in the sea, and in the mercurial column. But all this is owing to the agency of *gravity*, or *attraction*, which, we contend, has nothing to do with the production of wet or dry weather; the elevation and deposition of aqueous vapour being, as we have said before, subject to the agency of *temperature* alone.

As to the calculations, the results of which seem so irresistibly in favour of lunar influence upon the weather, we think it easy to show that they must be founded upon deceptive data, and will not bear a close examination. The estimates of Toaldo, a celebrated Italian philosopher, embrace a series of laborious observations, collected during many years, and compute the number of *changes* of weather to the different phases of the moon, as follows:

New moon, - - -	6 to 1;
Full moon - - -	5 to 1;
First quarter - -	2 to 1;
Second quarter - -	2 to 1;
Perigee - - -	5 to 1;
Apogee - - -	4 to 1.

That is to say, of 7 new moons, 6 were attended with a change of weather, and at one of them there was no change; of 6 full moons, 5 were attended with a change; and, at the quarters, the changes were twice as frequent as the continuance of the previous weather.

Now, such a computation, coming from so high an authority, might almost be deemed conclusive upon the subject. When, however, we come to inquire more closely into the circumstances involved in the calculation, we find ample grounds for suspecting its accuracy. In the first place, the term "*change of weather*" is used by Toaldo in an ambiguous and arbitrary sense, so that we are left ignorant of the specific change he refers to. But, worse than this, he does not restrict himself to the day when the change takes place, but includes any changes within 2 or 3 days preceding or following a phase. It is easy to conceive how a person, especially one prepossessed in favour of a prevailing opinion, might have been led, with such a privilege as to limit, to take or reject a change, to throw it into one quarter or another, as he might choose to dispose of it, for the purpose of endowing the moon with a power to which he thought her entitled.

The results of a series of observations made by Pilgram, make it appear that the new moon has less to do with the changes of the weather than the other phases; a conclusion diametrically opposed to that of Toaldo, just referred to. As the estimate of Pilgram is founded on observations extending through a series of no less than 52 years, it might be regarded, in point of authority, as at least equal to that of the Italian philosopher. How are these clashing results of observations, professing to be made with the utmost attention, to be reconciled with truth? Do they not leave us to infer that the data employed have been either

incidental or accidental circumstances have interfered with the estimates, and led to erroneous conclusions?

The belief in the moon's influence over the natural operations going forward upon our earth, has by no means been confined to the weather; and it would be a tedious task to enumerate all the agencies she has been allowed to possess over organic and vegetable life both animate and inanimate. "Many of the opinions vulgarly entertained upon this head," says M. Arago, "are founded on well-established facts, the error lying, not in the observations, but in the theory which makes the moon the *cause* of phenomena, of which she is only the silent and unconcerned spectator." The distinguished philosopher from whom we have just quoted, has cited a number of highly interesting cases, which show in the clearest manner how the effects that have been ascribed to the moon's influence, can be readily traced to natural agencies operating around us, and with which modern philosophy has rendered us familiar. Such, for example, as the pernicious influence upon vegetation, attributed by gardeners and agriculturists to the April moon; the effect of the moon's rays in hastening the putrefaction of animal substances, &c.; all of which effects are doubtless connected with the presence of moonlight, merely, however, as an incidental circumstance, for they would take place equally well in a clear atmosphere, even should there be no such body as the moon in existence.

Let us take, for example, the case of the April moon, denominated by the French gardeners "*la lune rousse*." The *change* in this case takes place in April, and the *full* either about the end of this month, or some time in May; at which particular season, in our climate, the mean temperature of the air is but little above the freezing point. Under these circumstances the radiation from the earth, during a clear night, will often reduce its temperature to, or even below, the freezing point; whilst a thermometer suspended in the air, a few feet from the ground, will remain several degrees above 32°. Thus, the tender plants in the soil may become actually frost-bitten, whilst the atmosphere has been apparently too warm to admit of such an occurrence. If, on the contrary, the night be cloudy, the plants will suffer no injury; not, as the gardeners allege, because there is no moonlight to hurt them, but because the radiation and cooling of the earth will not take place. Thus, moonlight or starlight, the injury to vegetation will be precisely the same, and the effect might as well be ascribed to the stars as to the moon.

And, again, it has been noticed by Pliny and Plutarch, and is generally believed in most countries at the present day, that the moon's light sheds a copious humidity on substances exposed to its rays, and hastens the putrefaction of animal substances. That a copious humidity is often shed during a moonlight night, is not to be disputed neither can it be doubted that meats will spoil sooner, if exposed to her rays, than if protected from them. The nature and source of this humidity can be no mysteries now that the rationale of the

ormation of dew is so happily explained; and it is sufficient to say, that the moisture deposited upon the meat causes it to spoil much sooner than if kept covered, when it would remain dry. Meats are constantly preserved by simple drying; and even the mummies in the dry caverns of Egypt have lasted thousands of years, mainly from their depositories being perfectly free from moisture. The preserving agency of embalming is, perhaps, a secondary consideration, when compared with the subsequent state of dryness in which the bodies are kept.

As to the notion of lunar influence on disease, which still counts numerous partisans, I regard it as upon precisely the same footing as the exploded doctrine of the agency of the stars, so long and stoutly maintained.

Upon the whole, therefore, I look upon it as clearly demonstrable, upon established philosophical principles,

1st, That wet and dry weather are matters regulated solely by changes of *temperature*, over which the moon has no control:

2d, That the mutual influence exerted between the earth and moon, as shown in the ocean and atmospheric tides, depends upon the play of another and entirely distinct principle, namely, *gravitation* or attraction:

3d, That most, if not all, the effects upon animal and vegetable substances, popularly ascribed to the action of the moon, are to be traced to natural agencies, entirely independent of this satellite.

MOON-TREFOIL. A name for one of the species of medick (*Medicago arborea*).

MOONWORT (*Botrychium*, from *botrys*, a bunch; in reference to the form of the fructification, which is much like a bunch of grapes). The species of this genus of ferns are curious and interesting plants; one only is indigenous, the common moonwort (*B. lunaria*), which is a perennial growing in mountainous pastures or meadows. The root consists of several simple, cylindrical, clustered or whorled fibres. The herb is very smooth, a little succulent, of a pale opaque green, erect, not a span high. Leaf solitary, pinnate; leaflets fan-shaped, notched.

MOOR. An uncultivated surface of country, without trees, and with few grasses or other herbage fit for pasture; and usually containing scattered plants of heath, with a dark peaty soil. Moor lands are generally the least fitted for culture of any description of surface, not rocky or mountainous. Moors are covered with a very thin layer of soft, black, sterile soil; and the subsoil is generally gravel or retentive ferruginous clay. By the destruction of the heath or other bad herbage, and by sowing down with grass-seeds, they may be improved. In many cases, also, trees will grow on drained moors; in which case the soil ultimately becomes ameliorated by the shade they afford, and the fall and decay of their leaves. See **HEATH**, **MORASS**, **PEAT SOILS**, and **WASTE LANDS**.

MOORBAND PAN. This is a name given in Scotland to an indurated combination of clay, small stones, and iron in a particular state, situated either immediately, or at some

distance below the path of the plough, and which is nearly impervious to water. All indurated incrustations, however, formed under the sole of the plough, says a writer in a valuable agricultural journal, are not *moorband pan*. In good alluvial loam of greater depth than the plough-furrow, and rendered adhesive by pressure, an incrustation or firming of the subsoil—that is, the bottom upon which the plough moves, is frequently formed by the sole of the plough rubbing constantly on the soil at the same depth. This incrustated earth can retain water, but its effects on soils and plants are innocuous compared to those of moorband pan. Nevertheless, its disruption by deep ploughing is of benefit to the soil, and we have experienced it in very fine deep mould. From an analysis by Mr. John Gray, of Dilston, of two portions of moorband pan obtained from Mylnfield Plain, 120 parts of one were found to contain 34 of oxide of iron, 74 of silex, and 6 of alumina or clay and loss; the other contained 43 parts of oxide of iron, 64 of silex, and 8 of alumina and loss.

MOOSE. See **DEER**.

MOOSE-ELM. See **ELM**, **RED**.

MOOSE-WOOD. The name of a species of maple (*Acer striatum*), so called in the northern section of the United States, but in the Middle States known by the common name of striped maple.

MOOR-GRASS (*Sesleria*, named in honour of M. Sesler, a physician and botanist of the 18th century). These are uninteresting grasses in an agricultural point of view.

MORASS. Moor lands saturated with water to such an extent as not to bear the tread of cattle. A morass is to a moor what a marsh is to a meadow. It is evident that the drainage of morasses and moors, by lessening the evaporation of water from their surfaces, must tend to improve the local climate. See **PEAT** and **PLANTATIONS**.

MORDANT. Any substance used to fix dyes or colouring matters upon different stuffs.

MOREL (Germ. *moschel*). The *Morchella esculenta* is one of the few edible fungi which may be used as food with safety. It occasionally occurs in woods and orchards, whence it finds its way to the markets; but it is of comparatively rare occurrence. It has a hollow stalk an inch or two high, and a yellowish or grayish indented head 2 or 3 inches deep. See **FUNGI**, and **MUSHROOMS**.

MORTAR. A well-known cement employed for building purposes, which is thus described by Dr. Thomson: "It is composed of quicklime and sand, reduced to a paste with water. When dry it becomes as hard as stone, and as durable; and adhering very strongly to the surface of the stones which it is employed to cement, the whole wall in fact becomes nothing else than one single stone. But this effect is produced very imperfectly unless the mortar be very well prepared. The lime ought to be pure, completely free from carbonic acid, and in the state of a very fine powder; the sand should be free from clay, and partly in the state of fine sand, and partly in that of gravel; the water should be pure, and if previously

sa. urated with lime, so much the better." The best proportions, according to the experiments of Dr. Higgins, are 3 parts of fine sand, 4 parts of coarse sand, 1 part of quicklime, recently slacked, and as little water as possible. The stony consistence which mortar acquires is owing partly to the absorption of carbonic acid, but principally to the combination of part of the water with the lime. This last circumstance is the reason that, if to common mortar one-fourth part of lime, reduced to powder without being slacked, be added, the mortar, when dry, acquires much greater solidity than it otherwise would do. This was first proposed by Lorient; and afterwards Morveau found the following proportions to answer best:—

	Parts.
Fine sand - - - - -	3
Cement of well-baked bricks - - -	3
Slacked lime - - - - -	2
Unslacked lime - - - - -	2
	—
	10
	—

The same advantages may be obtained by using as little water as possible in slaking the lime. Higgins found that the addition of burnt bones, in the proportion of not more than one-fifth of the lime employed, improved mortar by giving it tenacity, and rendering it less apt to crack.

When a little clay is added to mortar, it acquires the important property of hardening under water; so that it may be employed by the farmer in those edifices which are constantly exposed to the action of water. Limestone is found not unfrequently mixed with clay; and in that case it becomes brown by calcination, instead of white. These native limestones are employed for making *water* mortar; but good water mortar may be made by the following process: Mix together 4 parts of blue clay, 6 parts of black oxide of manganese, and 90 parts of limestone, all in powder. Calcine this mixture to expel the carbonic acid; mix it with 60 parts of sand, and form it into a mortar with a sufficient quantity of water. The best mortar for resisting water is made by mixing lime with puzzolano, a volcanic sand brought from Italy. Morveau informs us that basaltes, which is very common in this country, may be substituted for puzzolano. It must be heated in a furnace, thrown while red-hot into water, and then passed through a sieve.

MOSSES, in common language, are any minute, small-leaved, cryptogamic plants. Thus, club-moss is a lycopodium; Iceland and reindeer mosses are lichens; and the numerous species of *Jungermannia* are all comprehended under the same term. But in systematical botany no plants are considered mosses, except such as belong to the natural order, *Bryaceæ* or *Musci*. Such plants are simple-leaved; without spiral vessels or stomata; with a distinct axis of growth; and with the spores, or reproductive matter enclosed in cases called sporangia or thecæ, covered by a cap or calyptra. It is not a little singular that such plants should have cases called staminidia, containing powdery matter; among which are found animalcules, not distinguishable from

such as are called spermatic, and which swim about freely in water. None of the mosses are of any known use, except for the purpose of packing plants, and surrounding their roots when they are sent to a distance. They are bad conductors of heat, and might be employed, instead of straw, to guard delicate-growing plants from the influence of frost.

MOSS LAND. Land abounding in peat moss, but not so much saturated with water as to become peat bog or morass. Many remedies have been prescribed for the destruction of moss. A good scarifying or harrowing, with short, sharp tines, succeeded by a top-dressing of salt or soot, is probably the most efficacious: lime in any form is less powerful, though (especially when combined with sand) it remarkably promotes the growth of trefoil tribes and other grasses, highly palatable to cattle, but does not avail to the exclusion of moss. Mr. Bishop of Perthshire, who has obtained from the Highland Society of Scotland a prize for an essay "On the Management of Pasture in regard to the Destruction of Musci," suggests as the most certain remedy, that a great portion of the summer's grass should remain unconsumed on the ground until the following winter, when the barer it is eaten before the new growth of spring, the finer will be the following summer's grass. Breaking up the land, and sowing appropriate grasses after a course of culture, is a certain remedy, but often a very inconvenient one. Mr. W. Bell gives an account of certain experiments which he carried on very successfully for converting moss into manure by the application of whale oil.

Mr. A. Blackadder, speaking of the manures for decomposing moss, says: Adjacent rocks strata ought to be carefully explored, as in general they have each their corresponding earthy covering, more or less adapted to the purposes of vegetation. Where the rocks are of the primitive class, or of the coal formation, their disintegrated portions, and oftentimes their superficial covers, are of inferior value as a soil; but even the rock-earth of the latter, as also of clay-slate, lime, or even the old red sandstone, though not previously mingled nor superimposed in the moss, are yet valuable as ingredients of composts for top-dressing, as are also those of the finer sandstone, greenstone, and sea-sand containing calcareous matters in a state of decomposition, or even where these are absent. While sand laid over moss produces rapid decomposition, and consequent vegetation, no such effect is produced by the purer clays. Putrescent matters, whether animal or vegetable, possess the most powerful influence. Lime, unless in compost, seems to have no such effect on simple mosses; and its effects on mixed mosses, or those in a state of partial decomposition, must depend on the quantity of foreign matter and other circumstances. The value of moss greatly depends on local circumstances, and particularly with regard to the supply of operatives at the commencement of improvements; access to putrescent manures; markets for the sale of the produce; soils affording materials for top-dressing; and turf suitable for wedge-drain-

or for drain-tiles, or stone for drains, or clean gravel, if found preferable, the expense at which these can be laid down at the moss must enter into the calculation. Or, again, if the moss is to be entirely removed, whether an adequate supply of water can be obtained, with access to a river or to the sea, into which it may be floated off. Nothing adds more to the intrinsic value of moss than mixtures of other soils during the progress of its formation, either by means of the winds carrying drift sand, or by water transporting earthy particles. When, again, a considerable quantity is thus superimposed, the soil ceases to be a moss, properly so called, and is an alluvial soil upon a moss subsoil. In either case, little more is required than thorough draining, in order to the production, by the ordinary means, of the best crops; and such is the description of the greater part of the mosses hitherto successfully improved in Scotland. The same writer furnishes some causes of the failure in moss improvements.

MOTH. *Clothes-moth, Fur-moth, Grease-moth, &c.* The various kinds of destructive moths, found in houses, stores, barns, granaries, and mills, are mostly very small insects; the largest of them, when arrived at maturity, expanding their wings only about eight-tenths of an inch. The ravages of some of these little creatures are too well known to need a particular description. Among them may be mentioned the clothes-moth (*Tinea vestianella*), the tapestry-moth or carpet-moth (*T. tapetzel-la*), the fur-moth (*T. pellionella*), the hair-moth (*T. crinella*), and the grain-moth (*T. granella*), with some others belonging to a group, which may be called Tineans (*Tineadæ*); also the pack-moth (*Anacamptis sarcitella*), which is very destructive to wool and fabrics made of this material, and the Angoumois grain-moth (*A. cerealella*), both of which are to be included among the Yponomeutians. In the cabinet of the Boston Society of Natural History, the cases, containing the large and beautiful collection of shells, were formerly lined with fine white flannel. In this some moths soon established themselves, multiplied very fast, and, in the course of a few years, did so much damage that it became necessary entirely to remove the moth-eaten linings. In their winged state these moths were of a light buff colour, with the lustre of satin, and had a thick orange-coloured tuft on the forehead; the wings were deeply fringed, and the first pair were lance-shaped, and expanded rather more than half an inch. This species agrees very well with the description given, by the old naturalist, of the *Tinea flavifrontella*, or the orange-fronted tineæ, and with Wood's figure of *Tinea destructor*, the destroyer. Should it prove to be different from these, it may be named the satin-buff moth. Objects of natural history are very apt to be injured by another moth, closely resembling the foregoing, and differing from it chiefly in being somewhat smaller, and in having the hind-wings tinged with gray. Chocolate, as Réaumur has remarked, is devoured by another tineæ, whose little silken cases are often seen between the cakes, and I have also found them in chocolate put up in tin cases. Other articles of food are also devoured by some of these

tineæ, and even our books are not spared by them.

Habits of Moths, and Means of preserving Clothes, &c., from their Attacks.—The tineans, in the winged state, have 4 short and slender feelers, a thick tuft on the forehead, and very narrow wings, which are deeply fringed. They lay their eggs in the spring, in May and June, and die immediately afterwards. The eggs (according to Latreille and Duponchel, from whose works the following remarks are chiefly extracted) are hatched in 15 days, and the little whitish caterpillars or moth-worms proceeding therefrom immediately begin to gnaw the substances within their reach, and cover themselves with the fragments, shaping them into little hollow rolls and lining them with silk. They pass the summer within these rolls, some carrying them about on their backs as they move along, and others fastening them to the substance they are eating; and they enlarge them from time to time by adding portions to the two open extremities, and by gores set into the sides, which they slit open for this purpose. Concealed within their movable cases, or in their lint-covered burrows, they carry on the work of destruction through the summer; but in the autumn they leave off eating, make fast their habitations, and remain at rest and seemingly torpid through the winter. Early in the spring they change to chrysalids within their cases, and in about 20 days afterwards are transformed to winged moths, and come forth, and fly about in the evening, till they have paired and are ready to lay their eggs. They then contrive to slip through cracks into dark closets, chests, and drawers, under the edges of carpets, in the folds of curtains and of garments hanging up, and into various other places, where they immediately lay the foundation for a new colony of destructive moth-worms.

Early in June the prudent housekeeper will take care to beat up their quarters and put them to flight, or to disturb them so as to defeat their designs and destroy their eggs and young. With this view wardrobes, closets, drawers, and chests will be laid open, and emptied of their contents, and all woollen garments, and bedding, furs, feathers, carpets, curtains, and the like, will be removed and exposed to the air, and to the heat of the sun, for several hours together, and will not be put back in their places without a thorough brushing, beating, or shaking. By these means, the moths and their eggs will be dislodged and destroyed. In old houses, that are much infested by moths, the cracks in the floors, in the wainscot, around the walls and shelves of closets, and even in the furniture used for holding clothes, should be brushed over with spirits of turpentine. Sheets of paper sprinkled with spirits of turpentine, camphor in coarse powder, or leaves of tobacco, should be placed among the clothes, when they are laid aside for the summer. Furs, plumes, and other small articles, not in constant use, are best preserved by being put, with a few tobacco leaves, or bits of camphor, into bags made of thick brown paper, and closely sewed or pasted up at the end. Chests of camphor wood, red cedar, or of Spanish cedar,

are found to be the best for keeping all articles from moths and other vermin. The cloth linings of carriages can be secured forever from the attacks of moths by being washed or sponged on both sides with a solution of the corrosive sublimate of mercury in alcohol, made just strong enough not to leave a white stain on a black feather. Moths can be killed by fumigating the article containing them with tobacco smoke or with sulphur, or by shutting it in a tight vessel and then plunging the latter into boiling water, or exposing it to steam, for the space of 15 minutes, or by putting it into an oven heated to about 150 degrees of Fahrenheit's thermometer.

Stored grain is exposed to much injury from the depredations of two little moths, in Europe, and is attacked in the same way, and apparently by the same insects, in the United States. See CORN-MOTH, GRAIN-WEEVIL, and INSECTS.

MOTH MULLEIN. See MULLEIN.

MOTTLED. In botany, signifies marked with blotches of colour of unequal intensity, passing insensibly into each other. It is synonymous with maculated; as, for instance, in the stems of common hemlock (*Conium maculatum*).

MOULD. A general name for the finely divided earthy substance that forms the upper stratum or surface soil of land, and in which all kinds of vegetables strike root and thrive. See ANALYSIS OF SOILS, EARTHS, and HUMUS.

MOULD-BOARD. See PLOUGH.

MOULD ON HOPS. A vegetable disease, which is liable to affect the hop plant, in the more advanced periods of its growth, and produce much mischief to the crop. See MILDEW and HOPS.

MOULDEBAERT. This implement of Flemish husbandry resembles a large square balshovel: it is strongly prepared with three bars of iron on the lower side, secured by 12 bolts, and is drawn by a pair of horses with swingle-trees. It is used for transporting compost, mould, &c., from one spot to another. Its usual dimensions are as follows: breadth across, 3 feet 6 inches; length, 3 feet; height of back, 1 foot 6 inches; length of handle, 4 feet. The person who drives, with long reins, by pressing moderately on the handle as the horses go forward, collects and transports about 5 cwt. of earth to the place where it is to be laid down, which is done in the most expeditious manner, by his letting go the handle; this causes the front edge of the implement to dip and catch against the ground, whereby it is at once turned over and emptied of its load. The extremity of the handle, to which a rope is affixed, by this upsetting strikes against, and rests upon, the swingle-tree bar, and in this manner the mouldebaert is drawn along towards the heap of earth or compost; the driver then, by taking up the rope, draws back the handle, collects his load as before, proceeds to the spot which is to receive it, and the horses are never for a moment delayed.

MOULTING. The fall of the plumage of birds. It may be either partial or total: the complete moult generally takes place annually; the partial moult occurs at the change of plumage on which some species of birds are subject

at the breeding season. The moult is always accompanied by the development of a new plumage, which may be of a different colour from that which is lost.

MOUNTAIN ASH. See ROWAN TREE.

MOUNTAIN EBONY (*Bauhinia*; in memory of John and Caspar Bauhin, botanists of the sixteenth century). A genus of showy and interesting evergreen shrubs, which will succeed well in a mixture of sand, loam, and peat.

MOUNTAIN LAUREL. See KALMIA LATIFOLIA.

MOUNTAIN MAHOGANY (*Betula lenta*). Black Birch. See BIRCH.

MOUSE-EAR CHICKWEED. See CHICKWEED.

MOUSE-EAR SCORPION-GRASS. See SCORPION-GRASS.

MOW. A pile or heap of corn, straw, or hay placed together for the purpose of being kept dry. See STACK and RICK.

MOW-BURNT. A term applied to such substances as are over-heated in the mow by the process of fermentation.

MOWING. The act of cutting down corn, grass, &c., by the scythe.

MOWING MACHINES. See REAPING MACHINES.

MUCILAGE. A turbid, slimy fluid, produced by treating some vegetable substances with cold water, others with hot. It resembles gum, but is distinguished from it by not forming a thick curd with the solution of Goulard's extract. See STARCH, LINSEED, MARSH MALLOW, &c.

MUCK. A farming term for any sort of material, such as dung, straw, &c., that is moist, or in a fermenting or decomposing state.

MUD. The mechanically suspended matters of water deposited at the bottom of rivers, ponds, ditches, &c. As much of this kind of material should be collected as possible, and be thrown up into heaps in order to become mellow. It contains much carbonaceous matter, and is an excellent manure, either in the simple or compound state, mixed with compost, or with a bushel of lime or salt to each cubic yard.

MUDWORT (*Limosella*; from *limos*, mud, in allusion to the habitation of the species; whence, also, the English name). The common mudwort (*L. aquatica*) is an English annual subaquatic plant, growing in muddy spots, where water has stagnated during winter. The herb is diminutive and quite smooth.

MUGWORT (*Artemisia vulgaris*). This species of *Artemisia* grows very common about English hedges, in waste ground, and the rough borders of fields. This species is weakly aromatic, and bitterish; and has, from remote antiquity, been esteemed an active warm medicine in decoction.

MULBERRY TREE (*Morus*; from the Celtic word *mor*, signifying black, in allusion to the colour of the fruit). The species of *Morus*, or mulberry, grow from 10 to 30 feet high. A moist situation and loamy soil, with a free exposure to the sun, suit them best.

1. The common mulberry (*M. nigra*) is in general cultivation for the sale of its fruit, which is well known.

2. The white mulberry (*M. alba*) is extensively cultivated in many countries for its leaves, which form the chief food of silkworms.

The mulberry tree may be propagated by layers, cuttings, or grafting. The principal use of the fruit of the black mulberry is for the dessert; but from its cooling and laxative properties, its juice, diluted with water, is sometimes used as a beverage in fevers. It is also employed in the form of syrup for medicinal purposes, chiefly to colour other fluid medicines. The juice is also used to give a dark tinge to liquors and confections. When properly fermented and prepared, the fruit yields a pleasant vinous liquor, known under the name of mulberry wine. In the cider counties they are sometimes mixed with apples, to form a beverage known as mulberry cider. The bark of the root has an acrid bitter taste, and is a powerful cathartic; hence it has been successfully used as a vermifuge, in doses of a scruple, in powder. The wood of the tree is yellow, tolerably hard, and may be applied to a variety of uses in turning and carving. It is, however, necessary to steep it in water before it is worked, in order to remove the tough and fibrous bark, which is capable of being converted into strong cordage, ropes, and brown paper.

Linnæus has enumerated seven species of the mulberry known in his day, all which are employed to feed silkworms, except the *Tinctoria* and *Indica*, of which the first named furnishes the well-known dyeing substance called *fustic*.

The species of mulberry found growing wild in the United States, is the *Morus rubra* of botanists, the berries being of a round and oblong form, and red, or dark purple, the pulp enveloping numerous small seeds. When perfectly ripe they are pleasant and wholesome.

The varieties of mulberry employed in Europe for feeding the silkworm form a long list. They have usually been multiplied by engrafting the finer kinds on the stalks of the common white Italian mulberry. Hence, the fine, large, and firm-leaved kind called the Rose of Provence, Rose of Lombardy, &c. The exertions made to improve the tree and increase the size of the leaf by repeatedly sowing the seed of the best kinds, has resulted in the greatest success, and now the Moretta, Elata, and other varieties, are obtained from seed, with leaves sufficiently large to render grafting unnecessary.

Besides these long-known varieties of mulberry used for feeding silkworms, comparatively few of which have been employed in the United States, there are two others, namely, the Multicaulis and the Chinese, which have been very greatly multiplied, especially the former. The Chinese is usually produced from seeds imported from Canton. Its growth is exceedingly vigorous, and its leaves heart-shaped, flat, and very large. The Multicaulis is always propagated from cuttings or layers, and is more hardy than the Chinese, with larger leaves, which are always hollow and uneven. Even where the severe winter frosts of the Northern States cause the Multicaulis to be cut down, the suck-

ers spring up from the old roots so as to afford in good season an abundance of foliage. Of late years, a hybrid variety of mulberry has been produced in France by shaking the pollen of the Moretta flowers over the flowers of the Multicaulis. The seed of the Multicaulis produced by this mixture, produces a hybrid variety with more valuable qualities than the parent, and nearly as great a capacity for propagation by layers and cuttings. The hybrid Multicaulis has large flat leaves, like those of the Chinese or Canton seedlings. They are firm, and much relished by the worms. They endure frost equally well with the white mulberry, and are exceedingly well adapted to the silk-culture, both from their great precocity of growth, hardiness, and valuable qualities for feeding the worm and making good silk.

MULE. This is the well-known offspring of the ass and the mare, or of the she-ass and the horse. In the latter case, the produce is called a jennet, and is much less hardy, and therefore rarely bred. The term mule is generally applied in the animal creation in the same sense with hybrid in the vegetable world, signifying the intermixture of two distinct species. Mules are very hardy animals, and therefore much used in warm climates, where they are preferred to horses, either for the purposes of draught or carriage. Considerable numbers are likewise employed in Ireland, and in some of the northern counties of Britain, on account of their great strength and durability. No animal is more sure-footed or more hardy; but the pace of the mule is disagreeable to those unaccustomed to its action. The diseases to which the mule is liable are few. He attains double the age of the horse, and is much more easily maintained. The mules of the south of Europe are frequently very fine animals, 16 or 17 hands in height, active, handsome, and peculiarly patient of labour; but very inferior in beauty to the horse, particularly about the head and tail. The importation of Spanish asses into England has tended greatly to improve its mules, many of which, when bred with care, are sufficiently thick-set and heavy for all those purposes in which our largest draught-horses are employed.

To have large and handsome mules, the mare should be of a large breed, well proportioned, with rather small limbs, a moderate-sized head, and a good forehead; and the ass should be of the large Spanish breed.

MULLEIN (*Verbascum*; said to be from *barbasum*, bearded, in allusion to the bearded filaments). The English species of *Verbascum* are strong, robust-growing plants, producing an abundance of showy yellow flowers, and on that account they are well adapted for planting in the garden at the back of flower borders, or in shrubberies. They grow freely in any soil, and are readily increased by seeds; some of the perennial kinds by divisions of the root. (*Paxton's Bot. Dict.*) There are as many as 6 wild species common to Britain, viz., great mullein, or high taper (*V. thapsus*); white mullein (*V. lychnitis*); yellow hoary, or Norfolk mullein (*V. pulverulentum*); dark or black

mullein (*V. nigrum*); large-flowered primrose-leaved mullein (*V. virgatum*); and moth mullein (*V. blattaria*). The dark black mullein is a perennial, the moth mullein annual, and the rest are biennial in habit. They mostly grow to the height of 3 to 5 feet, in fields and waste places, on chalky and gravelly soils. The species of mullein common in the United States, in the fields of slovenly farmers, is the *Verbascum thapsus* of botanists.

MUNJEET. A kind of madder grown in the East Indies.

MURIATIC ACID, called also *Hydrochloric acid*; anciently *Marine acid*, and *Spirit of sea-salt*.

MURICATE. In botany, implies covered with short, sharp points.

MURRAIN. A contagious, malignant epidemic, which frequently prevails in hot, dry seasons among cattle, carrying off vast numbers. It once used to sweep off the horned stock of whole districts, and there are few years in which it is not now seen in some part of the kingdom. It principally appears in marshy and woody districts, or where under-draining has been neglected, or the cattle have been exposed and half-starved. The disease is known by the animals hanging down their heads, which are swollen, by short and hot breathing, cough, palpitation of the heart, staggering, an abundant secretion of viscid matter in the eyes, rattling in the throat, and a slimy tongue. The early stage of murrain is one of fever, and the treatment should correspond with this: bleeding and small doses of purgative medicine will be serviceable. The peculiar fetid diarrhoea must be met with astringents, mingled also with vegetable tonics. In combating the pustular and gangrenous stage, the chloride of lime will be the best external application; while a little of it, administered with the other medicines inwardly, may possibly lessen the tendency to general decomposition. Above all, the infected animal should be immediately removed from the sound ones. (*Youatt on Cattle*, p. 379.)

MUSCLE (Fr. *muscle*; Sax. *murcuta*). Fleishy fibres, susceptible of contractions and relaxations. They constitute what is commonly called flesh, the most nutritious species of animal food. See **FLESH** and **GELATIN**.

MUSHROOMS (Fr. *mouscheron*; Lat. *Agarius*, from *Agaria*, a city, or *Agarus*, a river of Sarmatia, now Malamonda). A more extensive genus than this is not known in the whole vegetable kingdom. Some species, as the common mushroom, *A. campestris*, *A. vaginatus*, &c., are well known for the wholesomeness of the food which is prepared from them. Others, as *A. muscarius*, *A. necator*, the whole genus *Amanita*, and many others, are very dangerous poisons: indeed, the latter quality exists more or less in so many species, and these resemble those that are wholesome so nearly as to render it advisable to be exceedingly cautious in the use of fungi, for the most dreadful effects are well known to have resulted from want of caution in this respect.

The edible mushroom (*A. campestris*), is nearly inodorous, but has a grateful flavour. The crown or hat is at first hemispherical,

then convex, and at last flat; fleshy; about 2 to 5 inches broad; white, or very light-brown, slightly scaly, the scales soft and fibrous; gills pink, changing to fuscous black; the flesh, when divided, usually changes to a reddish hue. The use of the mushroom, as an article of diet, was known to the ancients. See **FUNGI**.

To produce mushrooms artificially, beds variously constructed are employed; and, from the numerous modes which have been invented and adopted for their production, some accompanied with extraordinary expense, it is obvious that this "voluptuous poison" is with us, as it was with the Romans, in high estimation.

MUSSELS, or **MUSCLES** (*Mytilus edilis*). A species of shell-fish which abound on the rocky shores on the borders of the sea in many parts of the British islands, adhering to the rocks. Muscles are also found in immense beds, both in deep water and above the low water-mark, in the British seas. Where they can be collected in large quantities they may be made use of as an excellent manure, either alone or in the state of compost, with earthy substances.

MUST. A term applied to new wine and wort before it is fermented. It is also given to the saccharine juice of several fruits susceptible of the vinous fermentation, and particularly to the expressed juice of the grape before its conversion into wine.

MUSTARD (Fr. *moutarde*; Lat. *Sinapis*; from *σιναιπι*, on account of its making the eyes water, *σινυ ωπας*). A genus of upright, branching, annual or biennial herbs, often hairy or bristly. There are five wild species common to the British islands:—

1. Wild mustard (*S. arvensis*). A very troublesome annual weed in corn-fields; also abundant in waste ground newly disturbed. The seeds serve as an inferior kind of mustard, or rather, to adulterate that made from the common mustard. See **CHARLOCK**.

2. White mustard (*S. alba*), 3. Common mustard (*S. nigra*), are annuals, in general cultivation, but are also found wild on waste ground and by road-sides, &c. See **CULTIVATED MUSTARD**.

4. Narrow-leaved wall-mustard (*S. tenuifolia*). This perennial species is found growing on old walls and heaps of rubbish about most ancient cities. The root is tapering, rather woody. Herb for the most part entirely smooth, and more or less glaucous all over; fetid when bruised. Stem bushy, erect, 1½ or 2 feet high, with numerous round, leafy branches, occasionally besprinkled with a few hairs.

5. Sand mustard (*S. muralis*). This annual species flourishes on sandy, barren ground near the sea. The root is small and tapering.

MUSTARD, CULTIVATED. The species of *Sinapis* generally grown in the kitchen garden for domestic purposes are the white mustard (*S. alba*), and the common or black mustard (*S. nigra*). The first is the one grown for salads; but the seed of both is employed in the manufacture of mustard.

The soil they succeed in best is a fine, rich, mouldy loam, in which the supply of moisture

is regular; it may much rather incline to lightness than tenacity. If grown for salading, it need not be dug deep; but if for seed, to full the depth of the blade of the spade. In early spring, and late in autumn, the situation should be sheltered; and, during the height of summer, shaded from the meridian sun. For salading, the white may be sown throughout the year. From the beginning of November to the same period in March, in a gentle hotbed appropriated to the purpose, in one already employed for some other plant, or in the corner of a stove. From the close of February to the close of April, it may be sown in the open ground, on a warm, sheltered border; and from thence to the middle of September, in a shady one. Both the white and black, for seed, may be sown at the close of March, in an open compartment.

For salading, it is sown in flat-bottomed drills, about half an inch deep and six inches apart. The seed cannot well be sown too thick. The mould which covers the drills should be entirely divested of stones. Water must be given occasionally in dry weather, as a due supply of moisture is the chief inducement to a quick vegetation. The sowings are to be performed once or twice in a fortnight, according to the demand. Cress (*Lepidium sativum*), is the almost constant accompaniment of this salad herb; and as the mode of cultivation of each is identical, it is only necessary to remark that, as cress is rather tardier in vegetating than mustard, it is necessary for the obtaining them both in perfection at the same time, to sow it five or six days earlier. See CRESS.

It must be cut for use while young, and before the rough leaves appear, otherwise the pungency of the flavour is disagreeably increased. If the top is cut off, the plants will in general shoot again, though this second produce is always scanty, and not so mild or tender. For the production of seed, whether for manufacture of mustard or future sowing, the insertion must be made broadcast, thin, and regularly raked in. When the seedlings have attained four leaves, they should be hoed, and again after the lapse of a month, during dry weather, being set 8 or 9 inches apart. Throughout their growth they must be kept free from weeds, and, if dry weather occurs at the time of flowering, water may be applied with great advantage to their roots. The plants flower in June, and are fit for cutting when their pods have become devoid of verdure. They must be thoroughly dried before thrashing and storing. For forcing, the seed is most conveniently sown in boxes or pans, even if a hotbed is appropriated to the purpose. Pans of rotten tan are to be preferred to pots or boxes of mould. But whichever is employed, the seed must be sown thick, and other restrictions attended to as for the open-ground crops. The hotbed need only be moderate. Air may be admitted as abundantly as circumstances will allow. (*G. W. Johnson's Kitchen Garden.*)

MUSTARD, FLOUR OF. The seeds of both black and white mustard are employed in making the ordinary flour of mustard for dietetical use. In the dry state, mustard is inodorous,

and, were it possible to taste without the aid of moisture in the mouth, it would also be tasteless; the principle of its odour and taste not existing ready formed in the mustard, but requiring water for its development. The principles which exist in the mustard are two: one an acid, which has been named myronic acid, and is a compound of carbon, sulphur, hydrogen, nitrogen, and oxygen; the other a substance resembling vegetable albumen, which has been named emulsin, or myrosyne. When the myrosyne and the myrenic acid, which is united with potassa in the form of a myronate of potassa in the mustard, act upon each other by the aid of water, the volatile oil of mustard is formed, and odour and pungency given to the mustard. It is the volatile oil which reddens and blisters when mustard poultices are used; and it is important to know that vinegar checks the acrimony of the poultice, and should not be used. Tepid water only is required.

MUTTON (Fr. *mouton*). The flesh of the sheep. Although, by recent extensive improvements, the breed of sheep have been diminished in size, yet the smallness of bone and symmetry of form which the animals have thus acquired, have considerably decreased the quantity of offal, and added largely to the dead weight of marketable flesh. Before that time the mutton of those coarse sheep rarely amounted to more than one-half of their live-weight; whereas now, the common average is more than two-thirds; and Dishley wethers, when well fattened, are said to be in the proportion of an ounce of bone to a pound of flesh. The best and most nutritive mutton is that of sheep which are at least three, but not more than six years old, and which have been reared on dry, sweet pastures. The meat afforded by such as have been fed on salt marshes, or near the sea-coast, is likewise sweet and wholesome; for they have acquired both firmness and a fine flavour from the saline particles abounding in such situations.

A sheep, to be in high order for the palate of an epicure, should never be killed earlier than when five years old, at which age the mutton will be found firm and succulent, of a dark colour, and full of the richest gravy; whereas, if only two years old, it is flabby, pale, and savourless. To ascertain the age of mutton, Mr. Ellman directs: "To observe the colour of the breast-bone when a sheep is dressed, that is, where the breast-bone is separated: which in a lamb, or before it is one year old, will be quite red; from one to two years old, the upper and lower bones will be changing to white, and a small circle of white will appear round the edge of the other bones, and the middle part of the breast-bone will yet continue red; at three years old, a very small streak of red will be seen in the middle of the four middle bones, and the others will be white; and at four years old, all the breast-bones will be of a white or gristly colour." South Down wether mutton, in point of delicacy and flavour, is thought equal to any that is killed; and in summer as preferable to some other fine-flavoured breeds, especially Norfolk mutton. This circumstance is attributed to the closeness of the grain, or the specific gravity

being greater, rendering it more impermeable to the air than coarser and looser fleshed mutton, which is, of course, more subject to putridity. The older the mutton, the finer the flavour.

It is almost unnecessary to remark, that *wether-mutton* is always considered so far preferable to that of the ewe, that the flesh of the latter, although more commonly kept to a mature age, always sells at an inferior price. Connoisseurs, however, assert that a spayed or maiden ewe, kept until five years old before she is fattened, produces mutton superior to that of any wether.

The *live-weight*, with the offal, of a large, fat wether, and the joints when cut up for market, were as follows:—

Live weight	- - -	13 st. 10 lbs.	
<i>Offal.</i>			
Blood and entrails	- - -	13	0
Caul and loose fat	- - -	21	4
Head and pluck	- - -	8	12
Pelt	- - -	15	12
<i>Carcass.</i>			
First fore-quarter	- - -	29	0
Second	- - -	28	12
First hind-quarter	- - -	33	8
Second	- - -	32	0
<i>Joints of one side.</i>			
Haunch	- - -	23	0
Loin	- - -	10	4
Neck	- - -	12	0
Shoulder	- - -	10	12
Breast	- - -	4	8
Loss	- - -	0	12

See MEAT and SHEEP.

MUZZLE. The nose of a horse or other animal. It also signifies a kind of halter put upon the nose of a horse or mule, to prevent eating or biting.

MUZZLE OF A PLOUGH. A term sometimes applied to the copse or part to which the draught is attached. See PLOUGH.

MYRRH. See SWEET CICELY.

MYRTLE (From *myros*, perfume; *myrtos* of the Greeks, *myrtle* of the Dutch, and of almost every other European language). The myrtle, from the delightful perfume, the delicacy of its blossoms, and the glossy green of its perpetual foliage, is a favourite and well-known genus of plants, which grow well in sandy loam and peat; and cuttings, if not too ripe, will root freely either in sand or soil under a glass. There are nearly a dozen distinct species, besides numerous varieties. The *myrtus pimenta* yields the allspice or Jamaica pepper.

The common European myrtle (*M. communis*) is a native of the south of Europe, growing 5 or 6 feet high, with very fragrant leaves, and blowing small white flowers in summer. Being a tender shrub, this myrtle should have a southern or southwestern aspect, with protection in winter.

MYRTLE BILBERRY. See WHORTLEBERRY.

MYRTLE, THE DUTCH, or SWEET GALE (*Myrica gale*; from *myrio*, to flow, being found on the banks of rivers). This, in England, is an ornamental, aromatic, indigenous shrub, growing wild in bogs and marshes, especially on a gravelly soil. The stem is upright, bushy, 3 or 4 feet high, with numerous alternate branches. It bears berries which are

very small, covered with resinous dots, exhaling a delightful fragrance when rubbed between the fingers. The leaves are aromatic from the same cause. This plant, perhaps one of the more innocent substitutes for hops, is used for brewing by the poor in Sweden. Linnæus says the berries boiled in water yield wax like those of the candleberry myrtle (*M. cerifera*). See CANDLEBERRY MYRTLE.

N.

NAG. A provincial term applied to a horse, of a small size for the saddle; such a horse is very useful for many purposes, where light labour is required.

NAPIFORM. Formed like a turnip, tuberous.

NARCISSUS (from *narke*, stupor, on account of the effects produced by the smell upon the nerves). This is an old and very popular flower of great beauty, and some of the species are highly fragrant.

NARCOTIC (Fr. *narcotique*). Substances having the double property of exciting in the first instance, and afterwards stupifying and producing sleep or torpor. In medicine the term comprehends opiates, anodynes, and other drugs which induce sleep and allay pain.

NASTURTIUM (from *nasus*, the nose, and *torvus*, tormented). The acidity of *N. officinalis* affects the muscles of the nose. Few of these plants are worth cultivating; they are of the simplest culture. The seed of the annual kinds has only to be sown in the open ground in spring. See CRESS.

NAVE OF A WHEEL. The short, thick block in the centre of the wheel which receives the end of the axletree, and from which the spokes radiate: it is bound with hoops, called nave-bands, to strengthen it. It has likewise in each end of the hole through which the axletree passes, a ring of iron called the washer, which saves the nave from wearing.

NAVEL-ILL. See CALF, DISEASES OF.

NAVEL-WORT, *Cotyledon* (from *kotyle*, a cavity; in allusion to the cup-like leaves). A numerous and rather ornamental genus of succulent herbs or shrubs, with very thick, juicy, alternate, simple, entire, or jagged leaves. In England, the native species are two in number: both are perennial in habit, flowering about June and July.

NAVEW. The common wild navew (*Brassica campestris*) belongs to the cabbage tribe, and is an annual plant, found in corn-fields, marshes, and about the banks of ditches and rivers. The root is tapering; stem erect, 2 feet high, leafy, branched, glaucous; rough in the lower part, with small bulbous spreading bristles; smooth upwards. Radical leaves lyrate, toothed, and jagged, rough; stem-leaves smooth, clasping, oblong, partly pinnatifid; all somewhat glaucous. Flowers blowing in June and July, yellow, corymbose, almost as large as those of the turnip. Pods on longish stalks, 1½ inch long, nearly cylindrical, beaked. The roots are nourishing, containing a sweet juice, which is sometimes domestically used in coughs and asthma.

NAVICULAR. A botanical phrase, signifying boat-shaped.

NEAT CATTLE. See CATTLE.

NECTARY, in botany, is applied to those parts of a flower which secrete honey.

NECTARINE (*Amygdalus Persica*, var. *Nectarina*). A variety of the common peach, from which the fruit differs only in having a smoother rind and finer pulp. The culture is in every respect the same as the peach. The varieties of nectarines are numerous, nearly 70 being described in the catalogue of the Horticultural Society of London. Forsyth recommends for a small garden the following sorts:—Fairchild's Early, Eldridge's Scarlet, Newington, Red Roman, and Temple's. Nectarines, like peaches, are subdivided into free-stones and cling-stones.

NEP. See CATMINT

NERVES. In botany, the strong ribs upon leaves or flowers, which are bundles of vessels, chiefly spiral. Besides conveying the sap to the leaf, and returning the proper juice to the bark, they often afford distinctive characters to the leaf.

NETTED. A botanical term, implying that the veins or membranes are reticulated on the leaf, or variously intersected.

NETTLE, *Urtica* (from *uro*, to burn; in reference to the stinging properties of most of the species). An extensive genus of herbaceous or shrubby plants of little beauty, and which are justly looked upon in the eyes of the agriculturist as mere weeds. The herbage in all the species is copiously armed with venomous perforated bristles, each of which has a bag of liquid poison at its base. This liquor, by the slight pressure required to pierce the skin, is transmitted into it, causing great irritation. Many of the numerous exotic species have not this stinging property; but the sting of common nettles is not to be compared with that of some of the Indian species grown in the gardens of Europe. These are, however, all surpassed in virulence by one which in Timor is called *duoun setan*, or devil's leaf, the effects of which are said by the natives in many cases to cause death. In England, the indigenous species of nettle are three; viz. 1. Roman nettle (*U. pilulifera*), an annual plant, growing in waste ground amongst rubbish, chiefly near the sea. The herb is armed all over with peculiarly venomous stings. The stem is branched, leafy, bluntly quadrangular, often purple, about 2 feet high. 2. The small nettle (*U. urens*) is found to be in all cultivated ground a troublesome weed, especially on a light soil. It is annual in habit, flowering from June till October, smaller than the last, and of a much brighter green; its copious stings hardly less virulent. The several parallel ribs of the leaves form its distinguishing character. The whole plant being refused by every kind of cattle, should be carefully extirpated from pastures. 3. The common or great nettle (*U. dioica*), which is a noxious perennial weed, growing almost everywhere, and flowering in July and August. The root is branching and creeping, with fleshy roots, and many fibrous radicles. The herb is of a duller green than the last, erect, 3 feet high, with less irritating stings.

Leaves large, heart-shaped, spreading, pointed strongly serrated, veiny. The leaves are employed for feeding poultry, especially in the winter; when boiled, they are said to promote the laying of eggs. Asses devour nettles eagerly, but all other live-stock refuse them, unless they are dried. In the western islands of Scotland, a rennet is prepared by adding a quart of salt to 3 pints of a strong decoction of nettles; a tablespoonful of which is said to be sufficient to coagulate a bowl of milk. The young tops of the common and smaller nettles may be boiled as potherbs during spring, and eaten as a substitute for greens; being not only nourishing, but mildly aperient. The tough fibres of the stem may be manufactured like hemp, and are often found in winter naturally separated and bleached. The roots are astringent and diuretic. See DEAD-NETTLE.

NETTLE-HEMP. See HEMP-NETTLE.

NETTLE TREE (*Celtis*). This is an ornamental genus of trees and shrubs, varying in height from 6 to 50 feet. The most of them do very well in any common garden soil, and are suitable for the back of shrubberies and plantations. They are increased by seeds or layers.

NETTLE TREE, AMERICAN (*Celtis occidentalis*). Sugar-berry. This American tree, Michaux says, if not rare, is little multiplied in comparison with the oaks, the walnuts, and maples. As it is scattered thinly through the forest, it is difficult to fix the point at which it ceases towards the north, but it is believed not to extend beyond the Connecticut river. In the Middle, Western, and Southern States, it bears the name of nettle tree, whilst the French call it *bois inconnu*, or unknown wood. On the Savannah river trees are found 60 or 70 feet high, and 18 or 20 inches in diameter. In the Middle States it seldom grows above 10 or 15 feet in height. It is similar in its foliage and general appearance to the European nettle tree. The flowers are small and white, and open early in spring. The fruit consists of small berries disposed on stems singly, of a dull red colour, purplish when mature, and of a sweetish taste. (*Michaux*.)

NICKING. In farriery, an operation performed on the tails of horses to make them carry them well.

NIGHTSHADE (*Solanum*). A very numerous, principally tropical genus of shrubs or herbs, more or less narcotic; though in some cases rendered eatable by cookery, as in our common potato. Some of the genus are very dangerous and highly virulent poisons. Two species only are indigenous to England,—1. The woody nightshade (*S. dulcamara*). See BITTERSWEET.

2. The common or garden nightshade (*S. nigrum*). This is common everywhere, in waste as well as cultivated ground. The root is fibrous, annual in habit, occasionally perennial. Herb fetid, narcotic, bushy, with numerous angular or winged leafy branches. Stem herbaceous, without thorns. Leaves undivided, ovate, lengthened at the base, smooth. Umbels from the intermediate spaces between the leaves, lateral, drooping, solitary, stalked, simple, downy. Flowers white with a musky scent. The berries globular, black; some

times, as it is reported, yellow. A grain or two of the dried leaf has sometimes been given to promote various secretions. Both its poisonous and medicinal powers depend on an alkaline principle, which can be procured in a separate state, and has been called *solanina*. It is a powerful narcotic, and the poisoning principle of the solanums.

NIGHTSHADE, DEADLY, or DWALE (*Atropa belladonna*). A plant with narcotic and dangerous qualities, found growing in hedges and waste ground on a calcareous soil, frequently about ancient ruins. The root is fleshy and creeping. Stems herbaceous, annual, 3 feet high, round, branched, leafy, slightly downy. Leaves lateral, mostly two together of unequal size, ovate, acute, undivided. Flowers solitary, stalked, drooping, dark dull purple in the border, paler downwards, about an inch long. Berry of a shining violet black, partially enveloped in the calyx, which is persistent, the size of a small cherry; sweetish, and not nauseous, so that children have often been tempted to eat it to their own destruction. The poisonous principle is an alkali named *atropia*.

NIGHTSHADE, ENCHANTER'S. See ENCHANTER'S NIGHTSHADE..

NIGHT-SOIL. In agriculture, a powerful manure. This valuable fertilizer has not been employed in England to the same extent as on the continent, although it is certainly one of the most valuable of the organic manures; and to this neglect many causes have contributed. Its disagreeable odour, certain vexatious fiscal regulations with regard to its removal, and erroneous modes of applying it, either in excessive quantities, or mixed with other composts in such proportions that its powers could not be distinguished in the mass; its semifluid nature requiring for its removal carriages of a peculiar construction, the extent and completeness of the sewerage of our large cities, and several other minor obstacles, have rendered its use not nearly so extensive as, even in a national point of view, is desirable. Davy, however, described it, 25 years since, as "a very powerful manure, and very liable to decompose: a part of it is always soluble in water; and, in whatever state it is used, whether recent or fermented, it supplies abundance of food for plants." (*Lectures*, p. 229.) "The disagreeable smell," he adds, "may be destroyed by mixing it with quicklime; and if exposed to the atmosphere in thin layers in fine weather, and mixed with quicklime, it speedily dries, is easily pulverized, and, in this state, may be used in the same manner as rape-cake, and delivered into the furrow with the seed."

Night-soil is a mixture of urine and fœces; and these have been found to contain the following substances. Fœces were analyzed by M. Berzelius: the products were—

	Parts.
Water	73.3
Vegetable and animal remains	7.
Bile	0.9
Albumen	0.9
Peculiar and extractive matter	2.7
Salts	1.2
Slimy matter, insoluble residue, &c.	14.
	100.

The salts detected in this analysis, equal to 1.2 parts, were carbonate of soda, muriate of soda, sulphate of soda, ammonia, phosphate of magnesia, and phosphate of lime. (*Genl's Journal*, vol. vi. p. 536.) To the same great chemist we are indebted for an analysis of human urine. He found 1000 parts to contain—

	Parts.
Water	933.
Urea (peculiar animal matter)	30.10
Sulphate of potash	3.71
Sulphate of soda	2.16
Phosphate of soda	2.94
Muriate of soda (common salt)	4.45
Phosphate of ammonia	1.65
Muriate of ammonia	1.50
Acid matter	
Acetate of ammonia	} 17.14
Animal matter and urea	
Earthy phosphates and fluuate of lime	1.
Mucus	0.32
Silica (earth of flint)	0.03
	1000.

(*Annals of Philos.* vol. xi. p. 423.)

The chemical composition of urine shows, that it abounds in animal and mineral constituents which must afford a copious supply of food to plants.

According to very recent experiments reported by I. C. Nesbit, the excretions of one person were found, from actual daily weighings long continued, to average 7 to 8 oz. avoirdupois of solid matter, and 3½ lbs. of urine. This would make the annual amounts 170 lbs. of fœces, and 1277 lbs. of urine. But when these are perfectly dried, there remains only 45 lbs. from the solid matter, and 35.7 lbs. from the urine, making the annual amount of dry matter in both, about 80 lbs. From a comparison with other manures in the English market, the actual value of this 80 lbs. of dry matter is computed by Mr. Nesbit at \$2.50. This appears to be a lower estimate than that made by Boussingault, who considers the excrements of a single adult during a year sufficient to produce 14½ bushels of wheat; an estimate which agrees better with the views of the Chinese, who reckon the ordure of even a superannuated or disabled person as of sufficient fertilizing value to compensate for his bread. The odour of night-soil may be destroyed by any means which will dry it: such as additions of dry mould, peat, powdered charcoal, or plaster; also by sprinkling with a saturated solution of copperas in water, or oil of vitriol diluted with 10 parts of water.

Davy's plan of destroying the smell of night-soil by the addition of quick-lime, may answer very well to correct a nuisance; but the agricultural value of the manure produced, would be lessened, since the addition of caustic lime to animal matters drives off their ammonia, the most fertilizing portion.

The account of eastern customs, furnished by modern travellers, illustrates very remarkably the notices of the sacred historians. "In Arabia, says Niebuhr (vol. i. p. 91), "the dung of asses and camels is chiefly used for fuel, because these are the most numerous and common. Little girls go about gathering dung in the streets, and in the highways; they mix it with cut straw; and of this mixture make cakes, which they place along the walls, or upon the declivity of some neighbouring eminence, to dry them in the sun." Tourne.

fort, speaking of Georgia, says, "All this fine country yields not a single tree; and they are forced to burn cows' dung." (*Tournefort*, vol. iii. p. 137.) And again, when speaking of Ezeroon, he says, "You see neither tree nor bush, and their common fuel is cows' dung." And Le Bruyn speaks of the same custom as occurring in Persia:—"Wood is very dear, and is sold by weight; whence it is that they are obliged to make use of turf made of camels' dung, cows' dung, sheeps' dung, horses' dung, and asses' dung. They use it more particularly for heating of ovens, in which they bake most of their meats in this country. They even apply human dung in this way."

Long experience has taught many nations the value of this manure. In China it is preserved with the greatest care, mixed with a fat marl; and, according to Sir George Staunton, made into cakes, which, after being dried in the sun, constitute a regular article of traffic between the citizens and the cultivators of that singular empire. The same useful practice is carried on in Belgium. What we throw into our rivers the more thoughtful Belgians turn to account; what is a nuisance in London is a source of revenue at Brussels. To a report of my friend, Dr. Granville, I am indebted for a pretty copious account of the value assigned to this manure in the northern states of the continent; and this I will give chiefly in his own language. When describing a continental tour, made chiefly for the purpose of examining the mode of employing this description of manure in Germany, he says, "The kingdom of Würtemberg is so overstocked with population, and land, consequently, is of such value, that every inch of it is progressively brought into a state of culture by dint of labour and manuring, no matter how ungrateful the soil, or its situation, may at first sight appear."

"The cultivation of the vine is one which requires, in certain arid and mountainous soils, a liberal use of the human manure. Wishing to ascertain this fact from my own observation, I undertook a journey through the principality of Nassau, and along both banks of the Rhine, examining many of the vine districts, as I descended that river for the purpose of visiting Holland. On my return, I took French Flanders in my way, looking particularly to the great flax districts of Tournay, Lille, Valenciennes, and Cambrai, where the surprising results obtained from the application of human manure, like those obtained in Belgian Flanders by similar means, have induced agriculturists, within the last few years, to give to that species of manure the name of 'Flemish Manure.'"

And, when speaking of the little care taken in England of this fertilizer, he continues:—"In no part of France, Würtemberg, Bavaria, Bohemia, Prussia, Saxony, the Confederated States of Germany, Holland, and Belgium, is here a city in which, as in London, the general mass of filth, of every description, created by a vast population, is first allowed to enter the river which may happen to traverse that city, and is then returned, diluted with the water of that river, to the houses of the inhabit-

ants, to be used either for domestic or culinary purposes; although, by avoiding the latter disgusting alternative, foreign cities are less free from unpleasant smells than London is. In this respect, it may be truly said that foreigners smell the filth of their cities, but do not swallow it; whereas the Londoner swallows it, but seldom smells it.

"In no large city of that part of Europe which I have recently visited, possessing a river, is any portion of the contents of closets and cesspools suffered to find its way, or to be emptied into it, except at Amsterdam, Antwerp, Brussels, Stuttgart, and Leipzig; and even there only in a partial manner. In Paris the Seine is contaminated by one large drain only, conveying the urine from the large reservoirs of night-soil at Montfauçon, and by 2 smaller ones proceeding from cesspools. To convey generally, or to empty even partially any such matter into the river, is a practice against which the laws have provided by heavy fines and incarcerations. And such is the present feeling of all the governments on that subject, even in the great cities I have just enumerated as exceptions, that the superior authorities are seriously engaged in devising plans for preventing in future every possible infraction of those laws; not because it is desirable to preserve pure the water of such rivers (since no domestic use is made of it), but on account of the loss of a material, deemed most valuable, which such infractions must necessarily entail.

"Night-soil is husbanded in every part of the Continent I have visited, without exception, with a jealousy and care which prove how valuable it is considered by the people. In most of the cities of the second order, and the smaller capitals, night-soil is a source of profit, first, to the householder, next to a middleman, and, thirdly, to the farmer, who is the last purchaser, and employs it.

"In all the towns of the Grand Duchy of Baden, of the kingdom of Würtemberg, of Bavaria (except Munich and Würzburg), of the province of Salsburg, of Bohemia (except Prague), of Saxony (except Dresden), in some of the minor cities of Prussia, in all the confederated principalities, in all the cities on both banks of the Rhine, particularly Strasburg, Mayence, Coblenz, Bonn, Cologne, Dusseldorf, Nimeguen, &c., the householder disposes of the contents of his cesspool for a certain sum of money, besides getting the operation of emptying it performed gratuitously. By comparing the returns of the different prices paid in those cities for the commodity in question, one year with another, and equalizing them by an average price, the inhabitants appear to be benefited to the amount of 4 francs a head yearly, and the middlemen to at least 40 per cent. more on the sum he pays to the original seller. I will cite Strasburg as an example, since most of the other cities of the same extent (on the Rhine, and in many parts of Germany), and a few cities even larger presented the strongest analogy to the case I have selected. At Strasburg, a company of middlemen engage to empty the cesspools, of which every house has at least two (built air -

water-tight), once a year for nothing, and pays, moreover, 6 francs per *charette*, containing 96 *baquets*, of the capacity of 4 gallons each. This quantity the company sells afterwards to the farmers for ten francs. (The capacity of the *charette* being to that of a ton as 28,772 ounces are to 35,840, it follows that the price of a ton at Strasburg would be 10s.) Now, as there are 14,000 houses in Strasburg, 10,000 of which have cesspools affording the soil in question (which is always semi-liquid), supposing the latter to be emptied only once a year, and to furnish each 3 *charettes* only, at six francs, we have $10,000 \times 6 \times 3 = 180,000$ francs, which the company pays yearly to the inhabitants of a town having a population of 70,000 souls. But as the company resell to the farmer the said soil for manuring purposes, at ten francs per *charette*, it follows that this article of traffic produces yearly at Strasburg 300,000 francs, or just about $4\frac{1}{4}$ francs for each inhabitant."

The high prices paid for this manure by the Continental farmers betrays the estimation in which they hold it. "The contractor at Brussels, M. Champon," says Dr. Granville, "sells his manure for 13s. 4d. per ton—400 florins, or 33l. 6d. for a barge-load of 50 tons. M. Smet, the greatest trafficker, perhaps, in this material in East Flanders, gets for some of his 10s., and for the best and larger portion of it 15s. per ton; while the contractor at Antwerp disposes of all he has of Flemish manure at 52 florins the *put*, or 624 florins the barge-load, equal to 52l., or 11. 10s. 9d. per ton. But if we look to what takes place every day at Montfaugon, near Paris, where 200 cart-loads of the contents of the cesspools are daily deposited, to be converted into *poudrette*, we find the latter (a dry and compound manure made from night-soil) to fetch a much higher price than all the rest.

"But by far the most important point of practical knowledge in this matter, put forward by the same great authorities, and the truth of which was afterwards confirmed to me by more than one great farmer in East Flanders, is, that while the manuring with human soil has produced 14 times the quantity sown, where horse-dung has only yielded 10, the proportion of the human or Flemish manure employed was, to that of the horse-dung, as 1 to 5 only; so that with 1 ton of the Flemish a larger produce is obtained than with 5 tons of stable manure." See MANURES APPLICABLE BY THE DRILL.

In Sweden the value of night-soil has been long well understood by the farmers. Nearly half a century since the Baron de Schulze, when writing to Sir John Sinclair, observed, "They have now ceased to spoil the fine harbour of Stockholm with nuisances of every kind. The contents of the privies are now collected, by undertakers, in barrels, of which they are obliged to have a double quantity to replace those deposited in the reservoirs, from whence they are carried to the country. My eldest son, who has changed the sword for the ploughshare, has particularly attended to this manure, being favourably situated on the Lake Malar, 48 English miles from the capital; he conveys it in a covered boat, each loading of

which is sufficient to dress about 3 acres of spring corn, and between 4 and 5 of winter corn and meadow ground. This manure, by the motion of the boat, becomes more liquid; and it is conveyed from the hold of the vessel by a bucket at the end of a lever, through a spout into a close cart on shore drawn by two oxen. These carts are provided with a movable funnel, and with a strainer so regulated, by means of a pole, that the manure can be administered at pleasure by the driver, without further attention to spreading. That the land may not be overdunged, and the crop consequently lodged, care must be taken not to lay above 40 such cart-loads on the Swedish acre for spring corn; each cart containing 180 gallons English, or 1920 lbs. Except that other powerful manure produced by the refuse of the herring oil-works, none can come into competition, for richness, with the contents of the privy mixed with urine. The effects of this manure, no doubt, diminish gradually; yet its operation may be plainly perceived in the fourth successive crop. When clover is meant to be sown with the spring corn, this species of manure is unsuitable; for although the seed be diminished to one-third, the straw becomes so thick and strong as to choke the clover. A mixture of lime is sometimes recommended for this manure, in order to dry it and correct the smell; but, besides that lime is not plentiful here, the process would be found to require a considerable time and expense. A little addition to the wages of the labourers or cottagers soon reconciles them to the inconvenience of the smell, and it becomes still less offensive to them if they are allowed to use part of it on their own little fields. If any particular impediment occurs, such as harvest work, this manure is then from the vessel conveyed to great pits, to be, after a mixture with other substances, driven to the field at a more convenient season." (*Com. Board of Agr.* vol. i. p. 326.) The prejudice which some English labourers entertain against the employment of night-soil is readily overcome by a little management. The stream which flows through the village of Eastbourn, in Sussex, had become, a few months since, much contaminated through the night-soil which had been deposited in it from the adjoining cottages, and it was in vain that their owners were advised to use it for their gardens; until an excellent lady of the place, who is ever ready to promote the comfort of her poorer neighbours, desired her bailiff to go round and propose to purchase it of them. His offer was, however, rejected, universally rejected; and ever since they have no longer suffered the contents of their privies to be wasted, but have carefully applied them, and with the best results, to their own gardens; remarking, that if it was worth a farmer's while to buy it of them, it must be worth more to them for their gardens.

"By this term, night-soil," remarked the indefatigable Arthur Young, "at London, is to be understood the collections there made of what a French marquis calls 'l'espèce de fumier que la politesse empêche de nommer;' from which trait of him one would not have expected he should know so much of the value of it as he

really did. An Englishman says, 'tis more decent and better to let it alone; but as I conceive it perfectly decent and efficient, I shall consider human ordure as the very best manure that can be procured. But here, I shall first consider the farmer's conduct at home, where his great object is to raise as much manure as possible without being obliged to depend on purchases, which are only to be made in certain situations. If the farmer manages his necessary-house in such a manner as to suffer nothing to run off from it, and frequently throws malt-dust, saw-dust, fine mould, or sand into it, he may, every year, manure from 1 to 2 acres of land.

"If the farmer is within reach of any considerable town, and there are scavengers or people who will collect this manure and keep it separate, the farmer can hardly purchase it at too high a price. In the last century, the ordure of the galley-slaves at Marseilles was all saved, and sold to the farmers as a dressing for grapes, olives, and figs; the last of which produced by it were the best in the world. At Nice it sells high, and every peasant has a house of office for passengers. In China it seems to be a manure, of all others, in the most request; and in Italy they are well acquainted with its value. At London it sells at from 3s. to 6s. a load; at 17 miles distant, with turnpikes and all expenses, it costs 25s. a wagon-load; yet it answered greatly. It should be laid by the scavengers in very light swamps (not too deep) in a grass field, and in summer trenches cut through it to drain; and then being thrown in heaps, it is of very light carriage. Three wagon-loads, or from 240 to 300 bushels, are enough for an acre of grass land, upon which I think it answers best; but mixed with marl, loam, turf, or dry pond mud, its use for that application is excellent. I have compared it with all other manures, and found that none of them I could procure equalled it by many degrees. It is a vulgar error to imagine that manuring a field with this substance will give a bad taste to plants. I dressed part of a pasture with it, fed the whole of that year with horses, cows, and young cattle, and I remarked to various gentlemen that saw it how close into the ground that part was constantly eaten, while there was much longer grass, &c., in every other part of the field."

"On October 20th, 1772," adds Arthur Young, "I marked divisions each of 4 square perches on a summer fallow; the soil a poor blue pebbly gravel, and manured these compartments as follows:—

Produce of Wheat per Acre.

	Bushels.
Soil, simple - - - - -	12½
Bushels of night-soil - - - - -	320
Do. - - - - -	240
Do. - - - - -	160
Cubic yards of farmyard compost - - - - -	60
Do. - - - - -	30
Do., and 1 cubic yard of chalk - - - - -	30

"The effect of night-soil," he continues, "was prodigious; it just trebles the produce. In all the experiments I have made with this manure, I have ever found this result almost uniform." (*Annals of Agr.* vol. iii. p. 79.) It is evident, also, from the experiments of Arthur

Young, which are entirely confirmed by those of the Essex farmers, and my own, that night-soil is an excellent manure for potatoes. The following table contains the results of Arthur Young's trials. The soil on which these experiments were made was a poor gravelly loam.

Produce per Acre.

	Bushels
Soil, simple, produced - - - - -	120
Night-soil, 10 wagon-loads, each 96 bushels - - - - -	600
— 6 — — — — —	650
— 2 — — — — —	500
Bones 10 — — — — —	650
— 6 — — — — —	640
— 2 — — — — —	560
Hog-dung, 60 one-horse cart-loads - - - - -	480
— 30 — — — — —	480
Yard-compost, 60 one-horse cart-loads - - - - -	300
— 120 — — — — —	480
— 30 — — — — —	140

These experiments are useful, as indicating the comparative value of each fertilizer, although the quantities employed were evidently excessive. Mr. Hewitt Davis, of Spring Park, near Croydon, finds 6 tons of night-soil, mixed with peat, to be amply sufficient for an acre of ground. He thinks this manure the best for turnips. Night-soil is, however, in spite of all the obstacles of prejudice and inattention, much more extensively used in the neighbourhood of the large manufacturing towns of the north of England than it was formerly. Mr. Dixon, of Hathershaw, in Lancashire, thus describes his mode of using it. "For the conveyance of night-soil and urine, we have the largest and strongest casks, such as oils are imported in; the top of each is provided with a funnel to put the matters through, and the casks are fixed on wheels like those of a common dung-cart. I am fully aware that there are many localities where neither peat nor night-soil can be readily obtained; but it is worth a farmer's while to go even more than 20 miles for the latter substance, provided he can have it without deterioration: the original cost is often trifling. On a farm where turnips or mangel-wurzel are cultivated to some extent, the system here recommended will be almost incalculably advantageous. A single horse is sufficient for one carriage; mine holds upwards of a ton each; 6 tons of this manure in compost with peat, or, if that is not convenient, any other matters, such as ditch-scourings, or high headlands which have been properly prepared and laid dry in a heap for some time, would be amply sufficient for an acre of turnips or mangel. This manure is by far the most invigorating of any I have ever yet tried. Bones in any state will bear no comparison as a help for any crop; but it must be remembered that I write on the supposition that it has not been reduced in strength before it is fetched."

There have been various patents granted in France for the preparation of manure from night-soil, several of which have proved very successful. The *poudrette*, or dried night-soil, first prepared by M. Bridet, was found, after repeated trials, to be a very powerful dressing for land; 240 lbs. of this powder producing effects equal to 8 loads of stable manure. This substance has been recently examined by Professor Hermstadt, who reports it to be a perfect substitute for common dung; that it is most

efficacious in wet seasons; and that in dry seasons it is less useful upon sandy soils than upon greasy c.ays. There is no doubt but that very excellent composts may be made from night-soil; and, in fact, several are now prepared in London, on a very bold scale, for the service of the farmer; but the success of these is usually impeded by the preparers professing that their preparations may be used in quantities much too small. Then, again, one or two patents have been taken out in England for artificial manures, by persons who were evidently very grossly ignorant of what they professed to understand. (*Johnson on the Fertilizers*, p. 92.) See FARM-YARD MANURE; MANURES APPLICABLE BY THE DRILL; URINE.

NIPPERS. A term applied to the four teeth in the fore part of the horse's mouth, two in the upper and two in the lower jaw: they are cut forth between the second and third years. Nippers, in farriery, are the pincers which the smiths use in shoeing.

NITRATES OF POTASH AND SODA. Two salts lately much employed in agriculture. The first (nitrate of potash) is known in commerce under the name of saltpetre, and is principally procured from the East Indies, where it is found on the surface of the ground, especially in the district of Tihû, in Bengal. It also abounds in Ceylon, Persia, Egypt, and even in Spain; but that which is brought to England comes chiefly from India in an impure state, and contains about 70 per cent. of pure nitre. It, however, varies in quality; but the average loss in the purification is generally about 15 to 20 per cent. Nitre is also formed by artificial composts in various parts of Europe. When pure, nitre is composed of nitric acid 54.15 parts, or 1 equivalent; and potash 47.15 parts, or 1 equivalent; or 52.9 per cent. of acid + 47.1 of alkali = 100.

Nitrate of soda, which is known as *cubic petre*, is obtained chiefly from Peru, where it is found in a thick stratum, at an elevation of 3500 feet above the level of the Pacific Ocean. (*Darwin's Researches*, p. 443.) It is sold, it seems, at the ship's side on the coast of Peru, at 14s. per cwt. It is composed of nitric acid 62.1 parts, and potash 37.9 parts.

It is only in modern days that saltpetre has been extensively employed as a fertilizer; for it is not long that the nitre of commerce has been produced in quantities sufficiently large and reasonable to enable the farmer to profitably use it as a manure. That the knowledge of its enriching qualities, however, is not a modern discovery, is too self-evident to be doubted. Virgil (*Georgics*, lib. i. v. 193, 195) recommends it to the Italian farmers as an excellent addition to the dregs of olive oil, to form a steep to cause the seed-grain to swell and vegetate with vigour; and from his days to our own, hardly an agricultural writer has omitted to notice its powers. The very first English author who wrote upon husbandry, in 1532, Sir Anthony Fitzherbert, describes it as having the power to insure to the farmer the most abundant crops. And in 1570, a learned German counsellor, Heresbaschius, in his *Treatise upon Rural Affairs*, describes the use of this salt as not an uncommon dressing in his time

for coleworts. A century afterwards, Evelyn, in his *Discourse on Earth*, told the farmers of his age that if they could but obtain a plentiful supply of saltpetre, they would "need but little other compost to meliorate their ground." And even Jethro Tull, in the early part of the last century, who denied very zealously the necessary use of manures of all kinds—even Tull placed nitre at the head of his list of those substances which he deemed to be the essential food of plants.

Saltpetre, therefore, must not be regarded as a modern introduction into agriculture; for it has long been used in limited quantities by previous generations of cultivators, who, like us, were content to notice the effects which it produces, without being able to exactly comprehend its mode of action.

It is idle to merely substitute words in explanation of unknown effects, and to say that saltpetre is a stimulant, or that it yields nitrogen to the plant; and there is little evidence of its entering into the composition of any of the more commonly cultivated crops: there is, therefore, but a slight probability of its being a direct food of the plants to which the farmer usually applies it. The only common exception is that of barley, in which a minute portion of cubic petre (nitrate of soda) is found to exist.

But although these nitrates have not been detected in the farmer's crops, yet they are known to exist in many plants, most likely as essential ingredients. Thus saltpetre is found in the common horse-radish, in the nettle, and the sunflower. M. Chevalier discovered it in the *Chenopodium olidum*; M. Vauquelin in the deadly nightshade. Dr. John found it in the *Mesembryanthemum crystallinum*; M. Chevreul in woad. The growth of the sunflower is materially promoted by watering it with a weak solution of this salt. It languishes in soils which do not naturally contain it; but when the salt is added to the earth, then it immediately makes its appearance in the plant in the usual proportions.

And although we are not aware of its existence in the ordinary field-crops, yet still it may beneficially exist in them, and exert a considerable influence at certain periods of their growth, although in minute proportions: and, notwithstanding we have no direct evidence of the fact, it is not unlikely that its presence may tend to vary, in the vegetable world, the essentially present combinations of nitrogen, in a way which the skilful investigations of the chemist have not yet succeeded in tracing. Such researches, however, have already proved that nitrogen (of which, with oxygen, the acid of saltpetre is formed) performs a much more important part in vegetable economy than was once supposed; and many facts are already apparent which should encourage us to persevere in the examination. For instance, it has been observed by the farmer that these two nitrates (the base of whose acid is nitrogen) have a very powerful effect in adding to the deep green colour of plants. Now, this is precisely the effect produced by other fertilizers, which also contain nitrogen; such as gelatine, urine, oils, blood, soot, fish, &c. In fact, I am not aware-

of any manure producing this rapid, darkly-green, luxuriant growth, from which nitrogen is absent. Saltpetre is naturally generated on the earth's surface under favourable circumstances, and in situations much more frequent than the farmer is wont to suspect. Wherever ammonia is copiously generated, as in stables, farm-yards, &c., and wherever the nitrogen, which forms a component portion of ammonia, at the moment of its extrication has access to potash or calcareous matter, there saltpetre is usually formed. This is naturally done so copiously, in some of those situations in which the farmer is placed, as to form fine crystalline exudations on the walls; and it is in such places that those plants which abound in saltpetre, as the nettle, the horse-radish, &c., commonly flourish with uncommon luxuriance. It has been proved by those who gather the saltpetre from the earth's surface in southern Africa and Hindostan, as well as by those who prepare the artificial saltpetre beds in Spain from the sweepings of the streets of Madrid, that nothing more is requisite for the formation of saltpetre in these beds of earth, than the presence of a certain proportion of decomposing animal and vegetable matters, with some potash, and calcareous matter. Now all these essentials for the formation of saltpetre must in many situations be afforded by the farmer's own soils. There are, in fact, many lands in the cultivator's possession where, especially in dry summers, the formation of saltpetre in minute proportions is continually taking place; where the putrefaction of animal matters must in small proportions be productive of ammonia; and where an abundance of potash is already existing in the soil to neutralize the nitric acid produced, and form with it nitrate of potash or saltpetre. For it has been ascertained that if, at the moment when nitrogen is evolved, it is presented with oxygen gas, that it combines with it, and forms nitric acid. Here, then, we have explained to us the origin of the acid of the nitre, and we know that its base, or potash, is to be found in some form or other in all cultivated soils. And if we admit that this must in some instances be the case, then we shall be furnished with a ready explanation of many of the difficulties and discordant results which have attended the recent very general application of these two nitrates, since the fact that saltpetre has commonly been found to produce the least results upon those deep, rich, alluvial soils which must abound in decomposing organic matters, in some degree countenances the conclusion, as does the smallness of the quantity of saltpetre applied; for, if once we concede the possibility of the soil, under favourable circumstances, being able to generate this salt, then it will be allowed that one cwt. per acre is not a large crop for the soil to produce. That in this way it is generated in some of the richest soils of the East, to such an extent as to cover the surface with a white incrustation, is known to every oriental traveller. To a still greater extent is the land in those countries impregnated in many situations with the nitrate of lime, a salt which, possessing the same acid as nitre and cubic nitre, has lime instead of potash or soda for

its base; and from some experiments which I have made, I have little doubt but this nitrate, which is of much less cost than either the nitrates of potash or soda, will be found a valuable agent for the use of the cultivator. For its excessive deliquescent or moistening properties, which render it so unmanageable for many manufacturing purposes, make it more valuable to the cultivator of the poor, dry, thirsty soils, where artificial fertilizers are most in request. If nitrate of lime was imported at a reasonable rate, the farmer could readily, if he wished, make his own cubic petre, at a very low price, by mixing the nitrate of lime with glauber salts (sulphate of soda), by which means a rapid decomposition takes place, the result of which is nitrate of soda (cubic petre) and sulphate of lime (gypsum). The inferior, impure, refuse glauber salts, made by the cotton bleachers in the preparation of their bleaching powder, would answer for this purpose very well.

My experience of the enriching powers of saltpetre extends over several years. My earliest experiments were made in the kitchen and flower garden, in which I found very considerable advantage in increasing the beauty and in prolonging the bloom of several of the tenants of the latter; and in the former I found excellent results from applying it at the rate of 2 cwt. per acre to my beds of horse-radish, and in very small proportions, as one-eighth of an ounce per gallon, to the water with which I watered, to prevent mildew, &c., my early and late crops of pease, wall-fruit trees, &c. My experience with it as a field crop has been principally confined to the gravels of Essex and the chalks of Hampshire and Berkshire, in which, especially upon grass, I have obtained results exceedingly satisfactory. In 1840, I tried it upon the old clay grass soils of Knitbury, in Berkshire, with various other manures; 1st, at the rate of 1 cwt. per acre; 2d, nitrate of soda, 1½ cwt. per acre; 3d, Poitevin's manure, 14 bushels per acre; 4th, gypsum, 1½ cwt. per acre; 5th, nitrate of soda, 1½ cwt., and gypsum 1½ cwt. per acre. These were all applied by hand in the month of April; but although they all produced a better crop than the soil simple, yet the extreme dryness of the season operated very materially against the success of almost all artificial dressings, and the produce of the whole plot was much below an average crop. Nos. 1, 4, and 5 were decidedly the best, producing at the rate of rather more than 2 tons of hay per acre; while the produce of the soil simple was less than 22 cwt. per acre. The grasses were of the ordinary kinds tenanted the upland pastures, mixed with a considerable portion of nearly worn-out roots of lucern, which, in the plot No. 4, gypsum alone, and in No. 5, gypsum and cubic petre mixed, was revived by the application to a very remarkable degree; its plants nearly doubling in height any other portion of the land.

In some experiments, at which I was present, on the barley and wheat land of the chalk formation in the neighbourhood of Winchester, the effect of the saltpetre was excellent; the green colour of the crops was rendered much

more deep, and the increased produce far more than compensated for the expense of the salt-petre. And the same success attended its application to both red clover and sainfoin on the down lands; but when I tried saltpetre at the same rate per acre on the lawn of a rich old garden, whose earth was also principally chalk, there was no perceptible effect produced, even in the colour of the grass. This soil abounded in decomposing organic matters, was within reach of the soot and other ammoniacal matters of the city of Winchester, and, I have little doubt, in minute proportions already contained saltpetre. In fact, almost all the successful experiments with saltpetre have been made on light, poor land. Those of Mr. Lightfoot were on the gravels of Hertfordshire, which have a substratum of chalk; and yet he produced with 1 cwt. per acre of saltpetre effects more than equal to those produced by folding the land with sheep. And when Mr. Beadel, of Witham, tried it on the Essex clays, it produced hardly any effect, except increasing the colour of the wheat; but when he used the same quantity (1 cwt. per acre) on his light barley land, after Swedish turnips, the increase was 15 bushels of barley and 640 lbs. of straw per acre; and on a sandy field of oats, the increase from its application was 20 bushels of oats and half a load of straw. The successful experiments of Mr. Kimberley, of Trotsworth, on clover, in which he produced with 1 cwt. per acre of nitre results fully equal to that from 25 cubic yards of horse-dung, were upon the sandy lands of Surrey, "of moderate quality." Mr. Everitt, of North Creake, bears out entirely these conclusions, when he applauds its use "upon all light, warm soils," but predicts that, "on cold clay land, on an average of seasons, it will not more than repay the outlay;" and yet this excellent farmer had no reason to be dissatisfied with his success, having obtained from an application of 1 cwt. of saltpetre to "good light land," an increase of 6½ bushels of wheat. The experiments of Mr. R. Harvey, of Harlstone, entirely confirm those of Mr. Everitt; and in the *Report of the Harlstone Farmers' Club*, in 1839, it is stated to be "the unanimous opinion of the meeting," that saltpetre was excellent in its effects on heavy clover layers, but that on light land it was highly beneficial to "wheat, clover, and other layers and tares."

One of my neighbours, too, an excellent farmer of Essex, in 1839, found on the fine, light barley soils of his farm the following results from top-dressing his barley with 1 cwt. per acre of saltpetre, compared with the soil undressed, dressed with night-soil, with sprats, and with farm-yard manure:—

	Qrs.	Bushels.
The soil, simple, yielded - - - -	5	4½
Dressed with 1 cwt. of saltpetre - - -	6	6
Dressed with 50 bushels of sprats per acre, ploughed in - - - -	7	1
Dressed with 20 bushels per acre of disinfecting night-soil (Poittevin's) - - -	6	4½
Dressed with 10 loads of farm manure per acre - - - -	5	6

I have noticed, also (and the same remark applies to cubic petre), that the effect of saltpetre is the soonest apparent when it is finely powdered, and spread on the land in moist

weather. The explanation of this must, perhaps, be found in the superior rapidity with which, in such seasons, it mixes with the soil. The cultivator will remember that moist weather is also the best adapted for the application of other top-dressings, such as gypsum and soot. I have found in the application of crushed bones to grass lands, that they never produce such good effects as when rolled into the soil by a heavy roller, when the ground is softened by wet weather. The Staffordshire farmers will readily attest the same fact. If long-continued dry weather succeeds the application of the nitrates to clover, the leaves of the grass, wherever the powdered nitrate has fallen, become covered with yellowish spots.

The application, too, of either nitre or cubic nitre to grass renders it much more attractive to live-stock, who, if turned into a grass field only partially dressed with either, will almost invariably resort to the portion of the land dressed with the nitrates. This is one argument in favour of the conclusion that these salts are in minute proportions absorbed by the crops to which they are applied. We know that this is the case with other saline manures, such as gypsum (sulphate of lime) and common salt; and every cultivator who has dressed his grass with either salt or gypsum will attest how decidedly his live-stock prefer the grass so treated to every other portion of the same field.

The effect of cubic petre as a fertilizer for heavy soils, seems to be rather more favourable, as far as my observations extend, than that of saltpetre; and in this I am confirmed by the observations of many of my neighbours. Yet still I am of opinion that, in the great majority of instances, both the cubic petre and the saltpetre will be found much more valuable top-dressings for light lands than for the heavier soils; and I am not much inclined to alter my opinion from the results of many of the carefully observed experiments of the very dry season of 1840; for in such periods it is almost hopeless to expect that any kind of top-dressing will produce results such as may serve to guide us in our future practice. Thus, in seasons such as the last, I have repeatedly witnessed the failure of top-dressings of all kinds; not only of the salts, such as lime and salt, gypsum and soot, and malt coombs, but even of the richest manure. My neighbours in Essex know very well that if a dry summer follows the application of their sprats (perhaps the most powerful of all animal manures), the application is entirely useless. In my own experiments with nitrate of soda I have invariably found the most excellent effects produced by its application to barley at the rate of 1½ cwt. per acre, sown broadcast, as finely divided as possible, soon after the young plants were beginning to show themselves above ground. The soils on which these experiments were made were the barley soils of Hampshire and Essex; and the same increase to the green colour of the crop, and a similar large increase to the produce of seed which my neighbours experienced, resulted from my own experiments. The clover also, which was sown with the barley in most instances, seemed to derive a considerable benefit from the dressing; and

I have noticed on more than one occasion, the advantage of sowing the cubic petre in moist weather. In the dry summer of 1840, the effect of the cubic petre was very inferior to that produced by it on similar land and crops in 1838 and 1839—an effect which entirely supports my conclusions with regard to the inefficacy of all top-dressings in periods of long-continued dry weather. Of this opinion, too, is a very excellent and extensive farmer of Surrey.

Mr. Hewitt Davis noticed too the effect on some of the clays as well as the sands of Surrey in 1840,—that the effect of cubic petre upon young wheats at the rate of $1\frac{1}{4}$ cwt. per acre was excellent, not only in producing a very deep green colour, but in inducing a very considerable rankness of growth. But then, in his experience and observations, he has noticed that the wheat thus dressed has a stronger tendency to blight than that growing on the adjoining lands. On his farms, however, this rankness of growth is not felt as an evil; for on all soils, heavy as well as light, he practises an excellent system of *thin* sowing, the effect of which, as I can attest, is excellent in producing most abundant crops; either on the poor, hungry, black gravels and sands of Addington in Surrey, or on the tenacious clays of Sussex, he never drills more than 5 pecks of seed wheat per acre at intervals of 12 inches. It is true that by this plan the appearance of the wheat during the winter months is not so vigorous as many farmers would at first sight approve; but the plants gradually get together, stool out very abundantly, have all their ears of a uniform length; the produce is abundant, the sample generally excellent, and rarely subject to blight.

These valuable experiments of Mr. Davis entirely confirm those which I have been induced to make on several occasions, and may, in a great measure, perhaps, serve to explain some of the discordant results of the recent extensive, and, in the majority of instances, successful experiments, with nitrate of soda and saltpetre, as a top-dressing for wheat, barley, and oats. For in a great many instances where the cubic petre has failed to produce advantageous results, the seed has been sown in rather large quantities; the corn, therefore, by the action of the salt becomes darkly green, grows with great luxuriance—is perhaps too thick on the ground; and the farmer, as a natural consequence, finds that the nitrated corn has a tendency to mildew. In the first number of the second volume of the *Journal of the Royal Agricultural Society of England*, there is a mass of valuable information, collected by Mr. Barclay, which illustrates very considerably these observations on the advantages of thin sowing; such as the experiments of Mr. Barker, Mr. Hyett, and others. And although I am not prepared to contend that the effects of these two powerful salts will be in all cases the most apparent on thin-sown corn, yet I am much inclined to think that the farmer will find that this is very often indeed the case.

In most soils there is to be found a certain proportion of carbonate of potash, and in many it exists in sufficient quantity to decompose the

nitrate of soda, and form nitrate of potash and carbonate of soda. This may, perhaps, serve to account, in some instances, for the varying results obtained in some *apparently* similar soils from the application of the nitrate of soda, and may be one reason amongst others why moisture is found to be so essentially necessary for the beneficial action of cubic nitre; for it is a chemical axiom, that to produce any chemical action between two substances, one of them must be in a fluid state, perfectly dry substances hardly ever producing any chemical action on each other.

Such, then, are the results of the long-continued experiments and observations upon nitre and cubic nitre which I have been able to make, and to suggest to others to re-examine and verify; and such, too, are, I think, the reasonable conclusions to be derived from our united experience.

In pursuing a path so novel, and so extensive, it need hardly astonish us that there are yet several sources of error to be avoided, deceptive appearances to be scrutinized, and additional experiments needed, before we can expect to arrive at the knowledge of the best and most economical modes of applying these two valuable nitrates. The soils to which they are best adapted, and the causes of their not always producing even on apparently similar soils the same powerful effects, are amongst the objects of inquiry to which I have alluded in this paper. The advocates, however, of these saline manures have no need to complain of the progress which they have made; for admitting that on some soils they have *apparently* produced but trifling effects, and on other soils hardly any, yet still in the multitude of instances they have amply repaid the farmer for his outlay. There is no other instance, perhaps, of such a rapid introduction of a saline manure into agriculture, as that of the modern, extensive, and increasing use of cubic petre by the farmers of Great Britain; and if we only pause to remember the difficulties of experimental researches like those, exposed, as all examinations of the process of vegetation of necessity are, to innumerable sources of error, we shall find no reason to complain of the success of its introduction, or of the talent and enterprize with which the farmers of England have conducted their valuable experiments.

There are many experiments with these two salts to be met with in the agricultural journals of the last few years.

1. Memorandum of saltpetre, nitrate of soda, and common salt, used as top-dressings in the south-east garden park, of a lightish land, well drained, 11th April, 1840, on pasture laid down with grain in 1839: one acre sown with $1\frac{1}{2}$ cwt. of nitrate of soda, measured and marked as such; then a piece of one rood, without any dressing; again, one acre sown with $1\frac{1}{2}$ cwt. of saltpetre; next to this half an acre dressed with three-fourths of a cwt. of common salt.

Result.—In little more than a fortnight after this, having had some favourable showers, there was an extraordinary change on the two distinct acres dressed with saltpetre and nitrate of soda, as compared with the rest of the field. The grass continued to grow on these divisions

much stronger, close, and of an infinitely richer and darker colour; and the cattle lying much upon it, seemed very fond of it. This superior appearance continued through May and June, and perhaps later. The grass was, after this, eaten so close that no difference could be noticed, if any existed; it was particularly and frequently observed in September, October, November, and now, 8th December; and no difference was then, or is now, perceptible between the ground dressed with saltpetre and what was not so dressed. The pasture seemed equally benefited by the nitrate of soda as by the saltpetre; and as the latter cost in proportion to the former as 30s. to 20s. per cwt., there can be no question of preferring the nitrate of soda. No improvement could be perceived to have taken place from the dressings of common salt.

2. Another trial was made on pasture of the second year, in the lawn, on light land and dry, 14th April, 1840; one acre, measured and marked, sown with $1\frac{1}{2}$ cwt. of saltpetre; adjoining this, one acre sown with $1\frac{1}{2}$ cwt. of common salt; and next, one acre, measured and marked, sown with $1\frac{1}{2}$ cwt. of nitrate of soda.

Result.—Every remark applicable to the experiments in the south-east garden park applies equally to this. In both, in the different breadths sown by the cast of the hand where the two breadths joined, and the ground had got an extra quantity, the grass was richer and darker, showing that $1\frac{1}{2}$ cwt. per acre is not an over-dressing, whether of saltpetre or of nitrate of soda.

3. Memorandum of dressings of saltpetre, common salt, and of nitrate of soda, on the 16th of April, on oats already braided in Stott's Fauld, partly on well drained, dry, and partly on light land; one acre and fifteen falls, measured and marked, sown with saltpetre at the rate of $1\frac{1}{2}$ cwt. per acre; next to this, one acre and fifteen falls, dressed with common salt in the same proportion; next to this, one acre and fifteen falls, sown at the same rate with the nitrate of soda.

Result.—It was long before any effect was perceived on any of the oats dressed as above. About the end of June a difference was perceived on the acre and fifteen falls sown with saltpetre, which had previously shown worming, and then came away darker and stronger, and became a heavy crop of oats and straw. The acre and fifteen falls dressed with nitrate of soda never seemed to be benefited by the dressing. Being an inferior, light, sandy soil, with a red, iron bottom, it was injured by the early drought, and never recovered; the salt here, as on the pastures, seemed to have no effect.

4. Memorandum of dressings of saltpetre and nitrate of soda, in Laughlan Glenfield, principally strong clay, thorough-drained, and subsoil-ploughed, 26th April, 1840, on red clover, &c., for green cutting: one acre, measured and marked, sown with saltpetre, at the rate of $1\frac{1}{2}$ cwt. and $2\frac{3}{4}$ cwt. of nitrate of soda, were sown here in the same proportion.

Result.—The clover, &c., seemed equally benefited by the saltpetre and by the nitrate of soda; and, compared with what was not

dressed, the improvement was very perceptible in about a fortnight, and it became a much darker, stronger, and heavier crop than in that part of the field not dressed, and it was ready for cutting fully ten days earlier. It was not weighed, but it is believed there was from one-third to one-half more on the ground dressed than where it was not. The second cutting did not show a better crop than where it was not dressed. Nearly an acre was dressed with nitrate of soda after the first cutting, on the 10th of August, where one had before been applied, but it did not seem to do much good.

5. Memorandum of dressing of saltpetre and nitrate of soda on some winter-sown wheat in Bridge Park, on clay land, thorough-drained, and subsoil-ploughed, 20th April, 1840.

First Lot.—Twenty falls, measured and marked, dressed with 28 lbs. of nitrate of soda. *Produce:* Wheat 7 bushels, $17\frac{1}{2}$ lbs., or per acre (by an acre a Scotch acre is meant throughout, and a Scotch acre is about one-fifth longer than a statute acre; and by "a fall," a perch of land), 58 bushels, 26 lbs.; straw 64 stones, 18 lbs., or per acre 518 stones. Weight of wheat per bushel, $157\frac{1}{2}$ lbs. Sold to baker for 28s.

Second Lot.—Twenty falls, measured and marked, sown with 28 lbs. of saltpetre. *Produce:* Wheat 6 bushels, 38 lbs., or per acre 52 bushels, 24 lbs.; straw 95 stones, 12 lbs., or per acre 764 stones. Weight per bushel, 58 lbs. Sold to baker for 28s.

Third Lot.—Forty falls adjoining, measured and marked, without any dressing. *Produce:* Wheat 11 bushels, 1 lb., or per acre 44 bushels, 4 lbs.; straw 79 stones, or per acre 316 stones. Weight 59 lbs. Sold for seed at 35s. per boll.

Fourth Lot.—A small quantity of oats adjoining to this winter wheat was dressed with saltpetre, which produced a great effect on the strength and colour of the oats; but the produce was not weighed or measured after being cut.

Fifth Lot.—Trial of nitrate of soda on six drills of potatoes, at the rate of $1\frac{1}{2}$ cwt. per acre, sown over the stems when 5 inches long, on 10th June. *Result:* The shaws (*tops*) seemed much finer and richer than those not thus treated; but the potatoes being sold, the comparative produce was not ascertained.

Six drills of Swedish turnips, dressed at the same rate, 10th June, on a healthy braird, followed by fine showers and warmth. *Result:* Both shaws and turnips much improved, as compared with those near them not thus dressed; in appearance improved by several tons to the acre, but no comparative weights were taken.

In the trial with nitrate of soda, in the same proportions, on mangel-wurzel and carrots, Walls, the overseer, could not observe any difference between those so dressed and those which were not; and saltpetre and cubic petre were also mixed in small proportions with the compost from an old hotbed, and used in the garden for turnips, spinach, carrots, cauliflowers, asparagus, and onions, but without any apparent advantage.

Mr. S. Martin, of Warbleton, in Sussex, has given, in the *Sussex Express*, the following details of his experiments with nitrate of soda as a top-dressing for corn, on a four-acre field in

his occupation:—"The soil of the field selected is a thin, gravelly loam, with a substratum of sandstone, and was a rye-grass ley, fed with sheep and beasts until the last week in May, 1839, when it was ploughed up, and afterwards twice stirred and harrowed, and manured with 120 bushels of lime per acre, previously to its being sown with the wheat "*golden drop*" in the autumn. In the last week of April, this year, I applied 1 cwt. of nitrate of soda per acre over the whole field (with the exception of two lands in the middle of the field); in the second week in May, I applied to two lands adjoining those upon which none had been sown an additional 1 cwt. per acre. Previously to the application of the nitrate, the plants had a very sickly appearance, getting yellow in patches, and looking, as we call it here, "*speary*," but in a very few days subsequent, its appearance was much altered, it having (with the exception of the two lands on which none had been sown, and which remained in a very sickly state) changed from a faint yellow to a luxuriant green; the two lands upon which the 2 cwt. per acre were sown were much darker in appearance than the other, and easily distinguishable from the remainder at a very considerable distance.

"At harvest I measured off exactly 8 rods of each, and had it reaped (leaving a stubble about 16 inches high), and carted and thrashed separately; the result was as under:—8 rods without soda produced 1 bushel, 3 galls. 1 pint, or 27 bushels, 6 galls. 4 pints per acre; weight, 61 lbs. per bushel; straw 89 lbs., or 49 trusses, 16 lbs. per acre: 8 rods with 1 cwt. of soda per acre, 2 bushels, 1 gall., or 42 bushels, 4 galls. per acre; weight, 60½ lbs. per bushel; straw, 155 lbs., or 86 trusses, 4 lbs. per acre: 8 rods with 2 cwt. of soda per acre, 2 bushels 2 galls. 7 pints, or 47 bushels, 1 gall. 4 pints per acre; weight, 60½ lbs. per bushel; straw, 156 lbs., or 86 trusses, 24 lbs. per acre.

"On another piece of land, soil very thin and gravelly, sown with Talavera wheat in the autumn, I applied 1 cwt. per acre in the first week in May, and the result was equally satisfactory, the produce good, and weighed 64 lbs. per bushel.

"In an adjoining field of precisely the same description of soil, but which had been in hops for 11 years previously, and amply manured every year, I sowed on two rods at the end of one of the lands nitrate equal to 1½ cwt. per acre, which had a very prejudicial effect; the part with nitrate of soda being much mildewed and totally unfit for bread, while the straw on the remainder of the field was very bright and clean, and the grain full and handsome. I also used nitrate of soda on a meadow, 1 cwt. per acre, applied the last week in April; produce very trifling.

"As far as my experience goes, and from the effect of nitrate of soda on my neighbours' lands, I am of opinion that it is a very valuable manure for their light soils, exhausted by repeated croppings, particularly in districts where the arable lands have been repeatedly manured with lime; but I have great doubts whether it would answer for wheat on newly broken up or other land in a high state of cultivation and full of manure. In my experi-

ment on the old hop ground, although the straw was much longer, with a blade broad and flaggy, the yield was miserably deficient, both in quantity and quality, compared with the rest of the field.

"In respect to its effect on the second crop, I can only observe, that a very thin, wornout field of 18 acres, with wheat in 1839, on which 1 cwt. per acre was used (one land of which had a double quantity), was sown this year half with oats and half with seeds, that both oats and seeds were fully equal to any I ever grew on that field; and that the land where the 2 cwt. per acre was sown produced fully as many plants, with longer straw and more grains, and was, as far as I could judge from appearances (I did not keep it separate), much superior to the other."

NITRIFICATION. See EREMACAUSIS.

NODI. In botany, the knots or swelled articulations of stems; the place where one joint is articulated with another.

NONE-SO-PRETTY. One of the names of the London-pride Saxifrage. See SAXIFRAGE.

NONESUCH, or BLACK MEDICK. See MEDICK.

NOONINGS. A term provincially used to signify working during dinner-hours.

NORFOLK PLOUGH. See PLOUGHS.

NORTHERN LIGHTS, or AURORA BOREALIS. See LIGHTS, NORTHERN.

NOSE-BAND. That part of the head-stall of a bridle which comes over a horse's nose. It is sometimes termed maserole.

NUCLEUS (Lat). Literally, any thing round which matter has accumulated, or to which it is affixed. In botany, it is used in various significations:—1. The central, fleshy, pulpy mass of an ovule. 2. That part of a seed contained within the testa, and consisting of either the embryo and albumen or of the embryo only. 3. In lichens, the disk of the shield, which contains the sporules and their cases. 4. In the language of the older botanists, what is now termed by gardeners a *clove*; that is, the secondary bulb of a bulbous plant.

NUISANCES, in English law, are of two kinds: public or common, which annoy the king's subjects in general; and private, which are defined "any thing done to the hurt or annoyance of the lands, tenements, or hereditaments of another." A nuisance may be defined to be any act done which renders the lives of the neighbours less comfortable than they were before. The remedies allowed by the law are in some cases summary, as when a gate is erected across a public highway, or cattle trespass on the land; and in which cases the passenger or owner of the land is justified in removing the nuisance: or in other cases, the general legal remedies are, indictment or presentment, for public nuisances; or by an action on the case for damages, for private nuisances.

Indictable Nuisances.—Of the number of public nuisances which are punishable by indictment are setting spring-guns and man-traps, which, by the 7 & 8 G. 4, c. 18, is declared to be a misdemeanor; but the act allows such to be set "from sunset to sunrise in dwelling-houses for the protection thereof." Other indictable nuisances are for erecting a privy or

placing putrid carrion near a highway, or keeping hogs, and feeding them with offal near to a street; for keeping a dangerous bull in a field through which there is a public pathway (if the bull or other dangerous animal is *purposely* placed there to stop a disputed path, and death ensues, it is a murder); for keeping unmuzzled a ferocious dog; for baiting on the queen's highway a bull, &c. The punishment in any case of nuisance is fine or imprisonment, or both; and the court may order the defendant to pay the prosecutor his costs. It is no defence to prove that the nuisance has existed for a number of years; but in some cases the facts of the case may be taken into consideration by the jury, who are to determine whether the benefit derived by the public exceeds the annoyance. But in indictments for obstructing the highway by placing on it for a length of time carriages while loading and unloading, it is no defence to show that space was always left for two carriages to pass and repass on the other side of the street. The non-repair of a road or a bridge are also well-known nuisances, which are indictable.

Nuisances on which an Action on the Case is maintainable.—Accidents from the negligent use of loaded guns; placing baited traps so near to the premises of another, or the highway, that dogs are attracted into them and injured. For an injury by a vicious bull; and it is no defence by the owner of an animal that he has had notice of having done an injury, and has taken every precaution to prevent it doing so again. No action, however, lies for an injury by a dog let loose on the owner's closed premises at night for their protection; or on land on which the injured party has no right to go. If a person harbour a dog, or allows it to resort to his premises, he is liable for any damage it may cause. And the owner of a dog that destroys or injures sheep is, of course, liable to their owner. If the owner catch the dog in the act of worrying his fowls or sheep, he is justified in shooting him; but he must not follow the dog some distance, and then shoot him; nor may he shoot a dog merely trespassing; but he may if the dog is chasing deer in a park. And if any man do any thing on his own soil which is a nuisance to another, as by stopping a rivulet, and so diminishing the water used by him for his cattle, the party injured may enter on the soil of the other and abate the nuisance; and this right of abatement is not confined merely to nuisances to a house, to a mill, or to land.

NURSERY. In horticulture, a piece of land set apart and appropriated for rearing and preserving young plants and trees of different kinds, with a view to supply both gardens and plantations. The situation ought to be open and airy, and the soil of an average quality, neither too heavy nor too light, so as to be adapted to the majority of plants; but in a complete nursery there ought also to be shady borders for plants requiring shade, and beds or compartments of peat soil or other peculiar earths, for such plants as are not readily increased and grown in ordinary soils. Where tender plants are propagated, or where hardy

from cuttings, which are not easily germinated or rooted in the open ground and in the ordinary manner, hotbeds, frames, and handglasses are also requisite. Every private garden of any extent requires a nursery to raise and bring forward young plants, as a reserve for supplying failures by disease or accident in the general garden; and in every country where private gardens or plantations of trees are frequent, public or commercial nurseries are formed by persons who adopt nursery gardening as a business.

NUT, BLADDER. See **BLADDER-NUT.**

NUT, THE EARTH. See **EARTH-NUT.**

NUTRITION. The matter by which an animal or plant is supported, and its growth increased. See **FOOD** and **MEAT, GASES, EARTHS, SALTS, WATER, &c.**

NUTS (Lat. *nux*). In botany, seeds covered with hard shells; but in the general acceptance of the word, signifies the fruit of different species of hazel (*Coryli*).

NYMPH. See **PUPA.**

O.

OAK (Ger. *eiche*; Dut. *eik*; Dan. *eeg*; Sw. *ek*; Lat. *Quercus*; from the Celtic *quer*, fine, and *cuez*, a tree; others derive it from the Greek word *choiros*, a pig, because those animals feed on the acorns).

The oak is indigenous throughout Britain, and in former ages, before the clearing away of the forests had commenced, appears to have covered a very large portion of its surface; for, even in districts where the natural or self-sown oak is now rarely seen, the remains of noble and gigantic trees are frequently met with, sometimes in the alluvial deposits on the margins of rivers, or in boggy places covered with a layer of peat-moss, which has been generated around them by the stagnation of the water caused by their fall.

A fine oak is one of the most stately and picturesque of trees; it conveys to the mind associations of strength and duration, which are very impressive. The oak stands up against the blast, and does not take, like other trees, a twisted form from the action of the winds. Except the cedar of Lebanon, no tree is so remarkable for the stoutness of its limbs; they do not exactly spring from the trunk, and thus it is sometimes difficult to know which is stem and which is branch.

English oak warps and twists much in drying, and in seasoning shrinks about $\frac{1}{3}$ of its width. This wood is more durable than any other timber in water; and in a dry state it has been known to last nearly 1000 years. The more compact it is, and the smaller the pores are, the longer it will last; but the open, porous, and foxy-coloured oak, which grows in Lincolnshire and some other places, is not near so durable. The bark, leaves, and fruit of all the species abound in astringent matter, and in tannic acid. The bark in the spring contains more tannic acid, and is more easily separated, than at any other season: hence oaks are usually barked in May, June, and the beginning of July. When separated, the bark is dried by being set up in ranges, which are called *loftes*

In the greater part of North America, as well as in Europe, there is no tree so generally useful as the oak, which seems to have been multiplied in proportion to its utility.

Linnæus, in the third edition of his *Species Plantarum*, published in 1774, described 14 species of oak, of which 5 only are natives of the New World. Since then, owing to the labours of those indefatigable naturalists, Humboldt, Bonpland, and especially Michaux, the father, the number of American species of oak has been increased to no less than 44, all of which are comprised between the 20th and 48th degrees of North latitude. In the Old Continents, only 30 species are enumerated, and these are scattered on both sides of the equator. The species and varieties of the oak added to those described by the Michaux, are chiefly found in the extreme Southern States, Texas, and Mexican possessions.

The following classification of American oaks was made by the elder Michaux, who includes in it three European species :

FIRST DIVISION.

Fructification annual.

FIRST SECTION.—*Leaves lobed.*

1. White oak (*Quercus alba*).
2. Common European oak (*Quercus robur*).
3. European white oak (*Quercus robur pedunculata*).
4. Mossy-cup oak (*Quercus olivæformis*).
5. Over-cup white oak (*Quercus macrocarpa*).
6. Post oak (*Quercus obtusiloba*).
7. Over-cup oak (*Quercus lyrata*).

SECOND SECTION.—*Leaves toothed.*

8. Swamp white oak (*Quercus prinus discolor*).
9. Chestnut white oak (*Quercus prinus palustris*).
10. Rock chestnut oak (*Quercus prinus monticola*).
11. Yellow oak (*Quercus prinus acuminata*).
12. Small chestnut oak (*Quercus prinus chinca-pin*).

SECOND DIVISION.

Fructification biennial; leaves mucronated (except in the 13th species).

FIRST SECTION.—*Leaves obtuse or entire.*

13. Live oak (*Quercus virens*).
14. Cork oak (*Quercus suber*).
15. Willow oak (*Quercus phellos*).
16. Laurel oak (*Quercus imbricaria*).
17. Upland willow oak (*Quercus cinerea*).
18. Running oak (*Quercus pumila*).

SECOND SECTION.—*Leaves lobed.*

19. Bartram oak (*Quercus heterophylla*).
20. Water oak (*Quercus aquatica*).
21. Black Jack oak (*Quercus ferruginea*).
22. Bear oak (*Quercus banisteri*).

THIRD SECTION.—*Leaves multifold or many-clefted.*

23. Barren scrub oak (*Quercus Catesbæi*).
24. Spanish oak (*Quercus falcata*).
25. Black oak (*Quercus tinctoria*).
26. Scarlet oak (*Quercus coccinea*).
27. Gray oak (*Quercus ambigua*).
28. Pin oak (*Quercus palustris*).
29. Red oak (*Quercus rubra*).

The most valuable species of the American oaks is the white oak, which is found as far north as the small town of Trois Rivières, in Canada, lat. 46° 20', and the lower part of the river Kennebec, in Maine, and thence south on both sides of the Alleghanies down to the 28th degree of latitude. Its vegetation is repressed in the Northern States by the severity of the winters. In the lowermost Southern States it is found only on the borders of swamps, with a few other trees, which likewise shun a dry and barren soil. The white oak is observed to be uncommon on lands of extraordinary fertility, like those of Tennessee, Kentucky, and Genesee, and in all the spacious valleys watered by the western rivers. One may travel whole days in those states without seeing a single stock, though the few that exist, both there and in the Southern States, exhibit the most luxuriant vegetation.

The white oak abounds chiefly in the Middle States and in Virginia, particularly in that part of Pennsylvania and Virginia which lies between the Alleghanies and the Ohio. East of the mountains this tree is found in every exposure, and in every soil which is not extremely dry or subject to long inundations; but the largest stocks grow in humid places. In the western districts, where it composes entire forests, the face of the country is undulated, and the yellow soil, consisting partly of clay with a mixture of calcareous stones, yields abundant crops of wheat.

By the foregoing observations it appears that the severity of the climate, the fertility of the soil, its dryness or humidity, are the causes which render the white oak so rare over three-quarters of the United States that it is inadequate to supply the local demand, though the country contains but a small proportion of the population which it is capable of supporting.

Among the American oaks this species bears the greatest analogy to the European oak, especially to the variety called European white oak, *Quercus pedunculata*, which it resembles in foliage and in the qualities of its wood. The American white oak is 70 or 80 feet high, and 6 or 7 feet in diameter; but its proportions vary with the soil and climate.

The excellent properties of the white oak for the construction of houses, ships, and almost innumerable other purposes, are too well known to need any particular description in this place.

Great black oak (Quercus tinctoria). The wood of this tree is of a coarser grain than that of the white oak, and of a reddish colour. Between every year's growth, also, it appears porous, yet when dry and seasoned, it becomes strong and durable. The bark has, for a long time, been in great repute for tanning, and for the very excellent yellow dye which it affords. Dr. Bancroft, of London, learned the use of the bark as a dye, when in this country, during the revolutionary war; and introduced it in the manufactories of England, to which country many ship-loads of the article, ground, have been annually shipped, under the name of *Quercitron bark*.

Spanish oak (*Quercus falcata*, of Michaux); the bark of this species is somewhat rough, and light-coloured. The leaves are deeply and obtusely sinuated, and end in several acute, bristly points: the foot-stalks are pretty long. The timber is generally worm-eaten, or rotten at heart; but the bark is preferred to all other for tanning, and is much dearer.

Live oak (*Quercus virens*). This species is confined to Georgia, South Carolina, and Florida. The tree is of uncommon magnitude, and singularly beautiful. The moss hangs in lengths of several yards from the large branches of the old trees, and waving with the wind, gives the tree a venerable appearance. The wood is proverbial for its durability, when cut at a proper season, and is much used for ship timber. See ACORNS, DRY ROT, and PLANTATIONS.

OAK-APPLE. This is not to be confounded with those beautiful little excrescences so common upon the underside of the leaves of the oak, and known by the name of galls and spangles; they are the nidi of different species of *Cynips*, produced by the puncture of the ovipositor of the female, upon the different parts where they are found. The oak-apple is also formed by the puncture of a *cynips*, upon the twigs of *Q. pedunculata*. It rises rapidly, is usually spheroidal, in size about 1 to 2 inches in diameter. Its texture is spongy. It has some resemblance to the *Bedeyuar* of the Eg-lantine, but is not so rough and fibrous on the surface. The oak-apples are very astringent, containing tannic acid, and may be used in dyeing, making ink, and staining.

The largest galls or oak-apples, found in the United States, grow on the leaves of the red oak. They are round and smooth, and measure from 1½ to 2 inches in diameter. This kind of gall is green and somewhat pulpy at first, but, when ripe, it consists of a thin and brittle shell, of a dirty drab colour, enclosing a quantity of brown spongy matter, in the middle of which is a woody kernel about as big as a pea. A single grub lives in the kernel, becomes a chrysalis in the autumn, when the oak-apple falls from the tree, changes to a fly in the spring, and makes its escape out of a small round hole which it gnaws through the kernel and shell. This, says Dr. Harris, is probably the usual course, but I have known this gall-fly to come out in October. The name of this insect is *Cynips confluentus*. Its head and thorax are black, and rough with numerous little pits and short hairs; the hind-body is smooth, and of a shining pitch colour; the legs are dull brownish-red; and the fore-wings have a brown spot near the middle of the outer edge. Its body is nearly one-quarter of an inch long, and its wings expand five-eighths of an inch.

Clusters of three or four round and smooth galls are often seen on the small twigs of the white oak. They are nearly as large as bullets, of a greenish colour on one side, and red on the other. They approach in hardness to the Aleppo galls, and perhaps might be put to the same use. Each one is the nest of a single insect, which turns to a fly and eats its way out in June and July, having passed the winter as a chrysalis, within the gall, lodged in a clay-

coloured, egg-shaped case, about three-twentieths of an inch long, and with a brittle shell. These little cases appear to be cocoons, but are not made of silk or fibrous matter. Similar cocoons are found within many other galls, and I have some which were discovered under stones, and were not contained in galls, but produced gall-flies, the insects having left their galls to finish their transformations in the ground. The gall-fly of the white oak varies in colour. Sometimes it closely resembles the gall-fly of our oak-apple, differing from it only in size, and in wanting the brownish spot and dark-coloured veins on the fore-wings; and sometimes it is of a dull brownish-yellow colour, with a brown spot on the back. It is three-twentieths of an inch long, and its wings expand three-tenths of an inch. It is the *Diplolepis*, or more properly *Cynips oneratus* of Dr. Harris's "Catalogue."

Galls of the size and colour of grapes are found on the leaves of some oaks. Each one contains a grub, which finishes its transformations in June. The winged insect is the *Cynips nubilipennis*, or cloudy-winged *Cynips*, so named from the smoky cloud on the tips of its wings. Excepting in this respect, it closely resembles the dark-coloured variety of *Cynips oneratus*, and very little exceeds it in size.

One of our smallest gall-flies may be called *Cynips seminator*, or the sower. She lays a great number of eggs in a ring-like cluster around the small twigs of the white oak, and her punctures are followed by the growth of a rough or shaggy reddish gall, as large sometimes as a walnut. When this is ripe, it is like brittle sponge in texture, and contains numerous little seed-like bodies, adhering by one end around the sides of the central twig. These seeming seeds have a thin and tough hull, of a yellowish white colour; they are egg-shaped, pointed at one end, and are nearly one-eighth of an inch long. The gall-insects live singly, and undergo their transformations within these seeds; after which, in order to come out, they gnaw a small hole in the hull, and then easily work their way through the spongy ball wherein they are lodged. They are less than one-tenth of an inch long, are almost black, or of the colour of pitch, highly polished, especially on the abdomen, and their mouth, antennæ, and legs are cinnamon-coloured.

It has been observed that no tree in Europe yields so many different kinds of galls as the oak. Those described are not all that are found on oaks in the United States, and they seem to be sufficiently distinct from the galls of European oaks. (Harris.)

OAK BARK. The cortical layer stripped from the oak tree. Oak bark is preferred to all other substances in the tanning of leather, and in Europe brings a high price afterwards as a manure. The exhausted bark is used by gardeners to produce a slight equable heat by its fermentation, and may be advantageously used as a manure. The tan-balls, or muddy sediments of tan-pits, are used for summer fuel. The bark contains different quantities of tannic acid, according as it is near to or distant from the wood. Thus, the inner part, or *liber*, according to Sir H. Davy's experiments, yields

about 77 per cent. of tannic acid; the cellular layer, lying upon the *liber*, yields only 56 per cent; and the cuticle little or none. Dr. Higgins obtained 108 parts of tannic acid from the bark of an oak felled in the spring, and only 30 from an oak felled in winter. When the bark is set up to dry, the air, aided by moisture, acting upon the tannic acid, converts a portion of it into gallic acid, which is not originally a constituent of oak bark. See BARK and TAN.

OAK PRUNER. The ground beneath black and white oaks is, says Dr. Harris, often observed to be strewn with small branches, neatly severed from these trees, as if cut off with a saw. Upon splitting open the cut end of a branch, in the autumn or winter after it has fallen, it will be found to be perforated to the extent of six or eight inches in the course of the pith, and a slender grub, the author of the mischief, will be discovered therein. In the spring this grub is transformed to a pupa, and in June or July it is changed to a beetle, and comes out of the branch. The history of this insect was first made public by Professor Peck, who called it the oak-pruner, or *Stenocorus (Elaphidion) putator*. See Pl. 16, 1. In its adult state it is a slender, long-horned beetle, of a dull brown colour, sprinkled with gray spots, composed of very short close hairs; the antennæ are longer than the body, in the males, and equal to it in length in the other sex, and the third and fourth joints are tipped with a small spine or thorn; the thorax is barrel-shaped, and not spined at the sides; and the scutel is yellowish-white. It varies in length from four and a half to six-tenths of an inch. It lays its eggs in July. Each egg is placed close to the axilla or joint of a leaf-stalk or of a small twig, near the extremity of a branch. The grub hatched from it penetrates at that spot to the pith, and then continues its course towards the body of the tree, devouring the pith, and thereby forming a cylindrical burrow, several inches in length, in the centre of the branch. Having reached its full size, which it does towards the end of the summer, it divides the branch at the lower end of its burrow, by gnawing away the wood transversely from within, leaving only the ring of bark untouched. It then retires backwards, stops up the end of its hole, near the transverse section, with fibres of the wood, and awaits the fall of the branch, which is usually broken off and precipitated to the ground by the autumnal winds. The leaves of the oak are rarely shed before the branch falls, and thus serve to break the shock. Branches of five or six feet in length and an inch in diameter, are thus severed by these insects, a kind of pruning that must be injurious to the trees, and should be guarded against, if possible. By collecting the fallen branches in the autumn, and burning them before the spring, we prevent the development of the beetles, while we derive some benefit from the branches as fuel.

Oak trees are also subjected to the attacks of insects, which destroy the leaves, deposit their eggs in the branches which they destroy, and others which devour the solid wood. See BEETLES, BORERS, CATERPILLARS, LOCUSTS, &c.

OAT (Russ. *owes*; Pol. *owies*; Dutch, *haber*; Fr. *Avoine*; Lat. *avena*). A very valuable cereal grass, of which several varieties are cultivated for their seeds: the chief of these are—1. The *Avena sativa*, or common oat. Pl. 3, e. 2. The *A. orientalis*, or Tartarian oat, f. 3. *A. strigosa*, or bristle-pointed oat. 4. *A. brevis*, or short oat. 5. *A. nuda*, or naked oat.

The common oat is far the most important of these species. Its spikelets contain two or three seeds. Its florets are sometimes furnished with awns, and at other times are awnless. The oat is a native of cold climates: it flourishes in the temperate latitudes, but it degenerates, and at last refuses to yields profitable crops as it approaches the equator. It is, however, cultivated with success in Bengal, as low as the 25° of latitude. It flourishes remarkably well in Ireland and in Scotland, and constitutes the principal food of the inhabitants. In England it is cultivated to a very considerable extent in the fen districts of the eastern counties, as well as in the northern border districts, in which last the oats are considered to be very superior. By cultivation, difference of soil and climate, and other causes, the common oat (*A. sativa*) has produced several varieties, which have been divided by some authors into three classes, the black, the gray, and the white. Those of the first class are commonly hardy, have small seeds, become early ripe, and are hence well adapted for cold hungry soils, such as those which are usually found on considerable elevations.

The gray, or dun-coloured oats, although possessing more valuable qualities than the black oat, are still inferior in quality to the white, but on some soils yield very remunerative crops.

The third and most valuable class of oats is the *white*. "The most improved of these," says Professor Low, "are without awns. They are the least hardy kinds, but they are of the greatest weight to the bushel, and the most productive of meal. In this class the potato oat is that which has possessed the greatest reputation for a time in the districts where it is cultivated. It is not so well suited to inferior soils as some of the other white and darker-coloured kinds: it is also less productive of straw, though the grain is more plump, weighs heavier, and yields a greater weight of meal. The hardier kinds, however, are better suited to certain situations than the finer, just as the hardier red wheats are better suited to certain situations than the thin-chaffed and white varieties. The potato oat was the discovery of accident, and the produce of a single plant. It has, in many cases, shown a tendency to degenerate, by the husks becoming thicker and the body less plump, and by the partial appearance of awns."

The *Poland oat* is another valuable cultivated variety of the white oat. It comes early to maturity, and is a prolific bearer. Its defects are a tendency to be deficient in straw, and a liability to shed its seeds.

Besides these there are several other varieties of the white oat, as the Dutch, or Friesland oat, the Hopetoun oat of East Lothian, &c.

The *Hopetoun oat* was produced in 1824, by

Mr. P. Sherriff, of Mungo's well, in the way he thus describes. "Having frequently had occasion to pass the gateway of a crop of potato oats, in the summer of 1824, a stalk of remarkable height attracted my attention. When the crop was reaped, the grains supported by this stalk, and those upon a short one proceeding from the same root, were gathered and sown in the following spring. The crop from the grains of the gigantic stalk was again conspicuously tall, and after the crop of 1827 the new variety established its superiority." In some comparative trials by Mr. Boswell, "on a good free black soil," the Hopetoun exceeded the potato oat in produce, as, in some experiments by Mr. Forsyth, of Elgin, "on a rich loam," it exceeded the late Angus oat, and in those of Mr. Howden, at Traprain, in East Lothian, it proved superior to the gray Angus, the potato, and the early Angus oats.

The *early Angus* oat is well known for its early ripening, and the *late Angus*, says Mr. Sherriff, is also well known for its fine straw and grain; and although late in ripening, is the most esteemed species of oat in the early districts of Scotland, such as East Lothian and Morayshire. There is a difficulty, however (Mr. Sherriff very justly adds), of ascertaining the merits of different varieties of grain by experiment, from the many contingencies affecting the results, the most powerful of which is the nature of the season. Some kinds of oats grow rapidly in the early part of the season, and some attain their full height, such as the Polish and Georgian oats, both of which are stunted. Others grow slowly, and are later in arriving at their full height, such as the potato, Flemish, and early Angus oats, which are also short. Others continue to grow through the season, and are still later in arriving at their full height, as the Hopetoun and late Angus oats, which are taller than the others. When the early part of the summer proves wet, and is followed by drought, the Polish and Georgian oats have an advantage over other kinds, as they attain their full height before the drought commences. When the early part of the summer is very dry, and moisture succeeds, the Hopetoun and Angus oats benefit by the moisture, while the others mentioned do not. When the season proves wet throughout, and the different oats in consequence reach an extreme height, the smaller species have frequently an advantage over the larger in grain produce, in consequence of the straw of the latter becoming too luxuriant.

The *Cumberland early oat*, so named from being raised from a single head by a Cumberland gentleman, is of a longish grain, more like the early Angus variety than the potato; colour dark and dull. It is as much earlier than the potato oat as the latter is earlier than the Hopetoun, being ripe nearly a fortnight sooner than the Hopetoun.

Red Oat.—There is a peculiar variety of oat (classed with the gray oats), called the red oat, which is a favourite in some districts, and is thus described by the celebrated William Dawson, of Frogdon, in 1791:—"Happening to be at Linton, in Tweeddale, which is about the highest land kept in cultivation in the south

of Scotland, I found the farmers complaining much of the loss they had by late harvests, and I asked if they had tried the Dutch oats, which were so much earlier than the common kinds. They told me that they had tried the Dutch oats, but that they had a kind in their own country which were as early as the Dutch, and were superior in several respects; they were not so apt to shake even as the common oat; they suited every sort of soil if in good condition, and they yielded well in meal; that they had been sown in that country for fifty years, but no one knew where they came from. Upon this information I commissioned a boll for a trial, and found them answer so well that I have sown no other sort for several years. They do not produce much straw, but what they do produce is very good. I saw a second crop of these oats upon the same land last year, which was good. I have found that they answer the character given of them at Linton fully. That they answer best upon land in good condition, but that they produce very little straw upon poor land; yet the produce of corn is not even in these situations inferior to any other oats. These properties give them a great superiority over every other kind known in this country, and grown in high situations, and cold climates and soils." They are a kind of oat much relished by horses, who, if used to them, do not readily take to other, even richer kinds. Carters accustomed to them give them a decided preference.

The *Georgian Oat* was introduced about the year 1824, but it has not made much progress. In 1826, Mr. Wilson, of Preston, reported the following comparative trials between it and the potato oat (*Trans. High. Soc. vol. i. p. 153*), upon 2 English acres of equal land. The quantity sown upon an acre was 6 bushels, and of the potato 4 bushels. The Georgian was reaped 10 days earlier than the potato, but they might have been 14 days. The appearance of the Georgian was by far the most luxuriant during the summer, till the end of July, when the potato shot out considerably longer in the straw. They were carefully cut down, stacked, and thrashed in March, 1826; the result was, in—

	Stones.	lb.
Weight of straw of the potato oats per acre	317	6
Weight of straw of the Georgian oats per acre	238	12

The produce of the potato oats per acre was 69 Winchester bushels, and the Georgian 68.

	Stones.	lb.
Weight of meal from 6 bushels of the potato oats	11	5
Weight of meal from 6 bushels of Georgian oats	10	6

The *Tartarian Oat* is cultivated to some extent in England, but much more extensively in some portions of the Continent. "Its fascicle is contracted, and nods to one side, which distinguishes it from the common oat. The colour of its corolla is generally dark, but the plant improves by culture in a good soil, losing its awns, and that darkness of colour which appears to distinguish the oat in its less improved state." The breadth of this oat annually cultivated in England has much increased within the last few years. It is the best description

for the poorest exhausted soils, producing the most straw on those sorts of any other variety. The oat can be profitably cultivated upon, perhaps, a greater variety of soils than any other of the cereal grasses. It may be grown, too, successfully with less preparation of the soil, and less manure. The oat plant, however, succeeds best in fresh soils, in newly broken up old pastures, and in those abounding in organic matters.

The organic manures by which the oat crop is best nourished, appear to be green manures; fish, especially those like sprats, abounding in oil, and, in fact, all those of a readily decomposable description. Recently-drained marshes, peaty soils after being dressed with lime, newly enclosed commons after being chalked, all usually yield large crops of oats.

The land intended for oats should be ploughed, if possible, especially on clay soils, in the previous winter, or at least as early in the spring as possible: this is a practice almost always adopted by the best farmers of our island. A still more common course of cropping is to sow oats after turnips, or other green crops, and especially on the four-shift system with grass-seeds.

A miserable custom still prevails in some parts of England, of taking two crops of oats in succession, or an oat crop after wheat or barley. Arthur Young long since denounced this as bad husbandry. After observing that white oats should be sown in March, in preference to any other season, he remarked, that "in the general conduct of them the farmer should by all means avoid the common error of sowing after other corn crops, by which they exhaust the land. They should always receive the same preparation as barley, nor ought a good husbandman to think of their not paying him as well for such attention as that crop. It is a very mistaken idea to suppose it more profitable to sow barley on land in good order than oats. He was, from divers experiments, inclined to think that oats will equal, and in many cases exceed, barley. The superior quantity of the produce will ever be found to more than counterbalance the inferiority of the price; which, however, sometimes exceeds that of barley."

Oats are commonly sown from March to April, but it is very probable that they might be advantageously sown much earlier in many situations, and when on grass leys generally broadcast: from 4 to 6 bushels per acre of seed is the ordinary quantity. By the drill, after turnips, a much less quantity will be sufficient. I have known from 10 to 11 quarters per acre grown year after year from only 2 bushels of seed.

They are usually cut in the south by the scythe—in the north and western portions of Britain by the sickle; and they should never be allowed to become perfectly ripe before they are cut. The usual produce varies from 25 to 40 bushels per acre. In the fens of Lincolnshire, and in Essex and Suffolk on land previously dressed with 35 or 40 bushels of sprats per acre, the yield is usually much more considerable.

The weight of a bushel of oats varies from

35 to 45 pounds, and 14 pounds of oats commonly yield about 8 pounds of meal.

The following table will show the quantity of meal that is usually extracted from certain weights of oats; and though different results may be obtained by various qualities and seasons, yet the progressive ratio of the produce will generally be found nearly similar.

Weight per Bushel.	Produce in Meal.	Produce of Husk.
42 lb.	25 lb. 2 oz.	16 lb. 14 oz.
40	23 6	16 10
38	21 12	16 4
36	20 3	15 13
34	18 11	15 5
32	17 5	14 11
30	16 1	13 5

Oatmeal is a well-known article of food; it is the flour from which, in the northern portion of Great Britain, the bread of the working classes is partly procured. The oat-seed was examined by Sir H. Davy; he found in 1000 parts of Scotch oats 743 of soluble or nutritive matter, composed of 641 mucilage or starch, 15 saccharine matter, and 87 gluten or albumen. In 100 parts of oats from Sussex, 59 parts of starch, 6 of gluten, and 2 of saccharine matter, 33 husk.

The principal demand for oats in Great Britain is for horses. Its use for bread is chiefly confined to the northern districts. Meal is employed also for various domestic purposes, feeding pigs, dogs, &c.; and it has been used in brewing ale, and in the malt distilleries; but for this purpose its value is much inferior to that of barley.

The seeds were analyzed by Schraeder; he found in 227·8 grains of ashes, obtained from 2 lb. of oats—

	Grains.
Silica - - - - -	144·2
Carbonate of lime (chalk) - - - - -	33·75
Carbonate of magnesia - - - - -	33·9
Alumina (clay) - - - - -	4·5
Oxide of manganese - - - - -	6·95
Oxide of iron - - - - -	4·5
	<hr/> 227·8

The analysis of M. Vauquelin rather differs from this; he found in 100 parts of the ashes of the oat—

	Parts.
Silica - - - - -	60·7
Phosphate of lime - - - - -	39·3
	<hr/> 100·

But by burning the whole plant, stalk and seed together, he obtained a residuum composed of—

	Parts.
Silica - - - - -	55
Phosphate of lime - - - - -	15
Potash - - - - -	20
Carbonate of lime - - - - -	5
And some oxide of iron.	

M. Saussure obtained from 100 parts of the ashes of the seeds of the oat—

	Parts.
Soluble salts - - - - -	1
Earthy phosphates - - - - -	24
Silica - - - - -	60
Metallic oxide - - - - -	0·25
Loss - - - - -	14·75
	<hr/> 100·

Average price of oats in England, per Winchester quarter:—

	£	s.	d.		£	s.	d.		
1771	-	0	16	8	1810	-	1	9	4
1775	-	0	16	6	1815	-	1	3	6
1780	-	0	12	10	<i>Per Imperial Quarter.</i>				
1785	-	0	17	2	1820	-	1	4	9
1790	-	0	18	10	1825	-	1	5	8
1795	-	1	4	9	1830	-	1	4	5
1800	-	1	19	10	1835	-	1	2	0
1805	-	1	8	0	1840	-			

The account, in imperial quarters, of the foreign oats and oatmeal entered for home consumption every five years since 1815, was—

	Qrs.		Qrs.		
1815	-	214,000	1830	-	900,319
1820	-	726,848	1835	-	176,142
1825	-	15,000	1840	-	510,836

The annual average of oats, in Winchester quarters, imported into England from 1801 to 1825 was, from—

	Qrs.	
Russia	-	46,652
Sweden and Norway	-	2,446
Denmark	-	30,672
Prussia	-	39,209
Germany	-	75,828
Netherlands	-	84,269
France and Southern Europe	-	1,953
America	-	4

From Ireland were imported into this country, of oats and oatmeal, in Winchester quarters—

	Qrs.		Qrs.		
1810	-	493,231	1825	-	1,629,856
1815	-	597,537	1830	-	1,471,252
1820	-	916,250	1835	-	1,822,766

Table showing the average Price of Oats per Bushel in the Philadelphia Market, for the 1st, 2d, 3d, and 4th Quarters of the following Years:

Year.	1st Quarter.	2d Quarter.	3d Quarter.	4th Quarter.
1833	36 cts.	40 cts.	30 cts.	35 cts.
1834	27	31	30	33
1835	36	38	38	40
1836	50	42	38	50
1837	50	49	45	36
1838	33	37	41	41
1839	44	53	32	33
1840	28	27	25	26
1841	26	37	47	46
1842	43	37	23	25

Oats raised south of Philadelphia usually bring about 3 cents per bushel less than those raised in Pennsylvania and still further north, which are generally much heavier.

OAT-GRASS. See AVENA.

OATMEAL. The meal or flour of the oat is used in Great Britain to make porridge, gruel, bread, and poultices. In the mealing process, the oats, after being previously dried in a kiln, are made to pass through the mill-stone to divest them of their coarser husks or "shealings" before being ground. The kernels are then named "grits" or "groats;" and are next ground over again into a coarse, rough meal, varying in its fineness according to the custom of different districts. This is afterwards either baked upon a heated iron, called a *griddle* in Scotland, into thin, flat cakes, or made up with water into loaves, and baked. When gradually stirred into boiling water, and boiled into a thick consistence, it forms the porridge of Scotland. It is eaten either with skimmed milk, butter, molasses, or ale. It is thus very

generally used as the common porridge for breakfast and supper of the greater portion of the peasantry of the northern parts of England, Scotland, and Ireland, and forms a very nutritive and healthy food. It is, however, apt to prove ascetic in some stomachs, and to cause cutaneous diseases. See GOATS.

OCHRE. See FULLER'S EARTH.

OFFSETS. In gardening, young radical bulbs, when separated or taken off from the parent roots, are so called. One of the chief methods of propagating plants is by offsets.

OIL-CAKE. The marc which remains after the oil has been expressed from the seeds of flax and rape. See COLZA, LINSEED CAKE, PALMA CHRISTI, RAPE.

OILS (Ger. *oel*; Lat. *oleum*). This term comprehends two substances that have very distinct properties, namely, volatile and fixed oils; but, in general language, the term oil is indicative of the latter. Fixed oils are unctuous, fluid bodies, which, when dropped upon paper, sink into it, and make it semi-transparent, or give it what is called a *greasy* stain. They are composed of carbon, oxygen, and hydrogen. Train oil has been sometimes used as a manure, and is a powerful fertilizer. See FISH. Linseed oil is a common food for live-stock. See LINSEED OIL.

The following results of analysis show the variations in the proportions of elementary substances in olive and train, or fish oil, 100 parts of each:—

	Hydrogen.	Oxygen.	Carbon.
Olive oil,	13.36 +	9.437 +	77.213 = 100 parts.
Train oil,	16.1 +	15.03 +	68.87 = 100 parts.

The numerous uses to which unctuous oils obtained from the seeds of various plants are applied, for food, burning, soap-making, &c. &c., give great importance to their production and preparation. The proportions yielded by 100 parts of many seeds, are as follows:—

Palma Christi, 62 per cent.; garden cress, 56 to 58; poppy, 56 to 63; oily-radish, 50; sesamum or bene plant, 50; cabbage, 30 to 29; wild mustard, 30; weld, 29 to 36; gourd, 25; hemp, 14 to 25; flax, 11 to 22; black mustard, 15; white mustard, 36 to 38; rape, colewort, and Swedish turnip, 33½; colza, 36 to 40; rape, 30 to 36; euphorbium or spurge, 30; sunflower, 15; stramonium, 15; ground-nut with shells, 21; cotton, 16; the kernels of walnuts and hickory-nuts, 40 to 70; hazel-nuts, 62; sweet almonds, 40 to 54; bitter almonds, 28 to 46; beech mast, 15 to 17; plum, 33.3; grape stones, 14 to 22; horse chestnuts, 12 to 18.

The excellent oils expressed so abundantly from the seeds of the poppy and sesamum or bene plant, are largely substituted in commerce for olive oil.

OKRA (*Hibiscus esculentis*). This plant is cultivated extensively in the West Indies, from whence it has been introduced into the United States. The pods are gathered green, and used in soups. They form an important ingredient in the celebrated Gumbo soup of New Orleans and other southern places. The pods are filled with seeds and a mucilage of a bland and highly nutritious quality. Hence the okra is frequently recommended to persons afflicted with dysentery and other bowel complaints either eaten boiled, or made into soup. When

battered and spiced, they afford a rich dish, and with vinegar, they make a good pickle. The plant comes to maturity in the Middle States, and the pods are abundant in the Philadelphia market. Those who become once accustomed to this wholesome vegetable, contract a great fondness for its peculiar flavour.

In Louisiana and other southern states, a dinner is scarcely considered complete without okra cooked in some way or other, and the poor consider it one of their greatest blessings. Mr. Legare, editor of the *Southern Agriculturist*, has furnished the following recipe for making okra soup, after the celebrated method pursued in Charleston. The pods, he says, are of proper size when 2 or 3 inches long, but may be used as long as they remain tender. If fit for use, they will snap asunder at the ends, but if too old and woody, they must be rejected. One peck of the tender pods are to be cut crosswise into very thin slices, not exceeding one-eighth of an inch in thickness. To this quantity add about one-third of a peck of tomatoes, previously peeled and cut into pieces. The proportion of tomatoes may be varied to suit the taste. A coarse piece of beef (a shin is generally made use of) is placed in a pot or digester with about 2½ gallons of water, and a very small quantity of salt. This is permitted to boil a few moments, when the scum is taken off and the okra and tomatoes thrown in. With these ingredients in the proportions mentioned, the soup made is remarkably fine. Still, some think it improved by additions of green corn, Lima beans, &c. The most essential thing to be attended to is the boiling, and the excellence of the soup depends almost entirely on this being done faithfully. For if it be not boiled enough, however well the ingredients may have been selected and proportioned, the soup will be very inferior, and give but little idea of the delightful flavour it possesses when well done. A properly constructed digester is decidedly the best vessel for boiling this or any other soup in; but where such a utensil is not at hand, an earthenware pot should be preferred; but on no account make use of an iron one, as it would turn the whole soup perfectly black, instead of the proper colour, namely, green, coloured with the rich yellow of tomatoes. The time usually required for boiling okra soup is about 5 hours, during which it should be occasionally stirred, and the ingredients mashed. When taken off, the original quantity will be reduced to about one-half, and the meat "done to rags;" the whole forming a homogeneous mass, of the consistence of thick porridge.

OLEANDER (*Nerium*, from *neros*, humid; alluding to the habitat of the plants). This is a genus of noble evergreen shrubs, of easy culture, and flowering freely the greater part of the year. *N. oleander* and its varieties bear forcing remarkably well; and, although treated as green-house plants, yet they will not flower well unless they are kept in the stove. They grow well in any rich, light soils, and young cuttings root in any soil, if kept moist. The leaves of *N. oleander* contain tannic acid, and the leaves and bark of the root of *N. odorum* are applied externally as powerful repel-

lants by the Indian practitioners. *N. tinctorium* yields indigo. (*Paxton's Bot. Dict.*)

OLIVE (*Olea*). This is a very important genus of plants, on account of the oil, &c., which is obtained chiefly from the *O. Europæa*.

It is an evergreen, small tree, with lanceolate leaves, of a deep-green on the upper, and nearly white or hoary on the under surface. The flowers are small and white. The fruit is an elliptical drupe, of a bluish-purple colour when ripe. The tree lives to an extreme old age, and continues to bear good olives. It is also much admired for the fragrance of its flowers, which render it worthy a place in every green-house collection. They grow well in loam and peat; ripened cuttings root readily in sand, under a glass. They may also be increased by grafting on the common privet. The unripe fruit of the olive, preserved in salt and water, is a well-known article for the dessert.

With regard to the capacity of a portion of the Southern United States to produce the olive, the following extract from a communication of John Couper, Esq., will give interesting information:—

"I had a very pretty grove of 200 olives, imported about 10 years since, their stems from 8 to 12 inches diameter, and perhaps averaging 20 to 25 feet high to the top; they have borne fruit for some years. I had also near 600 trees, or plants, from 11 to 5 years old. From comparisons between the olive and orange, in previous severe frosts, where the orange was much hurt, the olive was uninjured. I have, therefore, no hesitation in believing the olive is well adapted to, and will succeed on our sea-coast, of both Carolina and Georgia.

"I have been personally acquainted with sour-orange trees, both on St. Simon's and Jekyll, for 58 years, and believe they were planted near 100 years since; and have never been killed by frost until last February, when they were all destroyed. I therefore conclude, that since the first settlement of Georgia the olive would have succeeded. It occurs to me that, notwithstanding the immense value of the olive in France, they have been cut down in some severe frosts.

"The olive and orange seemed so completely destroyed, even to some depth under ground, that I cut them down, and planted corn in their place; on examination about a month since, the lower roots still appearing fresh, I concluded that opening the ground around them might encourage vegetation; and have now the satisfaction to see the olives pushing out abundance of fine, strong shoots, not one failing. The oranges are doing the same, though some appear dead, not yet decided; by returning the earth to the olive shoots, they will throw out roots, and furnish fine plants. In fact, I am better satisfied respecting the success of the olive than I was before the severe frost." (*Farmer's Register*, vol. iii. p. 246.)

OLIVE, THE AMERICAN (*Olea Americana*). This American tree belongs exclusively to the Southern States, the Floridas, and Louisiana. Like the live-oak and cabbage-tree, it is confined to the sea-shore. "It is so little multiplied," says Michaux, "that it has hitherto received no name from the inhabitants of the

country, except on the banks of the river Savannah, where it is called *Devil wood*.

"This tree grows in soils and exposures extremely different: on the sea-shore it springs with the live-oak in the most barren and sultry spots; and in other places it is seen with the big laurel, the umbrella tree, the sweet leaves, &c., in cool, fertile, and shaded situations.

"This tree, or, to speak more accurately, this large shrub, is sometimes 30 or 35 feet high, and 10 or 12 inches in diameter: but this size is extraordinary; it commonly fructifies at the height of 8, 10, or 12 feet. The leaves are 4 or 5 inches long, opposite and lanceolate, entire at the edge, smooth and brilliant on the upper surface, and of an agreeable light-green. They are evergreen, or at least are partially renewed only once in 4 or 5 years. The fertile and barren flowers are on separate trees: they are very small, strongly scented, of a pale yellow, and axillary, or situated between the petiole of the leaves and the branches. The season of flowering, in the neighbourhood of Charleston, is about the end of April. The fruit is round, and about twice as large as a common pea. When ripe, it is of a purple colour, approaching to blue, and consists of a hard stone thinly coated with pulp. As it remains attached to the branches during a part of the winter, its colour forms, at this season, an agreeable contrast with the foliage.

"The bark which covers the trunk of the devil wood is smooth and grayish. The wood has a fine and compact grain, and, when perfectly dry, it is excessively hard and very difficult to cut or split; hence is derived the name of devil wood. It is, notwithstanding, neglected in use. On laying bare the cellular integument of the bark, its natural yellow hue changes instantaneously to a deep red, and the wood, by contact with the air, assumes a rosy complexion. Experiments should be made to detect the nature of this active principle in the bark, which causes it to change colour so suddenly by exposure to the air.

"From the temperature of the native skies of this tree, we may conclude that it is capable of resisting a greater degree of cold than the common olive: it becomes, then, on account of its beautiful foliage, its odoriferous flowers, and its showy fruit, a valuable acquisition." (*Michaux.*)

ONIONS (*Allium cepa*). Of this genus, there are eight individuals that demand the gardener's care.

They all require a rich, friable soil, on a dry substratum; a situation enjoying the full influence of the sun, and entirely free from trees, which are very inimical to them, especially to those which have to stand the winter. If the soil be poor, or exhausted, abundance of dung should be applied in the preceding autumn or winter, and the ground thrown into ridges. By these means it becomes well decomposed and incorporated with the soil; for rank, unreduced dung is generally injurious, engendering decay, and inducing maggots; if, therefore, the application of manure is neglected until the spring, it should be taken from an old hotbed, or other source whence it is to be had in a thoroughly putrescent state, and turned in only

to a moderate depth. Sea-sand, particularly if the ground is at all tenacious, is advantageously employed; coal-ashes, and especially soot, are applied with particular benefit. In digging over the ground, small spits only should be turned over at a time, that the texture may be well broken and pulverized. A considerable degree of attention is required from the difficulty of giving the requisite degree of firmness to light soils, which, if rich, are well suited to the growth of these vegetables. Old, soft, or light, sandy soils, Mr. A. Gorrie, of Rait, recommends to be dug rough in October, and about January to have a top-dressing of cow-dung applied and left on, to have its fertilizing matters washed in until the time of sowing, then as much as can be is to be raked off, and, without digging, the seed sown, trod in, and covered with earth from the alleys. By this management, soils will produce good crops which before were annually destroyed by the maggot. Onions for pickling, as well as those to stand the winter, should be grown on light, poor soils, which cause the first to be small in the bulb, and the latter, not growing so luxuriantly, to withstand the winter better.

There are 14 distinct varieties of this vegetable, as appears from the description given by Mr. C. Strachan, gardener to the Horticultural Society of London.

1. Silver-skinned onion. 2. Early silver-skinned. 3. True Portugal. 4. Spanish. 5. Strasburg. 6. Deptford. 7. Globe. 8. James's keeping onion. 9. Pale-red. 10. Yellow. 11. Blood-red. 12. Tripoli. 13. Two-bladed. 14. Lisbon.

In England the onion is raised from seed, which may be sown for the first main crop towards the close of February, if dry, open weather, otherwise only a small portion, in a warm, dry situation. The principal crop, however, must be sown during March, it being kept in mind that the close of February is to be preferred, for the earlier the seed is inserted, the finer will be the bulbs: main crops may even be inserted as late as the beginning of April, and, at its close, a small sowing to draw young in summer, and for small bulbs to pickle; again in July and early in August for salads in autumn; and, finally, in the last week of August, or early in September, to stand the winter for spring and beginning of summer. The seed is sown thinly, broadcast, and regularly raked in. An ounce of seed is abundantly sufficient for a rood of ground, especially for the main crops, as they should never be allowed to grow to a size fit for salads without thinning. No other seed ought to be sown with it; for the practice of stealing a crop is detrimental to both crops, without the slightest advantage to compensate. The beds should be divided by narrow alleys into portions about four feet wide, for the convenience of cultivation. In about six weeks after sowing, the plants will be of sufficient size to allow the first thinning and small hoeing, by which they are to be set out about 2 inches apart; if this is performed in dry weather, it will keep the beds free of weeds for six weeks longer, when they must be hoed a second time, and thinned to 4 inches apart; and now, where they have

failed, the vacancies may be filled up by transplanting some of those thinned out into the places; the best time for doing this is in the evening, and water must be given for several successive nights. In transplanting, the root only is to be inserted, and no part of the stem buried; for there is very good reason to believe that naturally the bulb grows entirely upon the surface, and that growing within the mould is a great cause of their not keeping well. After the lapse of another month they must be thoroughly gone over for the last time, the weeds eradicated, and the plants thinned to 6 inches asunder; after this they in general only require to be weeded occasionally by hand; they must, however, be kept completely free from weeds, and the stirring of the surface which the hoe effects is very beneficial. In order to prevent their running too much to blade, it is a good practice early in July, before the tips change to a yellow hue, to bend the stems down flat upon the bed, which not only prevents the rapid growth of the blade, but causes the bulbs to become much larger than they otherwise would be. The bend should be made about 2 inches up the neck.

About the close of August the onions will have arrived at their full growth, which may be known by the withering of the foliage, by the shrinking of the necks, and by the ease with which they may be pulled up. As soon as these changes appear, they must be taken up, the bed being frequently looked over; for, if the whole crop is waited for, the forwardest, especially in moist seasons, are apt again to strike root. They should be spread on mats, &c., in the sun, frequently turned, and removed under shelter at night. In 2 or 3 weeks, when the roots and blades are perfectly withered and void of moisture, and the bulbs become firm, they are fit for storing, being housed in dry weather, and carefully preserved from bruising: previous to doing this, all mould and refuse must be removed from them, for these are apt to induce decay, and spread contagion to all near them. To prevent this as much as possible, all faulty ones should be rejected: in the store-house they must be laid as thin as may be, and looked over at least once a month. Notwithstanding every precaution, many will decay, and more sprout, especially in mild winters; therefore, to preserve some for late use, it is useful to sear the roots and the summits with a hot iron, care being taken not to scorch the bulb.

For the winter standing crop the only additional directions necessary are, to tread in the seed regularly before raking, if the soil, as it ought to be, is dry and light. They must be kept constantly clear of weeds, as well as of the fallen leaves of trees, which cause them to spindle and become weak, but they need not be thinned, as they serve as protections for each other. Early in spring they are to be weeded, and, as may be necessary, transplanted for bulbing. There are several modes of cultivation lately introduced or revived, which produce onions of superior size and goodness. The great obstacle to the production of fine onions in England is the want of a sufficient continuance of warm weather; or, at least, the

inclemency of the early part of the year prevents the insertion of the seed until so late, that the most genial season to vegetation passes away whilst the plants are in their infancy; it is the obviating this unfavourable circumstance that causes the superiority of the several plans hereafter detailed.

It is a practice that originated in America, and which has met with the decided approval of Mr. Knight and others, to sow in May; to cultivate the plants as in the other crops; and, in October, the bulbs, being of the size of nuts, are to be taken up, dried, and housed, as directed for the full-grown bulbs. About the middle of the following March they must be planted out in rows 6 inches apart each way, and afterwards cultivated in the same manner as the other crops. If sown earlier than May, they run to seed when transplanted. Another mode nearly as efficacious, and which, I understand, has been practised for a great length of time in the south of Essex, is to sow in the latter part of August, to stand the winter, and in March, early or late, according to the forward growth of the seedlings, to be planted out in rows at the before-directed distance, and cultivated as usual.

In Portugal they sow in a moderate hotbed during November or December, in a warm situation, with a few inches of mould upon it; and the plants are protected from frost by hoops and mats; in April or May, when of the size of a swan's quill, they are transplanted into a light, rich loam, well manured with old rotten dung, to bulb.

It would seem, from the practice of Mr. Macdonald, gardener to the Duke of Buccleugh, at Dalkeith, that transplanting alone is of great benefit. "His soil," he says, "is not very favourable to the growth of the onion, being light and thin; and it was not until after many experiments he was able to obtain fine bulbs, and which he at length accomplished by sowing in the end of February, and about April transplanting them at the usual distance in drills, first dipping the root into a puddle, consisting of 1 part soot and 3 parts earth, mixed with water; the work being performed in moist weather." The puddle, as is observed by Mr. Sinclair, can be of no other use than to assist the rooting of the plants.

To obtain seed, some old onions must be planted during February, or early in March. The finest and firmest bulbs being selected, and planted in rows 10 inches apart each way, either in drills or by a blunt-ended dibble, the soil to be rather poorer, if it differs at all from that in which they are cultivated for bulbing. They must be buried so deep that the mould just covers the crown. Early in spring their leaves will appear. If grown in large quantities, a path must be left 2 feet wide between every 3 or 4 rows, to allow the necessary cultivation. They must be kept thoroughly clear of weeds, and when in flower have stakes driven at intervals of 5 or 6 feet each side of every 2 rows, to which a string is to be fastened throughout the whole length, a few inches below the heads, to serve as a support, and prevent their being broken down. The seeds are ripe in August, which is intimated by the

nusks becoming brownish: the heads must then be immediately cut, otherwise the receptacles will open and shed their contents. Being spread on cloths in the sun, during the day, and taken under cover every night and during inclement weather, they soon become perfectly dry, when the seed may be rubbed out, cleaned of the chaff, and, after remaining another day or two, finally stored. It is of the utmost consequence to employ seed of not more than one year old, otherwise not more than 1 in 50 seeds will vegetate.

The goodness of seed may be easily discovered by forcing a little of it in a hotbed or in warm water, a day or two before it is employed: a small white point will soon protrude if it is fertile.

Onions are raised in large quantities, in the town of Weathersfield, Connecticut, for exportation to the West Indies and Southern States. The business is there reduced to a perfect system. Early in spring the land is manured, by ploughing in fine manure from the stable or barn-yard, in the proportion of about 10 loads to the acre. That of neat cattle is preferred, as that of horses is considered to be of too heating a nature. It is then well harrowed and laid out into beds of 5 feet wide, by turning a furrow towards them each way; this raises the beds above the alleys, and allows the surplus water to run off. They are then well raked with an iron-toothed or common hay rake, and the alleys suffered to remain as left by the plough.

As early as the season will admit, the seed is sown in the following manner. A rake, with teeth a foot apart, is drawn crosswise of the beds, and drills made for the reception of the seed; it is then sown with the thumb and fingers and covered with the hand, allowing 10 or 12 lbs. to the acre. After the plants are up, they are kept clean of weeds, which generally requires four weedings, using a hoe of suitable width to pass between the rows, which saves much labour. When ripe, they are pulled, and the tops cut off to a suitable length for tying them to the straw in roping. Three and a half pounds are required by a law of the state to be put in each rope; and the ordinary crop is from 6 to 8000 ropes to the acre.

Onions may be raised in the same way in the Middle and Southern States, though the more common practice is to grow them from small bulbs raised from seed the previous year, by sowing thickly in rows, about 9 or 10 inches apart, about the middle of spring; if sown too early, they are apt to run to seed when transplanted. Cultivate and preserve as for full-grown bulbs. Plant early in spring, in well manured ground, in rows about 6 inches apart, and 5 inches in the row, allowing about 18 inches after every fifth row as an alley for convenience in weeding.

If the land is at all light, it is a good practice to tread or roll well before sowing or transplanting, and be careful to disturb the bulbs as little as possible in weeding.

Potato, or under-ground Onion.—This species of *allium* has received the above appellations, on account of its producing a cluster of bulbs or offsets, in number from 2 to 12, and even more, uniformly beneath the surface of the soil.

From being first introduced to public notice in Scotland, by Captain Burns of Edinburgh, it is there also known as the Burn onion. There evidently appear to be two varieties of this vegetable, one of which bears bulbs on the summit of its stems, like the tree onion, and the other never throwing up flower-stems at all. One variety is much larger than the other, and this vegetates again as soon as ripe.

Both varieties are best propagated by offsets of the root, of moderate size; for if those are employed which the one variety produces on the summit of its stems, they seldom do more than increase in size the first year, but are prolific the next; this also occurs if very small offsets of the root are employed.

They may be planted during October or November, or as early in the spring as the season will allow, but not later than April. In the west of England, assisted by their genial climate, they plant on the shortest and take up on the longest day. They are either to be inserted in drills, or by a blunt dibble 8 inches apart each way, not buried entirely, but the top of the offset just level with the surface. Mr. Maher, gardener at Arundel Castle, merely places the sets on the surface, covering them with leaf mould, rotten dung, or other light compost. The beds they are grown in are better not more than 4 feet wide, for the convenience of cultivation.

The only cultivation required is to keep them clear of weeds. The practice of earthing the mould over them when the stems have grown up is unnatural, and by so doing the bulbs are blanched and prevented ripening perfectly, on which their keeping depends. So far from following this plan, Mr. Wedgewood of Betley recommends the earth always to be cleared away down to the ring whence the fibres spring, as soon as the leaves have attained their full size and begin to be brown at the top, so that a kind of basin is formed round the bulb. As soon as they vegetate, they intimate the number of offsets that will be produced, by showing a shoot for each.

They attain their full growth towards the end of July, and become completely ripe early in September: for immediate use they may be taken up as they ripen, but for keeping, a little before they attain perfect maturity, which is demonstrated by the same symptoms as were mentioned in speaking of onion.

ONION, THE WELSH, or CIBOULE. This is a perennial, which never forms a bulb, but is sown annually, to be drawn young for salads, &c.: on account of its strong taste, it is greatly inferior to the common onion for this purpose; but from its extreme hardiness in withstanding the severest frost, it may be cultivated with advantage as a winter standing crop for spring use. In France two varieties are in cultivation, the white and the red; the first of which is the one in general use in England. As it may be sown at all times, in common with the onion, and is similarly cultivated, except that it may be sown thicker, and only thinned as wanted, the directions given for that vegetable will suffice. The blade usually dies away completely in winter, but fresh ones are thrown out again in February or March.

To obtain seed, some of the roots must be planted out in March, 6 or 8 inches asunder. The first autumn they will produce but little seed; in the second and third, however, it will be produced abundantly. If care is taken to part and transplant the roots every two or three years, they may be multiplied, and will remain productive for many years, and afford much better seed than that from one-year old roots. There is good reason for concluding, as Mr. T. Milne, of Fulham, ingeniously explains, that by a confusion of names, arising from similarity of appearance, this vegetable is the true scallion of Miller and others, whilst the hollow leek of Wales is the true Welsh onion; for the description of scallion, as given by Miller, accords exactly with that of the Welsh onion; and as he describes it as a distinct variety, we are reduced to the dilemma of receiving this explanation, or considering the variety as lost; for from Miller's known accuracy it is impossible to consider that he was deceived. At present all onions that have refused to bulb, and formed lengthened necks and strong blades in spring and summer, are called scallions.

ONION, THE TREE, or CANADA (*Alium Canadense*). This, which is a very hardy perennial species, like the ciboule, is without a bulbous root, but throws out numerous offsets. Its top bulbs are greatly prized for pickling, being considered of superior flavour to the common onion for that purpose, as well as others in which that species is employed.

It is propagated both by the root offsets, which may be planted during March and April, or in September and October, and from the top bulbs, which are best planted in spring, and not before the latter end of April. The old roots are best to plant again for a crop of bulbs, as they are most certain to run to stems. If the bulbs be planted earlier than as above directed, they are apt to push up the same season, and exhaust themselves without producing either good offsets or bulbs; but on the other hand, by planting the old roots in the previous autumn, or early in the spring, they will produce good bulbs the same year. They must be inserted in rows 12 inches asunder, in holes 6 inches apart and 2 deep, a single offset or bulb being put in each. Those planted in autumn will shoot forth leaves early in the spring, and have their bulbs fit for gathering in June, or the beginning of July; those inserted in the spring will make their appearance later, and will be in production at the close of July or early in August: they must not, however, be gathered for keeping or planting until the stalks decay; at which time, or in the spring also, if only of one year's growth, the roots may be taken up and parted if required for planting; but when of two or three years' continuance, they must at all events be reduced in size, otherwise they grow in too large and sprindling bunches; but the best plan is to make a fresh plantation annually with single offsets. The only cultivation necessary is to keep them clear of weeds; and when the stems run up, to give them the support of stakes.

The bulbs, when gathered, must be gradually and carefully dried in a shady place; and if kept perfectly free from moisture, will continue

in good state until the following May. (*G. W. Johnson.*)

OPEN. A term frequently applied to cows or heifers, signifying that they are not in calf.

OPEN CUTS. Such drains or gutters as are made in land by the spade, and left without being covered in. They are used in draining lands in particular cases. Open cuts, if effectual, are the best of all for forest draining, as they cannot be inconvenient, from the plough not being employed after the trees are planted. Cuts of this sort are frequently found useful in the practice of irrigation or watering of land.

OPHTHALMIA. See SHEEP, DISEASES OF.

ORACHE (*Atriplex*; from *atir*, black). A genus of herbaceous or shrubby straggling plants of little beauty, and the simplest culture and propagation. There are in England several native species.

The *A. hortensis* is cooked and eaten in the same manner as spinach, to which it is much preferred by many persons, although it belongs to a tribe whose wholesomeness is very suspicious. It flourishes best in a rich, moist soil, and in an open compartment. Those, however, of the autumn sowing, require a rather drier soil. It is propagated by seed, which may be sown about the end of September, soon after it is ripe, and again in the spring, for succession; the sowing to be performed broadcast, the seeds being scattered thin. The plants soon make their appearance, being of quick growth. When they are about an inch high, they must be thinned to 4 inches asunder; and those removed may be planted out at the same distance in a similar situation, and watered occasionally until established. At the time of thinning, the best must be thoroughly cleared of weeds, and if they are again hoed during a dry day, when the plants are about 4 inches high, they will require no further attendance than an occasional weeding by hand.

For early production, a sowing may be performed in a moderate hotbed at the same times as those in the natural ground.

The leaves must be gathered for use whilst young, otherwise they become stringy and worthless. To obtain seed, some plants of the spring sowing must be left ungathered from, and thinned to about 8 inches apart. The seeds ripen about the end of August, when the plants may be pulled up, and when perfectly dry, rubbed out for use.

ORANGE, OSAGE (*Maclura aurantiaca*). This is an American deciduous tree, which grows wild in Arkansas and Louisiana, where it attains the height of a tree of the second or third class, but in the Middle States it seldom grows higher than 15 or 20 feet. It is very branching; each branch being armed with numerous sharp thorns. The wood is remarkably tough, and said to be very durable. The male and female flowers are on separate trees. The fertile or female tree bears fruit abundantly in a very few years. These are round, rough, and greenish-coloured, resembling somewhat an orange, and weighing from 12 to 18 ounces, containing from 100 to 250 seeds.

Recently this thorny tree has received very considerable attention, with a view to making it useful in the construction of live fences,

which purpose it is extensively cultivated in nurseries. "Its great merit," says Mr. T. S. Pleasants, of Virginia, "consists in the spreading manner of its growth, the denseness of its branches, and the armature with which they are furnished. Planted in hedge-rows, the mac-lura would never become unmanageable on account of its size; at the same time its growth is sufficiently vigorous to make a fence in 3, 4, or at most 5 years, from the seed. It may be asserted with safety, that on land of tolerable fertility, the labour and expense of perfecting a system of hedges would not be greater than to keep ordinary enclosures in good condition for the time required to construct them.

"The Osage orange trees are readily raised from the seed, which, unlike those of the common thorn, require no preparation. On the contrary, they vegetate with certainty in 2 or 3 weeks after planting. With tolerable care the seedlings will grow 2 or 3 feet in height the first season; after which they are to be removed from the nursery rows to the place designed for the hedge. Fifty of the large orange-shaped berries yield at least a pound of seed, or from 8 to 10,000 grains. It is the usual practice to place the sets from 12 to 15 inches apart, in a single row." (*Farmers' Register*, vol. 5, p. 86.)

Though originally from a southern locality, the Osage orange is so hardy as to stand the winters not only of the Middle, but of the Eastern States.

ORANGE TREE (*Citrus*). The genus to which the orange tree belongs consists of ornamental species of fruit trees, growing from 3 to 15 feet high. The leaves are on more or less dilated and winged footstalks; the flowers are large, white, and odoriferous, existing at the same time as the fruit, which is too well known to require description. Orange trees thrive best in a good loamy soil, mixed with a quantity of rotten dung. The different kinds are procured by budding or grafting on common stocks. Stocks for working upon are raised from any oranges, lemons, &c. They are sometimes raised from cuttings, in which case they produce fruit when very small plants. The flowers of the orange tree yield, by distillation, a fragrant volatile oil, known by the name of oil of Neroli. The fruit of the big-naroll or bitter orange makes one of the best preserves which can be eaten, namely, Scotch marmalade. The unripe fruit is used for flavouring the liquor called curaçoa. The ripe fruit is wholesome, and a useful refrigerant in fevers.

ORANGE, WILD. See **CHERRY, WILD.**

ORCHARD (Gr.). In horticulture, an enclosure devoted to the culture of fruit trees. In England the surface of the soil in orchards is generally kept under pasture; which, while it prevents the earth from being washed away by rains, is favourable to the running of the roots immediately under the surface, by which they are sooner called into action by heat in spring, and sooner thrown into a torpid state by cold in autumn. The principal fruits grown in orchards of this description in Great Britain are the apple, the pear, the plum, and the

cherry; and wherever wheat can be ripened in the plains, these fruits will arrive at perfection on declivities exposed to the south and south-east.

ORCHARD-GRASS (*Dactylis glomerata*) Called in England cock's-foot. It is an imperfect perennial, native to the United States. See **COCK'S-FOOT**, and **GRASSES**.

ORCHIDACEÆ (*Orchis*, one of the genera). A natural order of herbaceous endogens, inhabiting all parts of the world, excepting those climates situated upon the verge of the frozen zone, or remarkable for their exceeding dryness. They are well known for the singular form of their flowers. Some of them grow in the earth, others inhabit rocks and the branches of trees, and a few appear to be true parasites. They all belong to the class *Gynandria* of Linnæus, are often very agreeably scented, and sometimes produce an aromatic fleshy fruit, as in the case of the vanilla, which contains a large quantity of benzoic acid. The nutritious substance called *salep* is prepared from the amyloseous tubers of the male orchis, merely drying them in ovens. They become semi-pellucid, and when pulverized, form a mucilage with boiling water. They are usually grown in the frame or hothouse, and thrive best in a mixture of loam, peat, and chalk, broken small. They can only be increased from seeds. It would be quite impossible to describe the characters of each species.

The species indigenous to England are—
 1. Butterfly orchis (*O. bifolia*). 2. Pyramidal orchis (*O. pyramidalis*). 3. Green-winged meadow orchis (*O. moris*). 4. Early purple orchis (*O. mascula*). 5. Dwarf dark-winged orchis (*O. ustulata*). 6. Great brown-winged orchis (*O. fusca*). 7. Military orchis (*O. militaris*). 8. Monkey orchis (*O. tephrosantos*). 9. Lizard orchis (*O. hircina*). 10. White cluster-rooted orchis (*O. albida*). 11. Frog orchis (*O. viridis*). 12. Marsh palmate orchis (*O. latifolia*). 13. Spotted palmate orchis (*O. maculata*). 14. Aromatic palmate orchis (*O. conopsea*). Most of the native species of orchis inhabit meadows and pastures, and hilly, chalky downs. The roots are doubly tuberous, fleshy; leaves chiefly radical; flowers numerous, spiked, purple, crimson, or whitish—in some highly fragrant. (*Smith's Eng. Flor.* vol. iv. pp. 8—24).

OREGON ALDER (*Alnus Oregonica*). A species of the alder genus, which, like the European alder, attains the height of 30 or 40 feet. (*Nuttall's Supplement to Michaux.*)

ORGANIC CHEMISTRY, is that portion of the science of chemistry which relates to animal and vegetable substances. "The object of organic chemistry," says M. Liebig, "is to discover the chemical conditions which are essential to the life and perfect development of animals and vegetables, and generally to investigate all those processes of organic nature which are due to the operation of chemical laws." In this article I shall confine myself principally to the results obtained by the analysis of vegetable and animal substances. Under the heads **ATMOSPHERE, EARTHS, GASES, TEMPERATURE, WATER, &c.**, will be found an account of their respective uses to vegetation

There is no branch of chemistry more difficult, and yet more interesting, than that of organic chemistry; for in this the chemist finds, added to his ordinary difficulties, and to his many sources of uncertainty, the presence, and very often the controlling influence, of a living principle, which in some instances seems to neutralize and overcome even the most powerful chemical affinities. "I would warn, therefore, the reader," to use the words of Dr. Thomson, "not to expect complete information in this branch of science: the wonders of the vegetable creation are still but very imperfectly explored; many of the organs of plants are too minute for our senses, and scarcely a single process can be completely traced. The multiplicity of operations continually going on in vegetables at the same time, and the variety of different and even opposite substances formed out of the same ingredients, and almost at the same time, astonish and confound us; the order, too, and the skill with which every thing is conducted, are no less surprising; no two operations clash; there is no discord, no irregularity, no disturbance; every object is gained, and every thing is ready for its intended purpose. This is too wonderful to escape our observation, and of too much importance not to claim our attention. Many philosophers, accordingly, distinguished equally by their industry and sagacity, have dedicated a great part of their lives to the study of vegetation. But hitherto their success has not been equal to their exertions. No person has been able to detect the formative *agent* in plants, nor even the principle which is always so busy in performing such wonders, nor to discover him at his work; nor have philosophers been much more fortunate in their attempts to ascertain the instruments which he employs in his operations." A great variety of curious and interesting facts, however, have been discovered. These I shall attempt to collect and arrange, to point out their dependence on each other, and to deduce such consequences as obviously result from the discoveries which have been hitherto made.

The farmer will, upon reflection, be able to call to mind many circumstances, showing the influence of the living principle upon the chemical substances of organic matter. He will remember, for instance, that the *living* substance flourishes in the very same position, and under the very same circumstances, where, when *dead*, it rapidly putrefies. Every plant growing on the soil, or on a dunghill, testifies to the fact. The living plants which *flourish* in the same solution of a salt in which they are *dissolved*, when dead, prove the same thing in another way; and these proofs may be multiplied very easily on very slight reflection. And as regards animal life, the very same results are obtained; the very gastric juice which the living stomach holds for an age, dissolves that stomach when dead. Animals can sustain a temperature considerably greater than that where the putrefaction of animal substances rapidly proceeds; and men even can exist for a considerable period in an atmosphere heated considerably above the boiling point of water.

In this sketch of organic chemistry, I shall

principally confine myself to the vegetable branch of it, and briefly follow the progress of a plant through its several stages of germination, its growth, and its decay, leaving the reader to refer to other heads of this work for the information he may need.

Germination. That all plants arise from seeds is now, I believe, undisputed by every person, notwithstanding the very many puzzling phenomena which occasionally occur; such as the profusion of some of the grasses, occasioned by the application of certain manures. Thus, "by dressing certain soils with bones and wood ashes, the white clover, which contains this salt, appears in great quantities. Now, phosphate of lime abounds in bones and in the ashes of wood; other plants, it is probable, require the same food. Thus, after the great fire of London, says Mr. Playfair, large quantities of the *Erysimum latifolium* were observed growing on the spots where a fire had taken place. On a similar occasion, the *Blitum capitatum* was seen at Copenhagen, the *Senecio viscosus* in Nassau, and the *Spartium scoparium* in Languedoc. After the burnings of forest pine in North America, poplars, according to Franklin, grew on the same soil. (*Liebig's Org. Chem.* p. 152.)

Seeds, therefore, the farmer may rest assured, are essential to the production of plants. Now, the first movement of the seeds towards the production of plants is denominated their germination. To this certain requisites are essentially necessary; such as moisture, moderate heat, and oxygen gas. That all seeds require a certain degree of moisture before they will vegetate, is known to every one: where there is no moisture, there can be no germination. This, however, varies according to the nature of the plant. Some of the mosses, for instance, will germinate on walls and other places where the supply is very limited; others, such as the water plants, will only grow immersed in water. The rice of Hindostan is grown in swamps abounding with water, which would be destructive to all the grain crops of the English farmer. The water-meadow grasses of our own country illustrate the same position. The plant, too, has the power of decomposing water, and assimilating its hydrogen in the formation of its own substances. Water is composed of hydrogen and oxygen, and these substances are always essential ingredients in vegetables.

Heat is also necessary to germination: thus few plants will vegetate below the freezing point of water; nevertheless, this low temperature does not destroy their vitality, for every farmer is aware that frozen seeds will vegetate after they have been thawed. As, however, there is a peculiar degree of moisture on which every plant vegetates with the greatest advantage, so there is a temperature peculiarly favourable to the growth of every plant. The ivy, the elder, and the honey-suckle, for instance, invariably produce their leaves long before any other English plant has felt the warm reviving influence of spring.

And, again, if the seed is not supplied with oxygen gas, the most favourable supplies of moisture and heat will not induce it to germi

nate. Ray tried this in the vacuum of an air-pump with some lettuce seed; they did not germinate in vacuo, but they grew very well when the atmospheric air (which contains 21 per cent. of this gas) was admitted. It is for this reason that the farmer is careful not to bury his seed-corn so deep in the ground as to be out of the influence of the oxygen of the atmosphere. Beyond a certain depth, which varies with different plants, no seeds, in fact, will vegetate. Seeds have been buried deep in the earth for centuries, and when, afterwards, they have been accidentally thrown upon the surface, have vegetated. There is reason for believing that it is not the entire atmospheric air, but only its oxygen, which is essential to germination. In the experiments of M. Saussure, the quantity of oxygen consumed by various plants during their germination varied very considerably in amount. Wheat and barley, weight for weight, consumed less oxygen than peas; and peas less than beans and kidney-beans. The oxygen consumed by wheat and barley amounts to between $\frac{1}{1000}$ th and $\frac{1}{2000}$ th of their weight, while that consumed by beans and kidney-beans may amount to $\frac{1}{100}$ th part of their weight. The oxygen absorbed by the seed is in all probability combined with the carbon of the plant, and emitted during its germination, in the state of carbonic acid gas. This gas is composed entirely of carbon and oxygen, in the proportion of 6·12 parts of the former and 16 of the latter; and the quantity of it emitted is exactly equal in amount to the quantity of oxygen absorbed by the seed that should unite with the carbon of the plant, to form the carbonic acid gas, and a certain quantity of carbon is always lost by the seed during vegetation.

When once a plant has vegetated, its growth proceeds with more or less rapidity; none that I am aware of remain stationary; indeed, it cannot remain stationary, and live. They increase in size, require a supply of various substances as food, and the examination of the nature of this nutriment constitutes one of the most valuable branches of organic chemistry; for under this head are included the assistance afforded to plants by the *gases*, the *earths*, and by *water*. In the examination of the food of plants will also be illustrated the important questions of rotation, of fertilizers, and of various other important questions, which in this work will be found treated of under their respective heads; and it will be useless to repeat what I have there at some length endeavoured to illustrate. That the atmosphere yields its carbon and its oxygen; the soil its silica, alumina, and magnesia, with various saline matters; and that water yields both hydrogen and oxygen for the service of the plant, is pretty well established by many valuable experiments which I have there given: and it is impossible to observe the results of the analysis of a perfect plant without being struck with the number of its ingredients, and perceiving at once the probable sources from whence it drew its supply. Take, for instance, the analysis by M. Cadet of the solid matters or ashes of the common garlic. From 172 parts of these he obtained of

Potash	-	-	-	-	-	Parts
Sulphate and muriate of potash	-	-	-	-	-	33
Alumina	-	-	-	-	-	58
Phosphate of lime	-	-	-	-	-	2
Oxide of iron	-	-	-	-	-	15·0
Magnesia	-	-	-	-	-	1·5
Lime	-	-	-	-	-	9
Silica	-	-	-	-	-	14
						8
						141·1

All these substances, there is little doubt, were absorbed by the plant from soil in which it grew; but in the fresh or unburnt garlic these are combined with about eight times their weight of mucilage, albumen, sulphur, vegetable fibre, and water. Now the three first of these must have been formed during the growth of the plant, from either the atmosphere or from water: the first (the atmosphere) being composed of oxygen, nitrogen, and carbonic acid; and the latter (water) of hydrogen and oxygen. Mucilage was found by M. Berzelius to be composed of

Oxygen	-	-	-	-	-	Parts
Carbon	-	-	-	-	-	51·306
Hydrogen	-	-	-	-	-	41·906
						6·788
						100

Albumen contains, according to the analysis of MM. Gay Lussac and Thenard,

Carbon	-	-	-	-	-	Parts
Oxygen	-	-	-	-	-	52·883
Hydrogen	-	-	-	-	-	28·872
Nitrogen	-	-	-	-	-	7·540
						15·705
						100

The same excellent chemists have shown woody fibre to be composed of

Oxygen	-	-	-	-	-	Parts
Carbon	-	-	-	-	-	42·25
Hydrogen	-	-	-	-	-	52
						5·75
						100

The chief vegetable matters of the garlic, therefore, the student will remark (and the same conclusion applies to other vegetables), are composed entirely of two or three principal ingredients. The composition of all plants is, in fact, much more similar than is commonly supposed. For instance, all the vegetable acids, such as vinegar (acetic acid), sugar, gum, starch, woody fibre, &c., are composed of three substances, viz., carbon, oxygen, and hydrogen, arranged in different proportions, as may be seen from the following table:

	Carbon.	Oxygen.	Hydrogen.
Acetic acid (vinegar)	50·224	44·147	5·629
Citric acid (of lemons)	33·811	59·859	6·330
Oxalic acid (of wild sorrel)	26·566	70·689	2·745
Sugar	42·47	50·63	5·90
Starch	43·55	49·68	6·77
Gum	42·23	50·84	6·93
Woody fibre of the oak	52·53	41·78	5·69
Woody fibre of the beech	51·45	42·73	5·82

The decomposition of vegetable substances.—All dead vegetable substances, when left to themselves, under favourable circumstances, speedily decay, or decompose, and are resolved into their constituents. This is commonly effected in two ways, either by fermentation or by putre-

faction, to this last phenomenon several requisites are necessary; moisture must be present, and the temperature must not be below 32° of Fahrenheit: in fact, it proceeds with extreme slowness at a temperature below 45°. It is retarded in its progress by the absence of the atmospheric air, but its presence is not essential: when water, however, is entirely absent, putrefaction cannot proceed.

The disagreeable odour which is emitted during putrefaction is owing to the gaseous substances which are generated. Those plants which contain nitrogen emit ammonia: onions produce phosphuretted hydrogen. By all of them carbonic acid gas and carburetted hydrogen gas are emitted in considerable quantities. These gases, being, when presented to the roots and leaves of plants, exceedingly invigorating, are one of the causes of the increased luxuriance of all crops manured with green vegetable matters. When the putrefaction of the vegetable substance is at an end, the carbon, hydrogen, and oxygen, of which it is composed, are gone, and nothing remains but the earths and salts with which the purely vegetable matters were once combined in the plant. The ashes which are left when putrefaction ceases, are in fact nearly the same as those left after combustion. See PUTREFACTION.

Animal substances.—The analysis of animal substances is attended with all the difficulties to which I have alluded as attendant upon the examination of vegetable substances; and the progress of chemical philosophy has not yet succeeded in demonstrating the composition of any great proportion of the many substances met with in the animal world. The great mass of animal matters contain nitrogen, and this is the chief general chemical difference between animal and vegetable substances; hence, when animal substances putrefy, ammonia is disengaged, for this alkali is composed of nitrogen and hydrogen.

The following analysis of several animal matters will show how generally present is nitrogen in this class of substances:—

	Carbon.	Oxygen.	Hydrogen.	Nitrogen.
Gelatin (glue, isinglass), &c.	47·881	27·207	7·914	16·998
Albumen (white of egg), &c.	52·883	23·872	7·540	15·705
Fibrin (fibre in clots of blood)	53·360	19·685	7·021	19·934
Urea (found in urine) - -	20·	26·66	6·66	46·66

These are the chief animal substances of which most others are compounded. Thus the principal solid matter of animal muscle is fibrin. The outer skin or cuticle of animals is composed of from 93 to 95 per cent. of albumen. The solid matter of the blood is chiefly composed of the same substance. Under the heads ANIMAL MANURES, FISH, BONES, GELATIN, &c., the reader will find all the animal chemistry bearing upon farming and rural affairs, with which I am acquainted. The relative proportions of the inorganic constituents of vegetable substances forms a topic of great interest; and Professor G. F. W. Johnston's lectures upon the subject, just published, will be read with satis-

faction. See *Lect IX., on the Application of Chemistry and Geology to Agriculture.*

ORNITHOLOGY (Gr.). The science which teaches the natural history and arrangement of birds.

OSIER. The name given to various species of willow or *salix*, chiefly employed in basket-making. Although under the heads **SALLOW** and **WILLOW** are noticed most of the species of this genus, it may be well to describe in this place, a few of those which are more generally known under the name *osier*. Osiers differ from salwos in their long, straight, flexible, and mostly tough twigs; thin, generally sessile gemens, and elongated styles and stigmas. The osier forms a hardy and useful hedge for excluding boisterous winds; and as it flourishes in wet situations is frequently planted with a view to prevent the banks of rivers being washed away by the force of the current. Osiers are divided into two classes: the first is known by their blunt and downy or mealy leaves, which in the other are more pointed, smooth, and green, resembling the myrtle.

The common osier (*S. viminalis*) is one of the most abundant species. This tree is found growing in wet meadows, osier-holts, the banks of rivers, and other moist situations. The branches are straight, erect, wand-like, very long and slender, round, polished, downy when young, with fine silky hairs. Leaves on short foot-stalks, almost upright, about a span long, and half an inch wide. The value of the common osier for various kinds of basket-work is universally known. There is a variety much esteemed, called the velvet osier, in which no external difference is discernible, but the twigs are said to be more pliant. There are also various species as well as varieties comprehended under the name of osiers, some of which, having smooth leaves, are noticed under the articles **SALLOW** and **WILLOW**.

The silky-leaved osier (*S. Smithiana*) is a shrub found growing in meadows and osier grounds, the branches of which are brittle and unfit for basket-work. It is therefore important for cultivators of osiers to distinguish carefully between this and the velvet osier; for while the latter is, for some kinds of work, greatly esteemed, the silky-leaved osier proves of no utility.

The auricled osier (*S. stipularis*) is a common species in osier-holts, hedges, and woods, and is easily known at first sight by its coarse, tall habit, and conspicuous stipules, but not worthy of cultivation for any economical purpose. The twigs are upright, tall, soft, and downy, of a pale reddish-brown, brittle, and of little or no use as an osier.

The fine basket osier (*S. Forbiana*) is a shrub grown in the meadows and osier-holts of the eastern part of England. The stem is erect, bushy, with upright, slender, smooth twigs, very flexible and tough, of a grayish-yellow, not purple hue, highly esteemed and much cultivated for the finer kinds of basket-work.

Green-leaved osier (*S. rubra*). This is a small tree, with long, upright, smooth, grayish or purplish, more frequently tawny branches, very tough and pliant, this being one of the

most valuable osiers when cut down annually. The very long and narrow leaves of this rather rare species agree in shape with the common osier (*S. viminalis*), but want its dense white pubescence.

In the fens of the east of England many holts (as they are provincially called) or plantations of osiers are raised, which beautify the country, keep the stock warm in the winter, and provide much useful wood for baskets and all kinds of wicker-work. The mode of planting is very simple; it is, first, to dig the land from 6 to 12 inches deep, and then to prick down cuttings of 4 years' growth, and 18 inches long, at about 3 feet distance from each other. The soil may be moor or clay, or any that is low and wet.

These holts or osier plantations must be fenced round, either with dikes, which are most common, or with hedges. The proper season for making them (they seldom fail of growing at any time), is from the fall of the leaf till very late in the spring.

OSIER, GOLDEN, or YELLOW WILLOW. See **WILLOW.**

OUZE. A deposit made by the sea.

OVEN. A domestic furnace used for baking bread, pies, tarts, &c. Ovens are generally constructed of brick-work in a semicircular form, with a very low roof, and the bottom of which is laid with stone: in the front is a small aperture and door, by the shutting of which the heat is confined while the bread is baking. They are usually heated by means of dry faggots, wood, &c. As these ovens, however, are not calculated for small families, on account of the quantity of fuel they consume, others have been contrived, on a more diminutive scale: these are usually formed of cast or hammered iron, and may be heated by the same fire which serves for the cooking of other provisions; but for baking bread these ovens are inferior to the brick ovens.

OVERLAND FARM. A provincial phrase usually applied to a parcel of land without any building or house attached to it.

OVER-REACH. See **CLICKING.**

OVER-YEARS. A country term applied to such bullocks as are not finished fattening at three years old when home-breeds, or the first winter after buying in; but kept through the following summer to be finished the next winter.

OVIPOSITOR (Lat. *ovum*, an egg; and *pono*, I place). In entomology, is the instrument by which an insect conducts its eggs to their appropriate nidus, and often bores a way to it; the same instrument is in some genera used as a weapon of offence, whence it is called the "aculeus." In the gall insect, and some others, the ovipositor is furnished at its root with a sac containing an acrid secretion, which is deposited in the wound made by the ovipositor at the same time as the eggs.

OWLING. In law, so called from its being generally committed during the night. An offence consisting in conveying sheep or wool to the sea-side, in order to export them clandestinely. The offence was formerly capital, particularly if the offender neglected to surrender after proclamation made for that purpose.

OWLS. A tribe of reptorial birds, including

those which fly by night, and have the eyes directed forwards. The owl, although frequently held in disrepute, should never be destroyed by the farmer, to whom he is a great friend; for his diet consists chiefly of field-mice, of which he consumes large numbers. The owls are usually arranged into two principal groups: one in which all the species exhibit two tufts of feathers on the head, which have been called horns, ears, and egrets; in the second group, the heads are smooth and round, without tufts.

OX. Synonymous with the generic name *Bos*; in a more restricted sense, it signifies the castrated male of the domestic variety. See **CATTLE.**

OXALIC ACID. See **ACIDS.**

OXALIS CRENATA. A perennial ornamental plant, native of Chili, lately discovered by Mr. Douglas. The flowers are beautiful, of a yellow colour, and in umbels; the stalks and leaves are succulent, of an acid taste, and useful as salads; the roots or tubers are produced in clusters; their taste, when boiled, somewhat resembles a chestnut. They are raised from the tubers, are extraordinarily productive, as easily cultivated as the potato, and decidedly superior in flavour. They require a rich soil, and, like the potato, are stored during winter in cellars. (*Kenrick.*)

OX-BOOSE. Provincially, a stall or place where oxen stand in the winter to be fed or fattened.

OX-EYE (*Chrysanthemum*, from *chrysos*, gold, and *anthemum*, a flower; alluding to the colour of some of the flowers). The great white ox-eye maudlin-wort, or moor daisy (*C. leucanthemum*), Pl. 10, *w*, is very common in pastures, fields, and by way-sides. The flavour of the whole plant is herbaceous, slightly, not pleasantly, aromatic. Its properties are not important; like many other herbs, mixed with grasses, it makes a part of the hay crop. The root is branched, tough, and woody, with many fibres. Stem erect, simple, or branched, according to the soil, from one to two feet high. Leaves deep-green, clasping the stem, oblong, obtuse, cut, pinnatifid at the base; radical ones obovate, stalked. Flowers large, terminal, solitary, not inelegant, with a broad yellow disk, and brilliant white radius. See **DAISY.**

Another wild indigenous species, the yellow ox-eye (*C. segetum*), has already been noticed under the head **CORN MARIGOLD.**

OX-FEET. A term applied to the feet of horses when the horn of the hind feet cleaves just in the middle of the fore part of the hoof, from the coronet to the shoe: they are not common, but very troublesome.

OX-HARROW. A term applied to a very large sort of harrow, called in some counties of England a drag.

OX-LIP. See **COWSLIP.**

OXYGEN GAS. A simple or undecomposed substance, discovered in 1774 by Dr. Priestley. It constitutes 21 per cent. of the atmosphere, and it is that portion of it which supports animal life and combustion. It is emitted by plants growing in the light, and is absorbed by them during the night. It is found in combination with hydrogen and carbon, and

less often with nitrogen, in all vegetable and animal substances. It unites with various bases, and forms alkalies, acids, and metallic oxides. It is tasteless, and soluble in water, which at a temperature of 60° absorbs about $\frac{1}{27}$ of its bulk. One hundred cubic inches of this gas weigh about 34 grains. See GASES, their Uses to Vegetation.

OYSTER SHELLS. As a manure, the use of crushed oyster shells has never been so extensive in England as in Ireland. Though consisting mainly of carbonate of lime, they contain a very minute proportion of phosphate of lime, $1\frac{1}{2}$ to $2\frac{3}{4}$ per cent., with a small proportion of magnesia. They are consequently not nearly so valuable as bones, which contain the phosphate of lime in so much greater quantity; and, unless pulverized, are not sufficiently quick in their effects to encourage the farmer to use them unbroken. In England they have been, therefore, little employed, even in districts, such as the clay and sand formation, where, from the absence of carbonate of lime in the soil, the calcareous matter supplied by oyster shells would be a very valuable addition. In Ireland, which is almost entirely destitute of chalk, the use of the broken oyster shells has been more considerable than in England; and in Dublin the parish authorities, in hard seasons, are glad to set the paupers to work to collect and break the shells which are thrown away as rubbish; and I am informed that the money received for the powdered shells affords a very tolerable remuneration for the labour bestowed in their preparation. The mother-of-pearl with which the oyster shells are lined is similar in composition to the outer shell or crust. This has been analyzed by M. Merat Guillot, who found in 100 parts of mother-of-pearl,—

Carbonate of lime (chalk) - - -	Parts.
Membrane - - - - -	66
	34
	<hr/>
	100
	<hr/>

Powdered oyster shells should always, if possible, be drilled in with the seed; for, by thus coming into close contact with the plant, all the volatile and earthy constituents of the decomposing shell are absorbed by its roots and leaves with the greater readiness, from being placed more immediately in contact with them. In this way they have been found to answer very well on the light, sandy soils of Norfolk, when drilled in with the turnip seed; as will be seen from the following account of Mr. Blakie, in a letter to Sir John Sinclair, dated Sept. 18, 1818:—"Oyster shells pounded or bruised (without having been burned) were first used upon Mr. Coke's farm as a manure in the year 1816. In the summer of that year, the experiment was tried upon a hungry, light, sandy soil, which had been cleaned for turnips. The oyster shell dust, or powder, was drilled in the usual way, upon 27-inch ridges, at the rate of 40 bushels per acre (without any other manure), was slightly covered with earth, and the turnip seed sown upon it. Another part of the same field, quality of land equal, was manured with farm-yard dung, at the rate of 8 tons per acre, put into the same sized ridges,

and sown with turnip seed as before described, no other manure having been applied. The turnips proved a good crop on both pieces: nor was there any perceptible difference in the bulk, but the produce was not weighed. The turnips were all eaten upon the ground by sheep; and the succeeding crop, barley, was good on both, and apparently equal, but the produce was not thrashed separate. The seeds or layer crop of clover, in the present season, 1818, is a good plant, and appears equally so. In this experiment, so far as it goes, it appears that 40 bushels of oyster-shell powder are equal in virtue as a manure to 8 tons of farm-yard dung, at least for the purpose to which it was applied.

"In the autumn of 1816, powdered oyster shells were tried as a manure for wheat, in competition with rape-cake powdered. The experiment was upon a one year's clover layer; the wheat sown after one ploughing; the soil a kind, light, gravelly loam. Oyster-shell powder, at the rate of 4 cwt. per acre, was drilled with the wheat seed on one part of the field; and on another part, of the same quality, rape-cake dust was drilled with the wheat at the same rate per acre as the shell powder; no other manure was applied to either part. The crop of wheat was good, nor was there any perceptible difference upon the ground; but the produce was not thrashed separate. A similar experiment was tried upon the same wheat field, the manure applied at spring; the operation as follows: the wheat seed was sown without any manure in the autumn of 1816, and in the spring of 1817 rape-cake dust, at the rate of 4 cwt. per acre, was drilled between the rows of wheat; at the same time an equal weight of shell powder was applied in like manner to another part of the field. The result of this was similar to the autumn experiment, viz., there did not appear to be any difference in the crop produced upon the shell manure from that on the rape cake. The field on which these experiments were tried is now in turnips, a good crop, and exhibits no difference where the manure, as before stated, had been applied for the wheat crop. These experiments are satisfactory, so far as they go, but certainly not conclusive; because the produce was in no one instance either weighed or measured. This I very much regret; but it appears to be almost impossible to conduct such experiments with a requisite degree of accuracy upon a farm establishment of such magnitude as that of Mr. Coke at this place. For, during the hurry incident to collecting the harvest, the farm manager has so many important concerns to attend to, that he cannot devote any portion of his time to superintending experimental objects; and were he to depute the management of such concerns to the labourers, it is not to be expected that they would pay the attention requisite. The oyster shells are here broken to pieces by passing them through the oil-cake crusher; or are bruised by repeatedly drawing a heavy iron roller over them when spread upon a stone or hard-burned brick or edge floor. I give it as an opinion, that oyster-shell manure is likely to answer for gardens, particularly to rake in with onions and other

small seed. I also think it may prove beneficial as a top-dressing for grass plants, to destroy moss, and prevent worms from casting.

Mr. Livingston, of New York, says (*Annals of Agr.* vol. xx. p. 87), "In April, 1791, I strewed 7 bushels of ground oyster shells over half an acre of rye, growing on a very poor soil, and 3 bushels of gypsum on another half-acre adjoining; sowed 10 lbs. of red clover seed over both. The rye was not better than the rest of the field; the clover seed being bad, came up but thinly; that, however, dressed with oyster shells, much better than that manured with gypsum."

It is certain, therefore, that oyster shells, when powdered or crushed, are an excellent manure; and, in many parts of England, where they can be obtained in considerable quantities, I have every reason to believe that they will be found very useful to the farmer. (*Johnson on the Fertilizers*, p. 368.)

P.

PACANENUT. See **HICKORY.**

PACE. In horsemanship, the peculiar manner of motion, or progression, in the horse or other animal. The natural paces of the horse are, a walk, a trot, and a gallop, to which some add an amble, as some horses have it naturally. See **CANTER**, **GALLOP**, &c.

PACK RAG-DAY. A provincial term in England signifying the day after Martinmas day, the time of changing farm servants.

PADDLE-STAFF. An implement used by ploughmen to free the share from stubble, earth, &c.

PADDOCK. A small field or enclosure. It also signifies a large toad.

PAIL. A wooden bucket in which milk, water, or other fluids are commonly carried.

PAIL-BRUSH. A hard brush, furnished with bristles at the end, to clean out the angles of the vessels more fully.

PALM. An ancient measure of length taken from the extent of the hand. The English palm is understood to be three inches.

PALMATE. In botany, divided so as to resemble a hand spread open.

PALMA CHRISTI. See **CASTOR OIL PLANT.** The cake left after the expression of castor oil is very advantageously applied to land as a manure for wheat and other crops. An interesting communication upon this subject may be found in the first volume of the *Farmer's Register*, from T. G. Peachy, Esq., of Williamsburg, Va., the results of whose experiments show the great value of the article. In one experiment he applied from 50 to 60 bushels per acre on $7\frac{1}{2}$ acres of land sown with 10 bushels of wheat, and the product was 26 bushels of wheat per acre. In this case the land was so poor that not over 5 bushels could be expected from it without the dressing. He recommends about 40 bushels as an ordinary dressing. Mr. Peachy does not think the common impression correct, that the chief efficacy of the cake resides in the portion of oil which it retains. His press, he says, "is a very powerful one, and

leaves a very small portion of oil in the cake. There is, moreover, other refuse matter in such an establishment as ours, which contains a vast deal more oil than the cake, which I have used as manure, and been uniformly disappointed in its effects. Accident has enabled me, I think, to solve the difficulty, and to declare my belief that the fertilizing qualities of the oil-cake reside chiefly in the farina it contains. Some time last year a vessel laden with flour was stranded near Jamestown, and the flour ruined. Mr. John Mann, who owns a farm in the neighbourhood, took two or three of the barrels and top-dressed a small portion of his wheat with it. I was not an eye-witness of its effects; but I was informed it produced as great an increase of that portion of his crop as my oil cake would have done.

"By experiment, I find that 50 bushels of the cake will weigh 1800 lbs.; and of this quantity I have discovered that $\frac{1}{3}$ is farina or flour—equal to 5 barrels of flour. The cotton seed, I fancy, contains more farina, in proportion to the oil, than the castor bean, and, I believe, would produce as great an effect after being deprived of its oil, as it would do in its original state. I should be much obliged to you to give us your opinion on this subject." See **LINSEED CAKE**, **RAPE CAKE**, &c.

PALMETTO (*Chamaeops palmetto*). Cabbage tree. This American tree belongs to the genus of the palms, and is found farther north than any other species in America. From its lofty height it is reckoned in the United States as a tree. It is first seen about Cape Hatteras, in the 34th degree of latitude, from which it spreads to the extremity of the Florida peninsula, and thence around the Gulf of Mexico. In the extreme south the palmetto is not entirely confined to the immediate vicinity of the sea. Its stem or trunk is erect, and rises 80 or 90 feet, embellished at top by a globe of plumed leaves, each somewhat like a large fan, and plicated in the same manner, each frond, with its stipes or stem, 30 feet in length; the frond, or expanded part of the leaf, 15 feet over. There are six species of the palm in Carolina and Florida, all of which have flabelli-formed leaves or fronds.

It is the central part of this vast plant at top which stands erect, like a sharp cone or sugar-loaf, surrounded by the expanding leaves, which is eaten roasted or boiled, like cabbage; and consists of the young frond, rudiments of fronds, with all the succeeding appendages of the future growth, involved together, white and tender as a curd, as rich, and of the like pleasant flavour.

A well grown palm stands perfectly erect, on a shaft or column of 60 or 80 feet high, its base 3 feet diameter, having 3 or 4 rings and circular mouldings, 3 or 4 feet upwards; from thence upwards to the top it diminishes almost imperceptibly, forming a model of a pillar for the architect, almost inimitable. A tree produces but one cabbage, and as soon as that is cut off, this glorious production of nature perishes. But, though the tree dies, yet it ceases not to be useful; the exterior ligneous part, of three-fourths inch thickness, is as hard as bone when dry, and the interior

spongy consistence being rotted out, or devoured by worms, it makes excellent trunks or conduits for draining off water, being almost incorruptible under ground. These shafts also, split in two, and set upright in the ground, make strong and durable palisades; and we are informed that they answered a very good purpose in South Carolina, at the time of the revolutionary war, particularly at Sullivan's Island. The ramparts of the fortifications being lined with the trunks of the cabbage tree, split in two, and set upright against the wall; their smooth, firm, and elastic surface, together with their spongy interior, united to repel the shot of their assailants.

The stems are also used in Charleston, S. C., for the facing of wharfs, as the salt-water worm never touches them. Pieces of the spongy part of the stem afford a very good substitute for scrubbing-brushes, and are even preferred for whitening floors.

The leaves of the smaller species afford excellent and durable thatch for covering barns and out-houses; and the younger leaves of the cabbage tree are manufactured by the negroes into beautiful, light, and durable hats, called Bermudian hats. The repent caudex of the saw-palmetto, being torn from the surface of the earth, cut into proper lengths, dried, and burned to ashes, produce the greatest quantity of potash of any known vegetable. And the drupes, or large berries of this species, which are of the size and figure of dates, and as sweet, afford good and nourishing food to the Indians and hunters. They are not palatable to white people till they become accustomed to them.

PALMS. A natural order of arborescent endogens, chiefly inhabiting the tropics; distinguished by their fleshy, colourless, six-parted flowers, enclosed within spathes; their minute embryo lying in the midst of albumen, and remote from the hilum; and rigid plaited or pinnate inarticulated leaves, sometimes called fronds.

Palms is a common name for the male flowers of the willow.

PALSY. In the horse this nervous disease is usually confined to the hinder limbs. Old carriage-horses, and horses of draught of every kind, although not absolutely paralyzed, have often great stiffness in their gait, and difficulty of turning. These are evident injuries of the spine. Bleeding, physicking, antimonial medicines, and stimulating embrocations are the most likely means of cure for palsy. See **SHEEP, DISEASES OF.**

PAMBINA. A species of North American bush cranberry, discovered on the Columbia river.

PAN. A term applied to the bed or flooring upon which the cultivated soil lies or is placed. See **MOORLAND PAN.**

PANIC-GRASS (*Panicum*). This is a very extensive genus of large, coarse grasses, mostly annual in Europe, of no agricultural use: the inflorescence spiked or paniced; the seeds in some instances used for food. There are three indigenous species: the rough, the green, and the loose panic-grass (*P. verticillatum*, *viride*, and *Crus-galli*). See **MILLET GRASS.**

PANICLE. In botany, a form of inflorescence in which the primary axis develops secondary axes, which themselves produce tertiary; or, in other words, a raceme bearing branches of flowers, in place of simple ones.

PANNAGE. An old manorial term applied to the food which swine consume in woods, as acorns, and the mast of beech. It also signifies the money taken by the king's agistors, for the privilege of feeding hogs in the king's forest.

PANSY. A term applied chiefly to the garden varieties of *Viola tricolor*, and others which are usually cultivated under the name of *heart's-ease*. See **VIOLET.**

PAPAW (*Anona triloba*). An American plant, which, though most frequently appearing in the form of a shrub, sometimes attains the size of a tree of the third order. By the French of Upper Louisiana the papaw is called *Assiminier*. It is not found north of the Schuylkill river, in the vicinity of Philadelphia; and it appears to be unknown, or extremely rare, in the low and maritime parts of the Southern States. "It is not uncommon," says Michaux "in the bottoms which stretch along the rivers of the Middle States; but it is most abundant in the rich valleys intersected by the western waters, where, at intervals, it forms thickets exclusively occupying several acres. In Kentucky, and in the western part of Tennessee, it is sometimes seen also in forests where the soil is luxuriantly fertile; of which its presence is an infallible proof. In these forests it attains the height of 30 feet, and the diameter of 6 or 8 inches, though it generally stops short of half this elevation.

"The leaves are borne on short petioles, and are alternate, 5 or 6 inches in length, and of an elongated form, widening from the base to the summit. They are of a fine texture, and the superior surface is smooth and brilliant. The flowers, which are attached by short peduncles, are pendent, and of a purple hue.

"When the fruit is ripe, which takes place towards the beginning of August, it is about 3 inches long, and 1½ inches thick, of a yellowish colour, and of an oval form, irregular and swelling into inequalities. Its pulp is soft, and of an insipid taste, and it contains several large, triangular stones. It is never brought into the markets, and is sought in the woods only by children. At Pittsburgh some persons have succeeded in making from it a spirituous liquor; but, notwithstanding this experiment, very feeble hopes can be entertained of cultivating the tree with profit for this purpose.

"The trunk of the papaw is covered with a silver-gray bark, which is smooth, and even polished. The wood is spongy, extremely soft, destitute of strength, and applicable to no use in the mechanical arts. I have noticed that the cellular integument of the bark, and particularly that of the roots, exhales in summer a nauseous odour, so strong as to occasion sickness if it is long respired in confined air. (*Michaux's Am. Sylva.*)

The papaw belongs to the *custard-apple* genus, which in the tropics produces several kinds of fruit highly esteemed. Among these is the

celebrated *Cherimoyer* (*Anona cherimolia*) found in perfection in Mexico, Peru, and Brazil; the *Alligator pear* (*A. palustris*), the *Sweet sop* (*A. squamosa*), all esteemed West India fruits, about as large as a middle-sized apple, and filled with a soft, rich, delicious pulp.

PAPILIONACEOUS PLANTS include many of the most common and valuable plants supplying food to man and animals, such as pulse, beans, peas, tares, sainfoin, &c. The papilionacæ take the name from the resemblance borne by their flowers to the butterfly, as is seen in the blossom of the common pea. The fruit forms a pod called a legume, and such plants are hence named *leguminous*.

PARASITICAL PLANTS are those which grow into the tissue of other species, and feed upon their juices. Of this kind are the mis-seltœ, the broom-rape (*Orobanche*), the *Lathræa*, &c. Such species have no proper roots. The term *parasitical* is, however, often applied to mosses, Orchidaceous plants, *Tillandsias* and the like, which are mostly epiphytes, growing upon the bark of trees, but deriving their food from the air, by means of their own roots.

PARING AND BURNING. This well-known operation of agriculture, once much more extensively practised in England than at present, consists in paring off the turf to a depth of two or three inches, generally with a breast-plough worked by a labourer, or by a turf-paring plough drawn by a horse; allowing it to dry, and then burning it in heaps. It is commonly best performed in the months of April and May. It is a practice now rarely adopted on sandy or calcareous soils, although productive of good results on peat, and some kind of clay soil; but even there it is very doubtful whether it is the best mode of treating the land.

The practice is certainly as old as the days of Virgil, who mentions it in the first book of the *Georgics*. Endless have been the theories brought forward to account for its operation. Dr. Home thought it dispelled "a sour juice" from the land. (*Prin. of Agr.*) Dr. Darwin considered it produced "a nitrous salt" in the ashes. "Many such obscure causes," says Davy, "have been referred to for the purpose of explaining the effects of paring and burning, but I believe they may be referred entirely to the diminution of the coherence and tenacity of clays, and to the destruction of inert and useless vegetable matter, and its conversion into a manure. All soils that contain too much dead vegetable fibre, and which consequently lose from one-third to one-half of their weight by incineration, and all such as contain their earthy constituents in an impalpable state of division, such as the stiff clays and marls, are improved by burning; but in coarse sands, or rich soils, containing a great mixture of the earths, and in all cases in which the texture is already sufficiently loose, or the organizable matter sufficiently soluble, the process of torrifaction cannot be useful. All pure silicious sands," adds Davy, "must be injured by it;" and here practice is found to accord with theory. Arthur Young found "burning injured sand;" and an intelligent farmer in Mount's

Bay told me that he had pared and burned a small field, several years ago, which he had not been able to bring again into good condition. I examined the spot; the grass was very poor and scanty, and the soil a silicious sand.

The process of paring and burning, therefore, seems to be most adapted for peaty or clay lands; for, as Davy continues, "the process of burning renders the soil less compact, less tenacious and retentive of moisture; and when properly applied, may convert a matter that was stiff, damp, and in consequence cold, into one powdery, dry, and warm, and much more proper as a bed for vegetable life."

Davy examined three specimens of the ashes from different lands that had undergone paring and burning. (See *ASHES*, *antè*, p. 115.) "The great objection," he adds, "to this operation is that it destroys vegetable and animal matter, or the manure in the soil: but in cases in which the texture of its earthy ingredients is permanently improved, there is more than a compensation for this temporary disadvantage. And in some soils where there is an excess of inert vegetable matter, the destruction of it must be beneficial; and the carbonaceous matter remaining in the ashes may be more useful to the crop than the vegetable fibre from which it was produced." (*Agr. Chem.* p. 344.)

Liebig thinks that all the benefit of burning the soil is attributable to its thus obtaining increased powers for the absorption of ammonia. He says, "Soils which contain oxides of iron, and burned clay, must absorb ammonia, which is favoured by their porous condition; they further prevent the escape of the ammonia once absorbed by their chemical properties. The ammonia absorbed by the clay, or ferruginous oxides, is separated by every shower of rain, and conveyed in solution to the soil. Powdered charcoal possesses a similar action, but surpasses all other substances in the power which it possesses of condensing ammonia within its pores, particularly when it has been previously heated to redness. Charcoal absorbs ninety times its volume of ammoniacal gas, which may be again separated by simply moistening it with water." (*Organic Chem.*)

And it is evident, from the experiments which Liebig gives, that charcoal powder is a very fertilizing application to some plants. The practice, however, of paring and burning is evidently one whose advantages the farmer and the chemist admit with reluctance. And it is very probable, that by other means, such as the use of lime, &c., most soils may be cultivated with more advantage to the farmer by the avoidance of this expensive and destructive process. "My practice," remarks Mr. Pearson, "in the use of turf for various purposes, convinces me that all lands must be injured by paring and burning, save those lands, which are few and far between, that possess too much inert vegetable matter; or, in other words, lands that grow their crops to such a state of luxuriance, as to prevent the desired intent of the cultivator. Those lands which possess too much inert vegetable matter might also be improved by having part of their

subsoils burned; but not by burning the turf even here, for that is the only thing that can be commended on the spot that will cause fermentation in the soil when it is ploughed in." See PEAT SOILS.

PARK. A considerable extent of pasture and woodland, surrounded or adjoining the country residence of a man of wealth, devoted to purposes of recreation or enjoyment, but chiefly to the support of a herd of deer, though sometimes to cattle and sheep. Parks were originally nothing more than portions of forest scenery appropriated by the lord of the soil for the exclusive use of animals of the chase; but this is now become, in many cases, a secondary consideration, and the chief uses of a park are as indications of wealth and extent of territory, and as grazing ground for domesticated animals.

PARSLEY, CULTIVATED (*Apium petroselinum*). There are two varieties of this well-known plant, the common plain-leaved, and the curly-leaved. It is somewhat singular that the first should be most cultivated, notwithstanding the superior beauty of the latter, as well as by reason of its curled leaves rendering it more easily to be distinguished from the *Aethusa*, or fool's parsley, a variety of the hemlock, often occurring in gardens: it requires much care in saving the seed, otherwise it degenerates into the plain-leaved. Parsley is raised from seed, which is recommended usually to be sown annually; but if never permitted to run to seed, and the stalks are cut down as often as they rise, it will last for several years. It may be sown from the close of February until the middle of June, and this is repeated about the middle of September, for the supply of winter and spring; but this is unnecessary if the plants are not allowed to seed. The seed is to be inserted moderately thick, in narrow drills barely an inch deep, 12 inches apart if in a bed by itself, or in a single one round the edge of a bed; the mould being raked level, and the stones immediately over them gathered off. The plants will not make their appearance in less than three or four, and sometimes six, weeks. When two or three inches high, it may be gathered from as required. In early June, when the plants make a show for seed, the stems should be cut down close to the bottom, and again in September, if it has acquired a straggling, rank growth; this will cause it to shoot afresh, and acquire a strong growth before the arrival of severe weather. On the approach of frost, if protection is afforded to the plants by means of haulm or reed pannels, so supported as not to touch them, it will preserve them in a much better state for use in winter and spring. To save seed, nothing more is necessary than to allow some of the plants to run up in June; they should not, however, be allowed to stand nearer than 18 inches to each other. The seed ripens in early autumn, and, when perfectly dry, may be beaten out, and stored.

PARSLEY, THE COW. For rough cow-parsley, see CICELY. Smooth cow-parsley, see CHERVIL.

PARSLEY, THE FOOL'S. See FOOL'S PARPLEY.

PARSLEY, THE HEDGE. See HEDGE-PARSLEY.

PARSLEY, HAMBURGH (*Apium latifolium*). This esculent is likewise known by the name broad-leaved and large-rooted parsley. It is cultivated for its root, which attains the size of a middling parsnip, boiling exceedingly tender and palatable. It is eaten both as a sauce to flesh-meat and in soups, &c. It is propagated by seed, which may be sown at monthly intervals from February until the middle of June. It is sown either thinly in drills, 9 inches apart, or broadcast and raked in. The plants appear in about a month after sowing, and when of tolerable growth require to be thinned to 9 inches asunder, and cleared from weeds either by hand or the hoe; which latter operation being performed as often as weeds appear, is the only cultivation required. By the end of July or during August, the earliest sowings will have acquired a sufficient size for occasional use; but they seldom attain their full growth until Michaelmas; and the latest crops not until the following year. On the arrival of frost some of them must be taken up, and after the removal of the superfluous fibres, decayed leaves, &c., buried in sand, in a dry situation, under cover.

To obtain seed, some plants must be left where grown, and allowed to run in May; their produce will ripen in July or August, when it must be cut, and, when perfectly dry, beaten out and stored.

PARSLEY-PIERT. See LADIES' MANTLE.

PARSLEY, SMALLAGE, OR WILD CELERY (*Apium graveolens*). This wild plant, the seeds and herbage of which in its native ditches are acrid and dangerous, with a peculiar strong taste and smell, by culture becomes the mild and grateful garden celery, for which and its name we are indebted to the Italians, and which has now supplanted our native Alexanders. It is biennial, and flowers in August and September. The root is tap-shaped, and the herbage smooth and shining. The plant grows in ditches and marshy ground, especially towards the sea. The stems are widely spreading or floating, long, branched, furrowed. Leaves bright-green, pinnate, or ternate; leaflets wedge-shaped, entire at their base, but variously notched above. Flowers in terminal and lateral umbels, small, numerous, greenish-white. Fruit almost globular, with permanent, wide-spreading, straight styles.

PARSNIP (*Pastinaca*, from *pastinum*, a dible, in allusion to the form of the root). The common wild parsnip (*P. sativâ*) is the well-known culinary root; the other species are unworthy of cultivation. The original is a biennial plant, and found in England growing wild about the borders of fields, on hillocks, and dry banks, in a chalky soil, the root being spindle-shaped, white, aromatic, mucilaginous, and sweet, with a degree of acrimony, which it loses by cultivation. The stem reaches to a yard high, erect, branched, deeply furrowed. Leaves oblong, simply pinnate, downy beneath; leaflets serrated and cut, bright-green. Umbels terminal, erect, of several unequal, angular, downy rays. Flowers small, yellow, appearing in July. Fruit large, pale-brown when quite ripe

The Field Culture of the Parsnip.—Colonel Le Couteur describes this valuable field crop as thriving in any deep land, whether stiff or light. It succeeds in the island of Jersey admirably on soil resting on granite or sienite, or argillaceous schistus, on red clay, or on a gravelly bottom; on almost pure sand, if mixed with a light coating of earth, and on soils derived from pudding-stones, or white and red felspar. This includes most of the British islands, exclusive of the chalky or limestone ranges. Some persons cultivate it on poor black heath soil, not above 7 or 8 inches deep, and by means of heavy dressings of manure raise a good crop; but the parsnip in such situations forms a large shoulder, and forks away into fingers when near the hard subsoil, whereas, in very deep land, it will run down a foot or two of a good size.

An old grass lay is broken up by some persons in September, by others just before the parsnip seed is sown; the former I consider to be the best mode. When the turf is well rolled, 20 tons per acre of stable manure are spread over the land. A trench is then opened through the centre of the field between 2 and 3 feet wide, and where the soil will admit of it, from 1 foot to 18 inches deep. A small two-horse plough then turns the manure and about 3 inches of soil into the trench, and is immediately followed by a large trench plough, with 3 or 4; and, in many cases, with 8 or 10 horses, which turns a foot or more of clean soil upon the manure and scurf when the land has been recently skim-ploughed. The soil is then harrowed, and the parsnip seed, which should be new, is sown at the rate of 3 or 4 pounds to the acre. The plants, when they are an inch high, are weeded, and are thinned out to 6 inches apart, and, according to the soil, should be again thinned out to 9 inches or more at the second hoeing. In September, when the fine aftermath begins to appear, some of this crop may be taken up for milch cows; as from 12 to 25 pounds of them given at milking-time will have a surprising effect on the cream, and produce fine yellow butter, which will keep admirably, if properly salted and prepared, preserving an excellent and superior flavour.

They are taken up with a fork, or ploughed up in October or November. The average produce, per statute acre, is 9 to 11 tons. The *dry* leaves of the parsnip are given to cows. The parsnip will fatten pigs (or poultry if boiled) in an extraordinary manner, and it is certainly one of the best preparatory crops for wheat. It will keep in store until April, and it is advisable to remove the leaves before the roots are stored. The parsnip being a very hardy vegetable, the frost does not injure the seed or the young plant; and, if thought desirable, the former may be sown as soon as they are ripe in autumn. There are only 1 or 2 varieties of parsnips, of which the common species is the best for field culture. 1000 parts of the parsnip yielded Davy 90 parts of saccharine matter, and 9 parts of mucilage.

Garden Culture.—The soil in which the parsnip succeeds best is a rich, dry, sandy loam, and the deeper the better. The most inimical to it are gravel or clay. It is always beneficial

to trench the ground 2 spades deep, a little manure being turned in with the bottom spit. If the soil is suitable to them, they are not much benefited by the general application of manure at the time of sowing, but often injured in consequence of numerous fibres being induced. Dr. Macculloch says, that in the island of Guernsey, which has long been celebrated for the fineness of its parsnips, sea-weed is the manure chiefly employed. Of excrementitious manure, that of pigeons is the best. Decayed leaves are also very favourable to its growth. The situation cannot be too open.

It is propagated by seed. The usual time for sowing is from the end of February to the beginning of April, but the earlier the better. It has been recommended in field cultivation to sow them in September; in the garden, when sown at this season, they also obtain a finer flavour, but many of them in general run to seed. In the isle of Guernsey they regulate their time of sowing according to the soil; in the most favourable soils they sow in January; or if the soil is wet or stiff, they do not insert the seed until the latter end of March.

The seed is sown broadcast, rather thin, and well raked in. The compartment being laid out in beds, not more than 4 feet wide, for the convenience of weeding, &c. When the seedlings are 2 or 3 inches high, they are carefully thinned to 10 inches apart, and the weeds removed both by hand and small-hoeing. The beds require to be frequently looked over to remove all seedlings that may spring up afresh, as well as to be frequently hoed, until the plants so cover the ground as to render it impracticable. The roots may be taken up as wanted, in September, but they do not attain maturity till October, and which is intimated by the decay of the leaves. In November, part of the crop may be taken up, and the tops being cut close off, laid in alternate layers, with sand, for use in frosty weather. The remainder may be left in the ground, and taken up as required, as they are never injured by the most intense frost, but, on the contrary, rendered sweeter. In February or March, however, any remaining must be extracted, otherwise they will vegetate. Being preserved in sand, they continue good until the end of April or May.

For the production of seed, some of the finest roots are best allowed to remain where grown; or else, being raised in February, planted in a situation open, but sheltered from violent winds. Seed should never be employed that is more than a twelvemonth old, as it has generally lost its vegetative power when of a greater age.

PARSNIP, THE COW. See COW-PARSNIP.
PARSNIP, THE SEA, or PRICKLY SAMPHIRE.

PARSNIP, THE WATER. See WATER-PARSNIP.

PARTERRE (Fr.). In gardening, a system of beds of different shapes and sizes, in which flowers are cultivated, with intervening spaces of gravel or turf for walking on.

PARTURITION. See ABORTION, CALVING OF COWS, GESTATION, PREGNANCY, &c.

PASSION-FLOWER (*Passiflora*, from *passio*, passion; and *flos*, a flower; in allusion to

the filamentous appendages or rays bearing a resemblance to the cross; the emblem of the passion of Christ). The species of this interesting and elegant genus are admirably adapted for stove and green-house climbers, being of easy culture, free growers, and, if allowed plenty of room, producing abundance of beautiful flowers. Many of the kinds produce fruit freely, from which, through impregnation, several fine hybrids have been raised. The fruit of some, as *P. edulis*, *P. laurifolia*, and *P. quadrangularis*, or *granadilla*, are eaten: the succulent pulp which surrounds the seeds is found to be fragrant, cooling, and pleasant, agreeably acid, and admirably adapted for allaying thirst in hot climates.

All the species will thrive well in a mixture of loam and peat, and are easily increased by cuttings planted in sand. The hardy kinds should be planted in sheltered situations.

PASTERN OF A HORSE. The distance that intervenes between the joint of that name and the coronet of the hoof.

PASTURE (Fr.). Ground on which cattle feed. I have, under the head **GRASS**, gone at some length into the question of the grasses best adapted for different soils. The pastures of England and Ireland exceed in extent and productiveness those of any other country of similar extent. "The excellence of pastures," observes the author of *The British Husbandry*, vol. i. p. 478, "depends greatly both upon their position and the different species of animals for whose support they are intended. Thus, uplands which are elevated, open, and dry, are the best adapted for the feeding of sheep; while a heavy stock is fed with more advantage upon ground which is lower in point of situation, as well as better enclosed. The soil of uplands, particularly if it be of a chalky nature, bears a sweet, though a short bite of grass, which is so favourable to the pasturage of the smaller breeds of sheep, that although it will support but a scanty stock, it yet produces the finest species of mutton. These flocks of sheep, too, by the folding system, keep in cultivation many a poor, thin soil, which would otherwise be worthless. There is an excellent paper, by Mr. Magillivray, on the natural pastures of Scotland, in which he traces the natural grasses which are found on the highest elevations down to the valleys and sea-shore. "The bleak summits of these mountains," he remarks, "exposed to the depressing influence of a low temperature, boisterous winds, and abundant rains, covered for a great part of the year with snow, and presenting either bare rock or a shallow, gritty soil, produce few plants of any description, and hardly a dozen of those which are selected by sheep as their food. These latter consist of 3 or 4 carices or hard grasses, 1 or 2 junci or rushes, some tufts of the common club-rush, together with the *Festuca vivipara*, and 1 or 2 other grasses. The extreme heights scarcely present any other vegetation than *Silene acaulis*, *Salix herbacea*, and *Statice armeria*. Farther down the mountains, extending downwards to about 3000 feet above the level of the sea, we find a vegetation still poor and stunted, but by no means deficient in beauty, and perhaps affording better

pasturage than some of the lower grounds. We here find irregular patches of verdure, consisting chiefly of Carices and *Scirpus cæspitosos*, which, however, are also eaten by sheep; by the streamlets are several species of Alpine plants. Farther down the mountains, *Aira flexuosa* grows in tufts, and of a large size. Several carices form a tolerable sward in many places; the *Agrostis vulgaris*, &c., occasionally occurs. *Calluna vulgaris*, or common heath, first makes its appearance. As we proceed downwards, and arrive at the places where the mountains begin to expand, we enter upon a region, the predominant feature of which is the *Calluna vulgaris*, mingled with *Erica cinerea* (the gray-leaved heath); the vegetation becomes more vigorous; various grasses present themselves. The valleys of this region, in which flow the streamlets, are generally more verdant than the open ground. The heaths are less abundant, and the pasturage consists chiefly of carices and graminæ, intermingled with many of the plants of ordinary pasture ground, such as *Lotus corniculatus*, *Polygala vulgaris*, &c. The general aspect of the vegetation, however, is healthy, and continues so until we reach the vicinity of the river." For every information, however, relating to the formation of pastures, and the cultivation of the grasses, the farmer cannot consult a better authority than the *Hortus Gram. Woburnensis* of the late Mr. George Sinclair.

In feeding pastures, it is usual with those fields which are shut up from stock at Candlemas, to graze them in the succeeding May. Those which are fed until April may, after being shut up, be grazed again at Midsummer. If it is intended to feed a pasture during the winter, it should be allowed to rest in the months of October and November. See **MEADOW** and **GRASSES**.

PEA, THE (*Pisum sativum*, Fr. *pois*, Span. *pesoles*). The English is evidently a corruption of the Latin name). This valuable plant is supposed to be a native of the south of Europe, and was cultivated by the Greeks and Romans. It is said by Acton to have been brought to England in 1548. There are only one or two kinds of pea: the gray pea (*P. arvense*), and the pea cultivated as a vegetable in gardens (*P. sativum*). Of the last, however, the varieties are endless.

Of field peas, the varieties are distinguished as the early and the late ripening. The common early are small and dark-coloured. The gray pea of this class is the most common.

The later sown varieties are generally similar in their characters to garden peas; they differ, however, from them in having usually purple flowers. The most common kinds are the white, the early Charlton, and the pearl. Field peas, especially where there is a considerable demand for them, as in the neighbourhood of large towns, are a very profitable crop to be gathered green, since there is time after the peas are gathered, in the month of June, to prepare the land for a crop of turnips.

Where they are grown for their seeds, the white peas are those generally cultivated for the purpose of boiling, the gray as food for animals.

The pea will succeed pretty well on both heavy and light soils; but it certainly does best on the latter, especially if the land abounds with carbonate of lime. It is an excellent crop to interpose between corn crops, for it affords considerable facilities to the cleansing of the land, and is not otherwise an exhausting crop. In many parts of England a pea crop is dibbled on the clover and grass leys, and afterwards a corn crop is taken with great advantage. In others a crop of oats is taken, and then a crop of peas. When this latter mode is adopted, the land is commonly ploughed in the autumn, and by cross-ploughing and harrowing in the spring, brought into some degree of tilth, and then the seed may be sown with the ordinary drill. The quantity of seed employed is about 3 bushels per acre, and the rows are usually from 9 to 27 inches apart. There is every facility afforded for the use of the horse-hoe. This instrument, with the early and occasional use of the hand-hoe, will cleanse the land; to which end the crop of peas will, as they approach maturity, materially assist, by overpowering and stifling the weeds.

Peas are usually one of the most uncertain of the English farmer's crops. They are subject to many casualties—to blight or mildew; to the attacks of a variety of insects, such as the grub, which devours the roots; lice, aphides, &c., which haunt the leaves; and a small beetle, the *Bruchus granarius*, lays its eggs in the green pods, which produce a grub that devours its seeds. Then, again, it is frequently injured by the weather, in very dry, or in continued wet, or late harvests; and hence in the east of England it is often designated by the farmers as "a gentleman farmer's crop." This crop, however, is too often mismanaged in the way to which Arthur Young so well alluded, when he told the careless farmers of his day that they were "too apt to sow this pulse when the land would yield nothing else. They have a proverb among them," he adds, "which signifies that the season does as much for peas as good husbandry; and they from thence take care that good crops shall be owing to season alone. Hence arises the general idea of peas being the most uncertain crop of all others. This is owing to their being scarcely ever sown on land that is in good order. Let," he continues, "the good husbandman lay it down as a maxim, that he should sow no crop on land that is not in good order; not merely in respect of fine tilth at the time of sowing, but also of the soil being in good heart, and clear of weeds. He would not, however, here be understood to rank all these crops together; because beans and peas will admit of cleaning while they grow. On that account, if a farmer comes to a field which his predecessor has filled with weeds, a horse-hoed crop of beans will be expedient, when a barley crop would be utterly improper; and, after land has yielded one crop of barley, certainly another should not be sown, but one of pulse substituted. If these ideas are well executed, the peas and beans, in every course, will find the land in heart enough for barley, the soil will always be clean, and the crop good. Peas, when managed in a spirited manner, will not have the

reputation of being so very uncertain a crop, which character has, he thinks, in some measure been owing to ill conduct."

Peas do not need any particular dressings with manure; in fact, few crops require it so little; and in many situations manure produces the ill effect of rendering the plant too luxuriant. Von Thaer found, by several experiments, that the dung applied to the pea crop is the most profitable when used as a top-dressing. And, moreover, he contends that on sandy loams it produces in this way a much better effect in the succeeding crop. Lime and soot are, perhaps, the best dressings for peas; and these may operate to some degree by killing the insects of the soil, which might otherwise prey upon them; besides, the pea plant seems to delight in every situation where it can have access to calcareous matter. The crop is commonly cut with a hook at the end of a staff, or the half of an old scythe set in a handle. By these the peas are severed, and made up into small bundles, called wads or wisps, and these remain on the ground until they are sufficiently dry to be carried. The straw of peas is very useful for the stock of the farm-yard: cows eat it, when it has been well gathered, with considerable avidity. See HAULM.

1000 parts of peas grown in Norfolk afforded Davy 501 parts of starch, 22 of saccharine matter, 35 of albuminous matter, and 16 parts of extract. The ashes obtained by burning the pea plant in flower and when ripe were examined by M. Saussure: he found in 100 parts of these ashes, procured from the *Pisum sativum* in flower, of soluble salts 49.8 parts, of earthy phosphates 17.25, earthy carbonates 6, silica 2.3, metallic oxides 1, and loss 24.65 parts. And from the ashes of the ripe plant, soluble salts 34.25 parts, earthy phosphates 22, earthy carbonates 14, silica 11, metallic oxides 2.5, and loss 17.25 parts.

The average price of peas in England, per Winchester quarter, was in

	£	s.	d.		£	s.	d.		
1792	-	1	12	6	1805	-	2	8	4
1795	-	1	18	4	1810	-	2	15	9
1800	-	3	7	5	1815	-	1	18	10

Per Imperial Quarter.

Garden Culture of the Pea.—Of the numerous varieties, which differ much in their hardiness, yield, height, &c., we may enumerate the following:—Cormack's early dwarf-pea, early Charlton, early golden Charlton, early Nichol's golden Charlton, common Charlton, Reading hotspur, early single-blossomed, early Warwick, early dwarf frame, early double-blossomed frame, dwarf marrowfat, tall marrowfat, green or Patagonia marrowfat, early green nonpareil, Knight's marrowfat or wrinkled pea, Spanish moratto, imperial blue, Prussian blue, egg, white Rouncival, gray Rouncival, green Rouncival, blue Rouncival, tall sugar (the sugar-peas are eaten like kidney-beans), crown or rose, Leadman's dwarf, dwarf sugar, dwarf Spanish, sickle pea.

A soil moderately rich and mouldy is best suited to this vegetable; rather inclining to aluminous for the lofty growers and main crops, but for the early and late ones, light and dry; if naturally otherwise, rendered so by the admixture of drift-sand with the earth of the drills. Dwarf varieties will grow on poorer and lighter soils than the others. In an extremely rich soil they grow luxuriant but unproductive. They are rather injured than benefited by the application of un-reduced dung at the time of sowing. Road dirt and rotted leaves form the best compost for them. For the early and late crops, that is, from October until the close of January, and during June and July, the sowings must be performed in sheltered situations, as south borders. In December, the rows are best drawn parallel with and within a foot of the fence. At other seasons their site cannot be too open.

They are propagated by seed, the sowing of which commences with the year. In January they may be inserted in sheltered borders, and large supplies in an open compartment, and thence continued throughout February and until July, once every two or three weeks. During this last month, and in the first week of August, the last sowings must be made for production the same year. For the first production in the following year, a small sowing may be performed at the close of October, and repeated about the middle of November and December, though it often happens that these are scarcely a week forwarder than those inserted in the following February. The necessary extent of the various sowings may be determined with tolerable exactness from the experiments of Bradley; he found on the average that 3 rods of ground, containing 18 double rows, afforded 36 quarts of shelled peas.

The seed must be inserted in drills, or by the dibble, in rows at a distance proportionate to the height to which the variety grows, as well as according to the season.

When the plants have advanced to a height of 2 or 3 inches, they are to be hoed, the weeds cleared away, and earth drawn round the stems. This should be performed twice or three times gradually as they ascend, previous to the sticks being placed. It should be performed in dry weather, and the leaves never covered, or in wet weather they decay. For the winter standing crops it should be especially attended to, as it protects them greatly from frost. Peas are

always best supported by sticks; if it is neglected, even for the dwarf varieties, they not only produce less, but sooner decay, are inconvenient to cultivate and gather from, and never so fine. Sticking is not required until the plants are 6 inches in height, or show their tendrils. If, during the time of blossoming, or swelling of the fruit, continued drought should occur, water may be very beneficially applied, it being poured between the rows, if they are in pairs, or otherwise in a shallow trench on one side of each. Watering the leaves is rather injurious. Failures in the rows of the earliest crops, whether from mice or other causes, may be rectified by transplanting. This is best performed in March; the plants thus removed must be watered until they have taken root, and also shaded, if the weather is hot. It is a good practice to nip off the top of the leading shoots of the early and late crops as soon as they are in blossom, as it greatly accelerates the setting and maturity of the fruit. Too much care cannot be taken when the pods are gathered, not to injure the stems. I have heard it stated from lengthened experience, that if the pods are cut off with scissors, the plants produced one-fourth more than when roughly gathered from. Bradley makes nearly a similar observation. From the main crops, or where there is no necessity for precipitation on account of bringing them to table early, the pods should not be gathered until the peas have become plump and moderately firm, yet green and tender. The more regularly the plants are gathered from, the longer they continue in production, as the later pods never attain maturity if the earlier ones are allowed to grow old before they are gathered.

In very severe weather the winter standing crops require the shelter of litter or other light covering, supported as much as possible from the plants by means of branches laid between the rows. Mr. J. Laird, gardener, at Portmore, N. B., employs straw ropes or twisted bands for this purpose, which he fixes along each side of the rows with wooden pins, driven into the ground. Whichever mode of shelter is adopted, it must be always removed in mild weather, otherwise the plants will be spindled, and rendered weaker. For the imperial blue, frame, and other dwarf varieties, the sticks need not be more than 3 feet high; for the Prussian blue, hotspur, and other middle-sized varieties, about 5; for the Knight's marrowfat, and other tall ones, at least 7; and for the Patagonian, not less than 8. The best wood for this purpose is the brush, or fan-shaped branches of the hazel, &c. Before they are employed, the ends that are thrust into the ground should be charred, or moderately burnt, which effectually preserves them from decay. If this is attended to, and, when no longer required, the sticks, if thoroughly dry, on a fine day are stored in a dry shed, they will last for three or more years.

For the production of seed, leave some rows that are in production during July, or sow purposely in March. Care must be taken, however, that no two varieties are in blossom near each other at the same time, but a lapse of at least three weeks should occur, otherwise no

perfect variety can be obtained. We are much in want of observations on this point. If hot-spurs and marrowfats are sown on the same day, the latter will not bloom for nearly four weeks after the first. If the frame variety and the moratto are similarly inserted, the latter will succeed the first in about five weeks. The plants intended for seed ought never to be gathered from. When in blossom, all plants which do not appear to belong to the variety among which they are growing should be removed. They are fit for harvesting as soon as the pods become brownish and dry. When perfectly free from moisture, they should be beaten out, otherwise, if hot, showery weather occurs, they will open and shed their seed. Seed-peas preserve their power of germinating for eight or ten years.

Forcing commences in December, in the early part of which month they may be sown in a hotbed to remain, or thick, to transplant during the succeeding month into others for production. These may be repeated in January, and the transplanting take place in February. It is also a common practice to sow in a warm border during October, and the plants being cultivated as a natural ground crop, are removed into a hot-bed during January.

The temperature employed in forcing may be either progressive, beginning at 40° and 50°, for the extremes, at the time of sowing, rising to 52° and 66° when in blossom, and to 55° and 70° while the fruit is swelling; or the temperature may be uniformly kept up throughout their growth, having 50° for the minimum and 70° for their maximum.

In New York and some other of the Northern and Eastern States, the pea forms a highly valuable crop, not only for its intrinsic value, but as useful in preparing the land for the reception of wheat, and other grain, for which purpose it is considered on a par with the turnip and other root crops of England. The soil best adapted to the pea is one that is good for wheat, and where that grain is certain, peas may be considered so. The preparation of the soil demands nothing peculiar; it must only be made in good order for seed, in the manner required for other spring crops, by being well ploughed, harrowed, and if necessary, manured. If manured too highly, however, the vine or haulm is apt to be too abundant, and the pea itself inferior in quantity and quality. In this, as in most other cases, too great a growth of vine or straw is incompatible with great crops of pulse or grain. Lime in all countries has been found an essential ingredient of pea or wheat soils; and where it does not naturally exist in them, should be applied previous to attempting the culture of these crops.

The kinds of pea most usually cultivated as a field-crop, are the small yellow pea and the marrowfat. We prefer the latter; as it is equally certain with the other, is excellent for the table as well as for feeding, is as nutritious for animals, and generally more productive. In some situations, or in exhausted soils, the small yellow pea may however be preferable. From 30 to 40 bushels per acre is not an uncommon crop, and this highest amount is often

exceeded. The quantity of seed required per acre may be stated at 2½ bushels, although some use only 2, and some put on 3 bushels per acre. For covering the pea the cultivator is a very good implement, as it gives them more earth than the harrow and less than the common plough. The ground should be left smooth by the roller or otherwise, as the ease of gathering is greatly depending on the state of the surface.

In harvesting the pea, some farmers hook them up with a scythe, some rake them by hand with the common hay-rake, but the most expeditious method by far, is to use the horse-rake in gathering this crop. In whatever way peas are gathered, it is necessary they should be ripe, and of course, if very dry at the time, there will be some loss by shelling, but not perhaps more by the horse-rake than by the other methods, and four-fifths of the time required by the two first methods is saved. This, where the land is to be put into wheat, is frequently of great consequence. Once gathered, there is no crop so easily thrashed and prepared for market as the pea, and few that better reward the cultivator.

There is no plant cultivated which will bring pigs forward more rapidly than the pea, if the feeding is commenced as soon as the peas begin to harden, and the whole plant is fed out to them. When gathered and hard, two methods of feeding have been adopted, both of which are far preferable to the barbarous practice of giving swine the pea without any preparation. The first is to soak and swell the pea in milk, if it can be had, if not, in water, and feed it to them in that state. The second is to grind the pea, either alone or with other coarse grain and feed it to animals in that way. This is preferable to feeding whole, as in corn or any other food, the finer it is made the more readily it will be assimilated, and in all cases, if cooked into pudding the advantage will be decisive. In England, where corn cannot be grown, a mixture of peas and barley is considered superior to any other food for making pork; here, closing the process of fattening with Indian corn, as giving more firmness to the pork, is preferred.

In the Southern States, a kind of pea, called there the *Cow Pea*, is cultivated for the purpose of making into hay, and for being ploughed under as a fallow crop, like clover.

PEA-BUG or BEETLE. In the spring of the year we often find, among seed-peas, many that have holes in them; and, if the peas have not been exposed to the light and air, we see a little insect peeping out of each of these holes, and waiting apparently for an opportunity to come forth and make its escape. If we turn out the creature from its cell, we perceive it to be a small oval beetle, rather more than one-tenth of an inch long, of a rusty black colour, with a white spot on the hinder part of the thorax, 4 or 5 white dots behind the middle of each wing-cover, and a white spot, shaped like the letter T, on the exposed extremity of the body. This little insect is the *Bruchus Pisi* of Linnæus, the pea-*Bruchus*, or pea-weevil better known in America by the incorrect name of pea-bug. The original meaning of

the word *Bruchus* is a devourer, and the insects to which it is applied well deserve this name, for, in the larva state, they devour the interior of seeds, often leaving but little more than the hull untouched. They belong to a family of the great weevil tribe called *Bruchidæ*, and are distinguished from other weevils by the following characters. The body is oval, and slightly convex; the head is bent downwards, so that the broad muzzle, when the insects are not eating, rests upon the breast.

The habits of the Bruchians and their larvæ are similar to those of the pea-weevil, which remain to be described. It may be well, however, to state here that these beetles frequent the leguminous or pod-bearing plants, such as the pea, *Gleditsia*, *Robinia*, *Mimosa*, *Cassia*, &c., during and immediately after the flowering season; they pierce the tender pods of these plants, and commonly lay only one egg in each seed, the pulp of which suffices for the food of the little maggot-like grub hatched therein.

Few persons, while indulging in the luxury of early green peas, are aware how many insects they unconsciously swallow. When the pods are carefully examined, small, discoloured spots may be seen within them, each one corresponding to a similar spot on the opposite pea. If this spot in the pea be opened, a minute whitish grub, destitute of feet, will be found therein. It is the weevil in its larva form, which lives upon the marrow of the pea, and arrives at its full size by the time that the pea becomes dry. This larva or grub then bores a round hole from the hollow in the centre of the pea quite to the hull, but leaves the latter and generally the germ of the future sprout untouched. Hence, these buggy peas, as they are called by seedsmen and gardeners, will frequently sprout and grow when planted. The grub is changed to a pupa within its hole in the pea in the autumn, and before the spring casts its skin again, becomes a beetle, and gnaws a hole through the thin hull in order to make its escape into the air, which frequently does not happen before the peas are planted for an early crop. After the pea-vines have flowered, and while the pods are young and tender, and the peas within them are just beginning to swell, the beetles gather upon them, pierce the pods, and deposit their tiny eggs in the punctures. This is done only during the night, or in cloudy weather. Each egg is always placed opposite to a pea; the grubs, as soon as they are hatched, penetrate the pod and bury themselves in the peas; and the holes through which they pass are so fine as hardly to be perceived, and are soon closed. Sometimes every pea in a pod will be found to contain a weevil-grub; and so great has been the injury to the crop in some parts of the country, that the inhabitants have been obliged to give up the cultivation of this vegetable. These insects, as Mr. Deane has observed, diminish the weight of the peas in which they lodge nearly one-half, and their leavings are fit only for the food of swine. This occasions a great loss, where peas are raised for feeding stock or for family use, as they are in many places. Those persons who eat whole peas in the winter after they are raised, run the risk of eating the weevils also;

but if the peas are kept till they are a year old, the insects will entirely leave them.

The pea-weevil is supposed to be a native of the United States. It seems to have been first noticed in Pennsylvania, many years ago; and has gradually spread from thence to New Jersey, New York, Connecticut, Rhode Island, and Massachusetts. It is yet rare in New Hampshire, and I believe has not appeared in the eastern parts of Maine. It is unknown in the north of Europe, as we learn from the interesting account given of it by Kalm, the Swedish traveller, who tells us of the fear with which he was filled, on finding some of these weevils in a parcel of peas which he had carried home from America, having in view the whole damage which his beloved country would have suffered, if only two or three of these noxious insects had escaped him. They are now common in the south of Europe and in England, whither they may have been carried from this country. As the cultivated pea was not originally a native of America, it would be interesting to ascertain what plants the pea-weevil formerly inhabited. That it should have preferred the prolific exotic pea to any of our indigenous and less productive pulse, is not a matter of surprise, analogous facts being of common occurrence; but that for so many years a rational method for checking its ravages should not have been practised, is somewhat remarkable. An exceedingly simple one is recommended by Deane, but to be successful it should be universally adopted. It consists merely in keeping seed-peas in tight vessels over one year before planting them. Latreille and others recommend putting them, just before they are to be planted, into hot water for a minute or two, by which means the weevils will be killed, and the sprouting of the peas will be quickened. The insect is limited to a certain period for depositing its eggs; late sown peas therefore escape its attack. The late Colonel Pickering observed that those sown in Pennsylvania as late as the 20th of May, were entirely free from weevils; and Colonel Worthington, of Rensselaer county, New York, who sowed his peas on the 10th of June, 6 years in succession, never found an insect in them during that period. (*Harris.*)

PEA, COW. The plant called by this common name in lower Virginia and the Carolinas, is there extensively cultivated. In some parts of Virginia it is called the Yeatman pea, from the person by whom it was introduced from the Eastern Shore. The pea is of a yellowish colour, is very productive both in vine and seed, unusually hardy in remaining uninjured by rain, after becoming ripe, and for table use is much esteemed. But it is chiefly cultivated, in common with several varieties of Indian peas, in fields, to plough under for the benefit of successive crops, as a substitute for clover, buckwheat, and other plants not so well adapted to southern culture. The vines of this and the varieties of the Indian pea, all make excellent long forage for common work-horses, oxen, milch-cows, or sheep. The curing of the vine is sometimes difficult, as it requires a longer time than most other forage plants. Some stack it away with layers of dry straw,

as is practised in the moist climate of England with clover.

PEA, EVERLASTING. See EVERLASTING PEA and LATHYRUS.

PEAS and OATS. These, in the Eastern and Northern States, are often sown together broad-cast, producing a mixed crop called *Meslin*. The common proportions are one-fourth of peas to three-fourths of oats. The pea commonly sown is the green pea from Canada, which ripens about the time of the oats, and for which, while growing, the oats act as supporters. Peas and oats are usually ground together as feed for their fattening cattle, and are deemed valuable, though not so good or so much relished as Indian meal without mixture. Forty bushels of peas and oats per acre would be regarded a large crop. This has been produced, however, on nine acres, in Deerfield meadows. Some farmers sow at the rate of one-third peas and two-thirds oats.

PEA, PARTRIDGE. The *Cassia Chamæcrista* of Beck; a native of the Middle and Southern States, where it goes by the common names of Sensitive pea and Magothybay bean. The stem is 1 to 2 feet high, rather erect, firm, and much branched, downy, and often purplish. Leaflets 8, 10, or 12 pairs, $\frac{1}{2}$ to $\frac{3}{4}$ inch in length and 2 to 3 lines wide. Petals of the flowers, deep bright-yellow, obovate, 2 or 3 of them with a purple spot at base. Stamens 10, unequal, all fertile; anthers very long, 4 of them yellowish and 6 purple. Legume about 2 inches long and $\frac{1}{2}$ to $\frac{3}{4}$ of an inch wide, with a short, abrupt, oblique acumination, hairy along the sutures. See WILD SENSITIVE PLANT.

PEACH (Fr. *pêche*; Lat. *Amygdalus*, derived from *amysso*, to lacerate, in allusion to the fissured shell). The tall and coarse portion of the ornamental, early flowering plants, of which the peach forms a species, may be advantageously disposed of in large plantations, and the dwarf kinds in small shrubberies at the front of the large ones. In England the common way of increasing them is by budding on the plum stock or the bitter almond. Rich mould is a proper medium for them. They are most valued for producing their showy pink blossoms early in the season, sooner than almost any other shrubs. The peach is now one of the most esteemed fruits: nearly 200 varieties are enumerated in the *London Horticultural Society's Catalogue*.

Although the peach is raised in the open air, in every part of the United States, it succeeds best in the states of New Jersey, Delaware, Maryland, Virginia, and some of the Western States in similar latitudes. The flavour of the peaches of the United States is far superior to that of the same kind of fruit in Europe. In the vicinity of the large cities, or where facilities of quick transportation to these are furnished, the culture of the peach is a source of great profit.

Mr. Thomas Hancock, a very intelligent nurseryman, near Burlington, New Jersey, gives the following description of the mode practised by him in planting and managing peach orchards. "When it is intended to plant out a good orchard of trees, we generally select an elevated position, entirely unprotected by any timber

or shelter of any kind; if a situation can be selected near the bank of a river, the crop is more certain, as the trees better withstand the frosts, which occasionally do much damage.

"Plough, and put the land in good condition for corn or vegetables, and plant the trees 20 feet apart each way; continue to till the land, taking off a crop of peas, beans, potatoes, or something that does not grow *too high*: wheat, rye, and oats are very injurious, and should *not* be planted. The land must not remain without tillage, as the trees would soon be injured: indeed, nothing will destroy a fine peach orchard sooner than to let it lie in sward.

"The trees should be 2 years old on the stock *from seed*, and 1 year from the *bud*, *the year after budding*. This is considered as the best age for transplanting. If the water stands near the surface of the soil, or if the land has springs near the top of the ground, I should not deem it advisable to plant with the expectation of very certain crops. I have lost two orchards planted in this manner, while in an adjoining field, where the land, or a part of it, was high, with a dry subsoil, the trees flourished and produced abundant crops.

"Light sandy soil, or light loam, we consider the most preferable for planting out peach orchards, and I should judge that on many of the elevated knolls, in the vicinity of Boston, the peach might be cultivated to good advantage, particularly the earlier varieties. It is at least well worthy of trial." (*Orchardist's Companion*.)

The peach crop is, however, limited in a great degree by the destruction of the trees effected by a worm which attacks the inner bark of the root about the crown, and by a disease of uncertain origin, generally termed the yellows. In some parts of the country where the peach was formerly very extensively raised, the culture has been abandoned in consequence of the destruction of the trees from these two causes. Mr. Samuel Reeve, of Salem, New Jersey, very advantageously known as a nurseryman, says that the attacks of the peach-worm may be obviated or the insect destroyed by frequently examining the root at the surface of the ground while the tree is in a state of vegetation, removing the insects, as far as possible, and then washing the tree at the earth's surface with strong soap-suds, every week or two. Rubbing the trunk and main branches with soap-suds several times a year, is also highly conducive to keeping the tree in a healthy state. The ground should be kept loose around the peach tree. (*Orchardist's Companion*.)

The application of a mixture of common salt and saltpetre has been recommended by a gentleman in Maryland, as successful in preserving peach trees against the attacks of worms. The proportions are, 1 part of saltpetre to 8 parts of common salt. Half a pound of this mixture to a tree of 7 years old and upwards, is to be strewed upon the surface of the ground around and in immediate contact with the trunk of the tree. The mixture is also recommended to be sown over the orchard in the proportion of 2 bushels to the acre. By this means, it is said, the fruit is improved!

in size and flavour, the worms destroyed, and the yellows prevented.

The Yellows. The immediate cause of this fatal disease with which the peach tree is so often attacked, is still a matter involved in great obscurity. The following observations, by Mr. Robert Sinclair, of Clairmont Nursery, near Baltimore, Maryland, contains the views of a person of great intelligence and experience, in regard to the disease in question.

As I have, for about 30 years, occasionally had my attention drawn to this subject, I am willing, says Mr. Sinclair, to throw in my mite of experience. I am fully satisfied that the complaint exists. Some persons say that the worm at the root is the cause of the yellows. I acknowledge that any disorder that destroys the trees will cause the leaves to turn yellow; but the complaint I call the yellows will kill a whole orchard, without any visible wounds, on or before the third or fourth full crop. I think where any neighbourhood abounds with peach orchards, it will be nearly impossible to keep clear of the disease.

On planting out young peach trees on the site of a peach nursery, two years after the nursery was removed, and although the ground was in other respects well suited for the growth of the peach tree, yet by the next autumn many of them were dead, and the balance so sickly that I had them all dug up, and there was no sign of the worm at their roots. From this, and other similar experiments, I think the disease may be generated by planting too near where a nursery or orchard of peach trees has been, or where the latter is; consequently, where a neighbourhood abounds with peach trees, there is danger of its becoming over-spread with disease, without greater care than is usually taken to prevent it.

I think I have seen evidences of its being in some degree contagious. Richard Cromwell, the respectable and worthy peach raiser, near Baltimore, has for upwards of 30 years supplied that city with peaches of the best quality, on a large scale. Some time since, when I was walking with Mr. Cromwell through his peach orchard, when the trees were hanging full of ripe fruit: he pointed out a tree that he said had the yellows, having a full crop upon it, at that time worth one dollar per peck, and to me it appeared healthy; but he observed to me, "as soon as I take the fruit from the tree, I shall dig it up, in order to prevent the disease spreading any farther, for I expect the side of the adjoining trees next to it will be affected next season." I had occasion to pass through Mr. Cromwell's orchard the next fruiting time, and the sickly tree had been dug up, but, as had been predicted, parts of the four neighbouring trees were evidently much affected, but only the sides next to the diseased tree, which made it the more striking, and convincing of the contagion, if this is a proper term.

On another occasion, I had a favourite early purple peach, before I had a nursery, that I suspected was partially affected by the yellows, and being desirous of preserving the variety, I cut the healthiest branch I could get, and I had 12 buds inserted in healthy peach stocks; but when they had grown about 3 feet, they showed

the disease so plainly, that in order to prevent it from spreading, I pulled up all the trees and had them burnt.

From these cases, it seems to me the disease may be generated by planting old peach orchards or nurseries too soon after the removal of the old trees, and also by planting too near those already affected with the disease; and if cuttings or scions are taken from diseased trees, their product will be also diseased. I also think the yellows may be communicated to young trees by planting seeds taken from diseased peach trees. (*Hovey's Magazine of Horticulture.*)

Drying Peaches. Several modes of effecting this are pursued. When done in-doors, furnaces should be placed in the cellar from which the heated air may rise into the building suitably provided with shelves, &c.

In some of the Southern States, says Mr. Kenrick, the process is facilitated by a previous scalding. This is effected by immersing baskets of the fruit a few minutes in kettles of boiling water. They are afterwards halved, the stone separated, and being laid with the skins downwards, the drying is effected in the sun in three days of good weather. They then may be stored in boxes.

In France, as we are informed, peaches and other fruits are thus dried whole. The peaches or other fruits, being pared, are boiled for a few minutes in a syrup consisting of 1 pound of sugar dissolved in 3 quarts of water, and after being drained by being laid singly on board dishes, they are placed in the oven after the bread is taken out, and when sufficiently dry they are packed in boxes. The following is the mode of drying practised by Mr. Thomas Bellangee, of Egg Harbour, New Jersey. He has a small house provided with a stove, and drawers in the sides of the house lathed at their bottoms, with void intervals. The peaches should be ripe, and cut in two, not peeled, and laid in a single layer on the laths, with their skins downward, to save the juice. On shoving in the drawer, they are soon dried by the hot air produced by the stove. In this way great quantities may successively, in a single season, be prepared, with a very little expense in the preparation of the building, and in fuel.

PEACH TREE BORER. Pl. 16, fig. 8. The following interesting description of the peach tree worm, with a mode of protecting against its ravages, is from Dr. Harris's *Treatise on Destructive Insects.*

The pernicious borer, which, during many years past, has proved very destructive to peach trees throughout the United States, is a species of *Aegeria*, named *exitiosa*, or the destructive, by Mr. Say, who first scientifically described it in the third volume of the *Journal of the Academy of Natural Sciences of Philadelphia*, and subsequently gave a representation and account of it in his *American Entomology*. In the fifth volume of the *New England Farmer*, I have given the history of this insect, have mentioned the principal authors who have noticed it, and recommended preventive measures, which have been found effectual in protecting the peach tree from its most serious attacks. The eggs, from which

these borers are hatched, are deposited, in the course of the summer, upon the trunk of the tree near the root; the borers penetrate the bark, and devour the inner bark and sap-wood. The seat of their operations is known by the castings and gum which issue from the holes in the tree. When these borers are nearly one year old, they make their cocoons either under the bark of the trunk or of the root, or in the earth and gum contiguous to the base of the trees; soon afterwards they are transformed to chrysalids, and finally come forth in the winged state, and lay the eggs for another generation of borers. The last transformation takes place from June to October, most frequently, however, during the month of July, in the state of Massachusetts. Here, although there are several broods produced by a succession of hatches, there is but one rotation of metamorphoses consummated within a year. Hence borers, of all sizes, will be found in the trees throughout the year, although it seems to be necessary that all of them, whether more or less advanced, should pass through one winter before they appear in the winged state. Under its last form, this insect is a slender, dark-blue, four-winged moth, having a slight resemblance to a wasp or ichneumon-fly, to which it is sometimes likened. The two sexes differ greatly from each other, so much so as to have caused them to be mistaken for two distinct species. The male, which is much smaller than the female, has all the wings transparent, but bordered and veined with steel-blue, which is the general colour of the body in both sexes; the palpi or feelers, the edges of the collar, of the shoulder-covers, of the rings of the abdomen, and of the brush on the tail, are pale yellow, and there are two rings of the same yellow colour on the shins. It expands about 1 inch. The fore-wings of the female are blue, and opaque, the hind-wings transparent, and bordered and veined like those of the male, and the middle of the abdomen is encircled by a broad orange-coloured belt. It expands $1\frac{1}{2}$ inch or more. This insect does not confine its attacks to the peach tree. I have repeatedly obtained both sexes from borers inhabiting the excrescences which are found on the trunks and limbs of the cherry tree; and moreover, I have frequently taken them in connection on the trunks of cherry and of peach trees. They sometimes deposit their eggs in the crotches of the branches of the peach tree, where the borers will subsequently be found; but the injury, sustained by their operations in such parts, bears no comparison to that resulting from their attacks at the base of the tree, which they too often completely girdle, and thus cause its premature decay and death. The following plan, which was recommended by me in the year 1826, and has been tried with complete success by several persons in this vicinity, will effectually protect the neck, or most vital part of the tree, from injury. Remove the earth around the base of the tree, crush and destroy the cocoons and borers which may be found in it, and under the bark, cover the wounded parts with the common clay composition, and surround the trunk with a strip of sheathing paper 8 or 9 inches wide, which should extend 2

inches below the level of the soil, and be secured with strings of matting above. Fresh mortar should then be placed around the root, so as to confine the paper and prevent access beneath it, and the remaining cavity may be filled with new or unexhausted loam. This operation should be performed in the spring or during the month of June. In the winter the strings may be removed, and in the following spring the trees should again be examined for any borers that may have escaped search before, and the protecting applications should be renewed.

PEACOCK (*Pavo cristatus*.) The peacock need scarcely be mentioned as a bird of economical use. Pea-hens and pea-chickens, indeed, are occasionally used for food, but this splendid creature is, and ought to be, regarded solely as an object of beauty. The advantages to be derived from rearing it for food are not to be thought of. See FOWL, THE PEA.

PEARL-WORT (*Sagina*; from *sagina*, fatness; in allusion to its presumed nourishing qualities for sheep). These are hardy annual weeds, growing in any soil. There are in England three indigenous species.

PEAR TREE (*Pyrus*, from *piren*, the Celtic word for pear). Like other species of cultivated fruits, there are now a very great number of varieties, more than 600 being enumerated in the Horticultural Society's catalogue. A deep, rich loam is necessary for pear trees. They are increased by seeds, or by budding and grafting, which is the more common method, upon stocks of their own kind, or upon the quince. The established kinds are multiplied by grafting the choicer on the common kinds. Almost the same treatment is required in pruning and training the pear as the apple. When we reflect on the labours of the horticulturists, who have by cultivation made the pear tree forget its natural thorns, and instead of an acerb berry, produce us a fruit so fair and nectareous, we find our warmest gratitude an insufficient return.

The wild pear tree (*P. communis*) is a tall, handsome tree, growing in woods and hedges, with thorny branches, and simple, ovate, serrated leaves; downy beneath, and fringed with soft, white hairs. The flowers are copious, terminal, in corymbs, snow-white, with pink anthers. Fruit obovate, generally hard and austere, but liable, even in a wild state, to many varieties, and sometimes eatable. The wood is light, of a fine grain, and tolerably hard. It is used by turners to make joiner's tools and picture-frames to be dyed black, and is also frequently stained and substituted for ebony. The white wild pear tree (*P. aria*), we have already noticed under the head **BEAM TREE**. The expressed juice of the pear, when fermented in the manner of cider, constitutes the well-known beverage, *perry*.

Grafting and Inoculating.—In Europe it is very common to set the pear on a quince stock for clayey and light soils, whilst for trees intended for sandy and calcareous soils, the free stock pear is preferred. Grafted on the white thorn (which, like the quince, renders them dwarfish), pears come very early into bearing, continue prolific, and, in respect to soil, will thrive

well on a strong clay, which is considered unsuitable to those on quinces and wildings. But they are supposed to have an unfavourable influence upon the fruit, in rendering it small and hard. The following observations relating to the pear tree, its fruit, diseases, and insect enemies, are from the *New American Orchardist*, by Mr. Kenrick, whose list of fruits is valuable.

By grafting or inoculating on the quince, pear trees come much sooner into bearing, their productiveness is increased, the good quality of the fruit is not changed, but the size and longevity of the tree are diminished. Such pear trees are termed *dwarfs*. This mode is extensively adopted in France; but all kinds of pears will not grow on the quince stock. Those dwarfs trained in the form of a distaff, are called in that country *Quenouilles*.

The pear tree is of an extreme hardihood, exceeding that of the quince, and is seldom annoyed by the borer. The quince, when exposed, is liable to danger from the borer in the same degree as the apple tree. Their attacks always commence in the parts exposed above ground, or at the surface of the earth, and never beneath. In transplanting the pears, therefore, the quince stock must always be completely buried more than an inch beneath the soil. Thus situated and protected, the quince stock, from its nature, will strike root suddenly, new and numerous roots being produced on all sides, quite to the junction of the pear. Such is the mode adopted in practice by S. G. Perkins, Esq., and by other experienced cultivators, for the complete protection of the quince stock from all dangers of every kind.

Soil and Distance.—The pear flourishes in rich soils and gentle declivities; they will succeed in the most common, deep, dry soil, and throw out numerous lateral shoots. But they do not flourish in moist situations; in a cold, strong, moist soil, with a clayey subsoil, they throw out very few lateral roots, the fruit is not so fair, or of so good a quality, and the trees are not so long-lived. They will even grow in poor soils, and in the clefts of rocks.

With respect to distance, the same observations to be found under the head of *APPLE* may here apply. But the pear, from its pyramidal form, requires much less space. 20 feet, in suitable soils, is a good distance; but less answers in poorer soils. *Quenouilles* are found to answer even at 4 or 5 feet distance, producing large crops; and, as they occupy but little space, and come suddenly into bearing, they are, for profit, extensively cultivated in France. The specimen pear trees at the Jardin du Roi, or Garden of Plants at Paris, in the autumn of 1840, were under the particular care and management of Mons. Dalbret, the pupil of Thouin, and himself the author of a most valuable work on pruning. These trees were kept in the most perfect *Quenouille* or pyramidal form, from the summit quite down to the ground, by the system of short or spur pruning; and although at the distance of but about 7 feet asunder, yet they appeared to have ample space, and bore most abundant crops. But M. Dalbret then stated that 10 feet was the most suitable distance. In the climate

of the United States, and with more heat and sunshine, and finer skies, less distance might suffice. Pears produced on quince stocks are found to be much improved in flavour; but all some particular winter kinds, which are said in some cases to become worse.

The young, luxuriant shoots of the pear tree, by being bent downwards, generally produced the finest possible bearing wood for the second year; and, by grafting on the quince, and bending the branches, fruit may be produced from a seedling pear in the third or fourth year from the seed, which, in the common course, would require from 7 to 14 years. That system of rendering trees productive is fully described in Mr. Kenrick's *Orchardist*. He believes it to be the best system of all others.

As to standards, very little other pruning is necessary, except taking out those few limbs that interfere in keeping the tree well balanced.

The *blight*, or, as it is sometimes called, *fire-blight*, is a malady which sometimes affects the pear tree during the months of June and July, causing the tree, or a portion of its branches, suddenly to turn black, with a mortal affection; its leaves wither at once, as by a stroke of the sun, and in a few hours become of a brown or black colour. Mr. Lowell is of opinion that this disease is caused by an insect called the *Scolytus pyri*. He observes, "On the first appearance of this disease, I instantly sawed off all the limbs affected, and proceeded to examine them. I found at last the enemy, not at the point where death ensued, but some inches below it. The insect was very small, and apparently incapable of such extensive mischief; but the effect was certain, and the manner of producing that effect was obvious. It had eaten a complete circle of the alburnum, or sap-wood, not exceeding the size of a knitting-needle, so as completely to intercept the passage of the sap." This insect was shown by Mr. Lowell to the late Professor Peck, and in the account of the insect which was soon after published in the *Massachusetts Agricultural Repository*, the professor observed, that the mischievous effects of this insect may be observed in June and July, and that the dead part of the branches should be cut off without delay and burned. Mr. Lowell has stated (*New England Farmer*, vol. v. p. 2), that by steadily pursuing the system of cutting off the limbs many inches below the apparent injury, and burning them, the insects have been extirpated from his estate.

The account of Professor Peck was republished in the *New England Farmer*, vol. ii. p. 42. Some writers have attributed this disease to a stroke of the sun; others attribute it to manuring too high; some to excessive moisture at the roots, and too much pruning, which is supposed to cause a surfeit and produce a stagnation. But all agree that the only remedy is to saw off the limb. (*Kenrick's Am. Orchardist*.)

Some years ago, it was ascertained that a species of *Aegeria* inhabited the pear tree in the State of Massachusetts, and it is said that considerable injury has resulted from it. An infested tree may be known by the castings thrown out of the small perforations made by the borers

which live under the bark of the trunk, and subsist chiefly upon the inner bark. They make their cocoons under the bark, and change to chrysalids in the latter part of the summer. The winged insects appear in the autumn, having, like others of this kind, left their chrysalis skins projecting from the orifice of the holes which they had previously made. In its winged form, this *Ægeria* is very much like that which inhabits the currant-bush; but it is a smaller species. It was described by Dr. Harris in the year 1830, under the name of *Ægeria pyri*, the pear tree *Ægeria*; and his account of it will be found on the second page of the ninth volume of the *New England Farmer*. Its wings expand rather more than half an inch; are transparent, but veined, bordered, and fringed with purplish black, and across the tips of the fore-wings is a broad, dark band, glossed with coppery tints; the prevailing colour of the upper side of the body is purple-black; but most of the under-side is golden-yellow, as are the edges of the collar, of the shoulder-covers, and of the fan-shaped brush on the tail; and there is a broad yellow band across the middle of the abdomen, preceded by two narrow bands of the same colour. (*Harris*.)

Drying Pears.--When dried in ovens, the fruit will keep for years. This mode of preserving is common in France. Bosc has described two modes of drying pears, and adds, that, in some of the cantons of that country, the cultivators annually preserve, by these means, supplies of subsistence extremely agreeable and wholesome during winter and spring. He invites cultivators not to neglect this resource. In this mode of drying, those varieties of middle size, melting and sweet, are preferred. After the bread is drawn from the oven, they are placed on the swept hearth, or on hurdles or boards. This operation is repeated a second, a third, and even a fourth time, according to their size and the degree of heat. The heat must not be so great as to scorch, and the fruit must not be dried to hardness. Lastly, they are placed in bags, and preserved in a dry place. The second mode of preserving is practised chiefly on the Rousselets and finest-flavoured varieties. Bosc states that he has tried them after three years' preservation, and found them still good; but they are better during the first year. They are gathered a little before their maturity, and after being half-boiled in a small quantity of water, they are peeled and drained. They are next carried on hurdles to the oven, after the bread is drawn, or the oven is heated to a suitable degree; here they remain twelve hours; after which they are steeped in the syrup, to which have been added sugar, cinnamon, cloves, and brandy. They are again returned to the oven, which is now heated to a less degree than at first. This operation is thrice repeated, until they are sufficiently dried, or of a clear brown colour, and firm, transparent flesh; and finally they are packed in boxes lined with paper. (*Kenrick's Orchardist*.)

PEAT. A collection of vegetable remains, commonly collected together in considerable masses, either on the surface of the earth, or in strata, at various depths. Owing to the

changes which the plants composing it have undergone, it contains much tannic acid, which preserves the vegetable matter from further decomposition. It contains elements for the formation of the richest manure when substances are added to it to decompose the tannic acid, and hasten the decomposition of the vegetable matters, such as lime or marl. Peat has been found, when used alone as manure, not to possess any fertilizing qualities, as might be expected from its nature; but it has been advantageously employed as a mixture with compost. See FARM-YARD MANURE.

It often happens that in extensive agricultural districts at a distance from cities and other places from which they might obtain supplies of animal manures, the domestic resources of the farm-yards are entirely inadequate to preserve the fertility of the extensive fields. It becomes a question of deep interest whether it be possible to enrich barren fields without the aid of animals and the resources of the farm-yard. Under the head of FARM-YARD MANURES it will be seen that by Lord Meadowbank, Mr. Dickson, and other English agriculturists of high reputation, one load of dung has, by judicious mixture with peat and other matters, been made into six loads of manure, possessing equal fertilizing power.

The regular peat formation of geologists, so extensive in Britain, can hardly be said to exist in the United States. But a substance is found in abundance in bogs and marshes throughout the Union, sufficiently analogous in composition to answer most, if not all, the valuable purposes of European peat.

Dr. Samuel L. Dana, of Lowell, Massachusetts, has published a work of the highest interest to agriculturists, under the title of *A Muck Manual for Farmers*. After treating of the various matters relating to soil, its elements, and the agencies brought to act upon it, he introduces, under the head of Artificial Manures, chiefly consisting of *geine*, the subject of swamp-muck, mud, or peat.

Peat, he states, is the result of a spontaneous change in vegetable matter, which ends in the production of *geine*, a term which he applies to designate humus and humic acid. Among manures, consisting chiefly of *geine*, peat, he says, is what bone-dust is among manures, consisting of animal matter. Peat is highly concentrated vegetable food. Under the general name of peat, Dr. Dana comprises several varieties, distinguished as, 1st. Peat, the compact substance generally known and used as fuel, under this name. 2d. Turf, or swamp muck, by which is to be understood the paring removed before the peat is dug. It is a less compact variety of peat, common in all meadow swamps, and includes the hassocks or tussacks. It includes also the mud of salt marshes. 3d. Pond mud, the slushy material found at the bottom of ponds when dry, or in low grounds, the wash of higher lands. This seldom contains more than 20 per cent. of *geine*. These varieties comprise probably a fair sample of all the peat, and swamp muck, and pond mud, which occur in the various parts of the country. Dr. Dana has given analyses of 12 specimens representing the different va

ricities, the average of the 10 best being per 100 parts, dried at a temperature of 300° Fahrenheit,—by which process it loses 73 to 97 per cent. of water:—soluble geine, 29·46; insoluble geine, 55·03; total geine, 85·39; salts and silicates, 15·59. The poorest varieties of pond mud gave only 5 to 8 per cent. soluble geine, 6 to 9 per cent. insoluble geine, or about 14 per cent. total of geine, and 85 of salts and silicates.

When fresh-dug peat, of average quality, is analyzed in its wet state, it is found to contain:—

Water	-	-	-	-	-	85·
Salts of lime	-	-	-	-	-	·50
Silicates	-	-	-	-	-	·50
Geine	-	-	-	-	-	14·
						100·

It is an interesting fact that this result differs very little from the result of the analyses of fresh cow dung, so far as the proportions of geine, water, and salts are concerned.

When allowed to drain as dry as it will, pond-mud still contains about two-thirds of its weight of water. It shrinks from two-thirds to three-fourths of its bulk, a cubic yard wet becoming one-fourth to one-third of a yard when dry.

A cord of pond mud weighs, when dug, 6117 lbs., and contains solid matter, 3495 lbs.; composed of geine, 495 lbs.; of silicates and salts, 3005 lbs.

The salts and geine of a cord of peat are equal to the manure of one cow for three months. It is certainly a very curious coincidence of results, that nature herself should have prepared a substance, whose agricultural value approaches so near cow dung, the type of manures. The power of producing alkaline action on the insoluble geine, is alone wanted to make peat good cow dung.

The great question comes, how is to be given to peat, a substance which in all other respects is so nearly allied to cow dung, that lacking element, ammonia, without which cow dung would be no better than peat, nay, not so good, since in peat nearly one-half of the geine or humus is already in a soluble state. It is well understood that the various matters used as manure, either solid or liquid, from whatever source derived, all possess a common property of generating ammonia. Peat in its ordinary state contains traces of ammonia, which is evolved freely on the addition of caustic potash or common ashes. Peat, then, is a source of nitrogen, since this with hydrogen constitutes ammonia. Without going into all the nice chemical reasoning of which Dr. Dana avails himself, we will simply state his main conclusion, namely: that by the addition of alkali to peat, it is put into the state which ammonia gives to dung.

With regard to the quantity of alkali required to be added to swamp-muck or peat, in order to bring it to an equality with cow dung, "It is found," says Dr. Dana, "that

52 parts of ammonia are equal to
58 parts of soda, or white ash, or to
72 parts of 1st quality pot or pearlash, or
86 parts of 2d quality pot or pearlash.

For all agricultural purposes, it may be considered, that salts of hartshorn, or carbonate of ammonia, and white or soda ash, are equal, pound for pound, and that pots and pearls may be taken at one-half more.

"If all the nitrogen in dung becomes ammonia, then each 100 lbs. affords 2 lbs. 2 oz. Hence, if to 100 lbs. fresh-dug peat, there are added 2 lbs. of soda ash, or 3 lbs. of pot or pearl ashes, all the good effects of real cow dung will be produced. Peat or muck thus requires 2 per cent. of soda ash, or 3 per cent. of potash.

"A cord of green peat weighs 9216 lbs.; 2 per cent. is 184 lbs. Hence, a cord requires that amount of soda ash, or 276 lbs. of potash. But if the peat is quite dry, so as to have lost $\frac{3}{4}$ of its bulk, then 736 lbs. of soda ash, or 1104 lbs. potash will be necessary. Two per cent. of alkali seems enormous. It is stated, in the hope that it may lead to experiments on the free use of alkali. But as it will be hereafter shown, that this is to be reduced by mixing with loam or other matter, this quantity, even if applied to one acre, will probably produce very good effects.

"There are other practical facts, which may help to a solution of the question, how much alkali is to be added to a cord of peat. According to the experience of Mr. Phinney, of Lexington, an authority which may not be questioned, a cord of green dung converts twice its bulk of peat into a manure of equal value to itself—that is, a cord of clear stable dung, composted with two of peat, forms a manure of equal value to three cords of green dung. Indeed, the permanent effects of this compost, according to Mr. Phinney, exceed those of stable dung. On this fact, 2 lbs. of ammonia in 100 lbs. of cow dung, should convert 200 lbs. of fresh-dug peat into good cow dung. The equivalents of these, as has been shown, are 2 lbs. of soda ash, or 3 lbs. of potash. Allowing the gaseous ammonia to be divided equally among the 300 lbs. of dung and peat, this is in proportion of 10 $\frac{2}{3}$ oz. of soda ash, or 1 lb. of potash to 100 lbs. of fresh peat. Now this calculation, deduced from actual experiment, confirms the theoretical proportions, supposing only $\frac{1}{3}$ of the nitrogen acts, though that was made before the author met with the statement of Mr. Phinney."

Dr. Dana furnishes another striking evidence of the favourable results from applying artificial manure. "Mr. George Robbins, of Watertown," he says, "is an extensive manufacturer of soap and candles, and of starch, and, still better, a man who employs the refuse of those trades in enriching and gladdening his land. For four years (and it is believed his crops will compare with any of the best cultivators around him) he has not used a spoonful of manure made by any animal, walking either on two legs or on four. He keeps 11 horses, 4 cows, 100 hogs; he uses not a shovelful of their manure, but, selling that, he uses peat and swamp-muck, mixed with his spent barilla ashes. The proportions are, 1 part of spent ashes to 3 of peat, dug up in the fall, mixed in the spring. After shovelling two or three times, it is spread and ploughed in. The effect is

mediate, and, so far, lasting. The effects of this spent ashes alone on sandy loam, are excellent; it makes the whole quite 'salvy.'

"In the preparation of manure," says Dr. Dana, "price is every thing. Let the cost be estimated per cord, of artificial manure, prepared in the proportions stated. Peat or muck may be called worth 50 cents per cord, and the labour of digging, say \$1.

92 lbs. potash, 6 cents -	\$5 52	} average of } alkalies }	\$1 50
or 61 " soda ash, or white ash, 4 cents -	2 44		3 65
or 24 bush. ashes, 12½ cents	3 00		\$5 15
	3)10 96		
	3 65		

"Were they really good hard wood-ashes, about 16 bushels would be sufficient, but an excess here is allowed, to compensate for variation in quality. But this may appear a very high price; but it is to be remembered, that its value is to be compared with that of a cord of clear cow dung. What is the value of cow dung? It appears from the barn account of the Merrinack Manufacturing Company, that for 9½ years, ending October, 1838, a bushel of clear cow dung costs 21½ cents. During the same time dung of inferior quality was delivered at the printworks, by the neighbouring farmers, at 20 cents per bushel. Clear dung is delivered at the printworks in Dover at 12½ cents per bushel, and at several of the printworks in Rhode Island, at 16 cents per bushel, giving an average of 17.45 cents per bushel, and as a cord contains, in round numbers, 100 bushels, its price is \$17 45

Deduct from this the price of an artificial cord, 5 15

\$12 30

"It is hence evident that an artificial cord is only about one-third of the price of a natural cord, and if the last may be mixed with two parts of loam or swamp-muck, so may the first, which will reduce the price of a cord of artificial manure to \$2 71. Now this is equal, according to all experience, cord for cord, to stable manure; the value of that may be estimated at \$5, so that an artificial cord costs only about one-half. The best plan for preparing the artificial manure, would be to dig the peat or swamp-muck in the fall; in the spring of the year let this be mixed in the proportion of 30 lbs. of potash, 20 lbs. of soda ash, or 8 bushels of common house-ashes, to every cord of fresh-dug peat, estimating this by the pit dug out, and allowing nothing in the spring for shrinking. If ashes are used, they may be mixed in at once with the muck, but if soda ash or potashes are used, they must be dissolved in water and the pile evenly wet with the solution. The pile is then to be well shovelled over, and used as is other manure. But it has been found by experience, that the peat may be dug in the spring, immediately mixed with the alkali, and used forthwith. If spent ashes are used to prepare this muck, add one cord of spent ashes to three cords of peat or swamp muck.

"There are other sources of alkali, for converting peat into soluble manure. Of these the

chief is animal matter. Here we have ammonia produced. It has been actually proved by experiment, that a dead horse can convert 20 tons of peat into a valuable manure, richer and more lasting than stable dung; a barrel of alewives is equal to a wagon load of peat. The next great and prolific source of ammonia is the urine. The urine of one cow for a winter, mixed up, as it is daily collected, with peat, is sufficient to manure half an acre of land with 20 loads of manure of the best quality, while her solid evacuations and litter, for the same period, afforded only 17 loads, whose value was only about one-half that of the former.

"It need only be added in confirmation of all that has been advanced, that those who have had the prudence to fill their yards and hog-pens with meadow-mud which has thus become saturated with ammonia, have in no wise lost their reward. If they have been satisfied with their practice, perhaps they will be no less firm in their belief of success, when science offers them a reason for the faith that is in them. (*Muck Manual.*)

PEAT SOILS. The improvement of peat soils is a subject of very considerable agricultural importance in England, where it involves not only the permanent improvement of large estates, but these peat soils include a very large proportion of several counties in the United Kingdom.

The deep peat mosses, or bogs, which are naturally the most difficult to bring into cultivation, often extend to a depth of many feet, contain but little earth, are usually tolerably level, and consist of a mass of light vegetable fibres. This peat, even in the midst of summer, is commonly saturated with water; at other periods semi-fluid, and very often a trembling, dangerous quagmire. Its soil, if I may call it such, is usually of a dark brown, changing to a blackish colour when thoroughly dried by a gentle heat. In this state the peat is easily inflammable, is commonly used for fuel, and has been occasionally employed by the gas manufacturer, the lime-burner, the charcoal maker, and even the iron-smelter.

The common masses of peat existing on the earth's surface in England are the products of the decay of the mosses, common heath-plants coarse grasses, and the sedges which often accompany them. But the varieties of peat are numerous, according to their age and situation. There are some of the peats which are found *beneath* the soil, in the lower portions of the valley of the Thames, which are evidently the remains of considerable masses of under wood, and contain sulphate of iron. Many others, dispersed over the coast of Essex and in Ireland, abound with the remains of large forest trees, and were most probably produced by some great convulsion of the earth in a distant period. In the southern counties, except in those of the banks of the Kennett and the Thames, the depth of the peat has not often exceeded a few inches; but in the places mentioned, and in those in the northern counties, the depth generally extends to several feet.

The formation of bog-moss is first commenced in very many instances by the rapid

growing broad-leaved bog-moss (*Sphagnum latifolium*), a plant of very curious habits, whose growth under favourable circumstances (and it is strictly an aquatic) extends from an inch in length to 2 or 3 feet. In dry situations, or in those only periodically flooded, its progress is not rapid; but when it vegetates always immersed in the water of low, stagnant situations, there it increases with great vigour. It is true that this plant is an annual; but it sheds an abundance of hardy seeds, producing seedlings, which vegetate and easily support themselves in the water, with a slight assistance from the mere remains of their preceding generation. Their thread-like stems remain on the surface of the water till the seed is ripened; they then fall to the bottom and form distinct layers, which, in some specimens of peat, may be distinctly traced. The bog-moss thus commenced, gradually gets mixed with a variety of lichens, mosses, and scirpi, which annually add to the depth of the accumulating peat; and as the moss becomes firmer, other plants gradually establish themselves, such as several varieties of the rushes and sedges. It is only when the peat-moss is raised by the gradually-accumulated remains of these peats from beneath the surface of the stagnant waters, that the heaths, the cranberry, the bilberry, and the grass-weeds make their appearance. The few plants which commonly tenant peat moors and bogs are of the most worthless kind, such as all live-stock commonly refuse. Besides the common heath-plants there are various rushes (*Juncus*), sedges (*Carex*), rush-grasses (*Sclærus*), club-rushes (*Cyperus*), cats'-tail rushes (*Typha*), bur-weeds (*Sparanium*), &c.

Amongst the few specimens of the common grasses which are found in such places, struggling, as it were, for existence, are the marsh-bent (*Agrostis palustris*), the awnless brown-bent (*Agrostis canina*). This is a very common grass in bogs whose winter waters are deep. The awned creeping-bent (*A. stolonifera* var. *aristata*), the small-leaved creeping-bent (*A. sto. ang.*), the black couch-bent (*A. repens*), the white bent (*A. alba*), the fote fescue (*Glyceria fluitans*), tall fescue (*Festuca elatior*), turfey hair-grass (*Aira caspitosa*), knee-jointed fox-tail grass (*Alopecurus geniculatus*), water hair-grass (*Aira aquatica*), water meadow-grass (*Poa aquatica*), long-leaved cotton-grass (*Eriophorum polystachion*), and the sheathed cotton-grass (*E. vaginatum*).

It is of primary importance that the farmer should clearly understand the chemical composition of the peat with which he has to contend, and that of the watery solution with which it is usually saturated. The common varieties of peat, when dried by a moderate heat, lose a very considerable portion of their weight, and are materially reduced in bulk. The dry mass consists chiefly of woody fibrous remains of a dark-brown colour, of which a very inconsiderable portion is soluble in water; and even by exposure to the unassisted action of the sun and air, under the most favourable circumstances, it decomposes with extreme slowness. When burnt to an ash, the solid product thus obtained, varies commonly in its composition with the nature of the stratum of

earth on which the mass of peat rests. If this is of a gravelly or argillaceous nature, the ashes are generally composed chiefly of siliceous earth, and a small portion of alumina, oxide of iron, with some carbonate of lime and sulphate of iron: if, however, the substratum immediately under the peat is calcareous, then the ashes commonly yield a considerably larger proportion of carbonate of lime, the sulphate of iron (green vitriol) is absent, and the sulphate of lime (gypsum) abounds in its place. The celebrated Dutch ashes, which are productive of such large crops of clover, are composed of—

Silicious earth - - - - -	Parts
Sulphate of lime (gypsum) - - - - -	32
Sulphate and muriate of soda (Glauber salt and common salt) - - - - -	12
Carbonate of lime - - - - -	6
Oxide of iron - - - - -	40
Loss - - - - -	3
	7
	<hr/>
	100

The liquid with which peat is usually soaked is also equally varying in its composition. It almost always contains a very small portion of brown vegetable extract, a quantity of the red oxide of iron, and when pyrites (sulphur and iron) are contained in the gravelly or other substrata, these are gradually, by the action of the water and the oxygen of the atmosphere, converted to sulphate of iron, which dissolves, and is found in the water. When however, this solution comes in contact with chalk or other calcareous matter, the lime decomposes the green vitriol, the iron is precipitated, and sulphate of lime, so enriching to some of the artificial grasses, is very commonly found with red oxide of iron, dissolved in the peat-water.

The chemical composition of peat soils of course varies in the proportion of their constituents. The following analysis of a specimen of an entirely barren peat moss, in a perfectly dry state, will give the farmer a tolerable idea of their general composition:—

Fine silicious sand - - - - -	Parts
Inert vegetable matter - - - - -	29
Alumina - - - - -	289
Oxide of iron - - - - -	14
Soluble vegetable matter, with some sulphate of potash - - - - -	30
Sulphate of lime (gypsum) - - - - -	11
Loss - - - - -	12
	15
	<hr/>
	400

Such is the composition of a barren peat moss. The analysis of an active or fertile peat moss, with which it will be well to compare it, gave the following results, after being also dried in a gentle heat:—

Fine silicious sand - - - - -	Parts
Unalterable vegetable fibre - - - - -	156
Decomposing vegetable matter - - - - -	2
Silica (flint) - - - - -	110
Alumina (clay) - - - - -	102
Oxide of iron - - - - -	16
Soluble vegetable and saline matter - - - - -	4
Muriate of lime - - - - -	4
Loss - - - - -	4
	2
	<hr/>
	400

Such is the usual chemical composition of peat. This, however, is occasionally varied

by the presence of other substances, but the above sketch will afford a tolerably correct view of its ordinary properties; and this kind of knowledge will very materially aid the farmer in proceeding to examine the mode in which the composition of such soils may be altered so as to be rendered tenantable by useful varieties of plants.

The most common delusion in which the possessors of peat soils are apt to indulge, is the belief in the possibility of rendering them permanently productive without either previous drainage or the application of earth. The melancholy attempts of this kind which I have witnessed on the peat land of various parts of England, especially in timber planting, can only excite the pity of those who witness the effects of such misspent time and money. The young trees too, which are most commonly employed in these ill-judged attempts, are usually of the fir tribe, precisely the kind the least adapted to prosper in a bog of water and peat. Common reflection would suggest that, if any kind of trees could be expected to vegetate with even moderate vigour in soils such as these, composed as they are often of merely a mass of hard inert vegetable matters, saturated with a weak solution of green vitriol—if any kind of plantations would progress, it would be the alder, the willow tribe, or the hardy birch tree, tenacious of life, which can endure more moisture and subsist on poorer soils than most other plants. After the slightest consideration we should hardly decide upon placing on such swamps trees which delight in dry upland slopes, as the Scotch fir and the larch; yet we can hardly traverse a single line of railway, driven as their constructors have too often been to take for their line of country the most trembling, dangerous bogs, the most worthless heaths, without being struck with the ludicrous appearance of bright yellow-topped larches and ragged, sickly-looking Scotch firs, soaking in bog-water—and that too not in mere patches, but over hundreds of acres. I do not confine these observations to the north of England—to Lancashire and Yorkshire—but the remark applies to many of the southern counties: for instance, by the road-side between Wareham and Poole, in Dorsetshire, may be seen similar wet, peaty, heath plantations of Scotch firs.

In effecting the underdraining of peats, the first error to be carefully avoided is placing the drains too near the surface. I have invariably found in deep peats, that where the drains cannot be placed beneath the peat, they should be constructed at least at a depth of from 4 to 6 feet or even more; and this is not adding materially to the expense, for the peat-owner will find that one drain at the depth of 5 or 6 feet will produce more powerful and far more permanent good effects than three drains at a depth of three feet. The good results of depth in peat-land drainage will be found by the farmer years after the soil is reclaimed—for, as the peat is dried and its upper portion decomposed and rendered solid by cultivation, the mass of peat gradually and very materially sinks, and this too in deep peats for a lengthened period. And as this contraction is chiefly confined to the upper portion of the peat, the

result is that the improving soil of the surface gradually approaches the drains, and that in some varieties of the softer kinds of peat to a very injurious extent. Such too is the porous, spongy nature of most peat soils, that it is difficult to remove entirely the water from those portions of them lying on a level with the sides of the drains, and in consequence the roots of many cultivated crops are apt to penetrate, under the shallow-drain system, into the corrosive water of the peat, which they never do without material injury.

For let me again remind the farmer, it is not the mere presence of too much water which renders the peat moss sterile, but the noxious, astringent, irony quality of that water.

In the reclamation of peat soils, the necessary drainage being effected (see *DRAINING*), the next important object is to furnish the soil with a sufficient quantity of earthy matter to support vegetation, and this may be done in several ways: that by paring and burning, so common in various parts of Cambridgeshire and Lincolnshire, I consider the worst of all modes; for it merely furnishes the soil by an expensively rapid progress with the freed earths of the peat, which its gradual decomposition would by other modes more profitably and steadily effect.

The first operation after the water has been drained off is to break up as deeply as possible, by the common and the subsoil-ploughs, the surface of the peat; and then, if good well-burnt lime can be procured, there is no earthy addition so rapid and so powerful in dissolving and rendering pliable the peat as this. A few ploughings, assisting the combined operations of the atmosphere and the lime, will, in a few weeks, bring the soil into such a state as to enable it to bear a first crop. The quantity of lime should be about 250 or 300 bushels per acre; but the quantity of necessity must vary with the readiness with which the lime is procurable; where it is very expensive, the cultivator is obliged either to reduce the quantity, or mix it thoroughly with a proportion of clay or marl before he spreads it over the surface of the peat. Where limestone is to be obtained in the immediate neighbourhood, and other fuel is not to be readily procured, peat may be employed in many cases in the process of lime-burning without much difficulty, it chiefly requiring that the peat should be thoroughly dried previous to its being used. For a first crop on the thus so far reclaimed peat soils, I have found no other crop equal to potatoes. These are best planted in ridges; the horse hoe-plough can then be easily kept at work, which not only considerably promotes the decomposition of the peat, by facilitating the introduction of the moisture and gases of the atmosphere, but this very operation adds very materially to the vigour and produce of this valuable root, than which no other plant more delights in fresh soils, such as that produced by well-drained, fresh earth-dressed peaty lands.

It is well to avoid for a year or two all attempts to produce grain crops on land like that I am describing. The course of cropping which the farmer will almost always find the most profitable, is to follow the potatoes with

peas, then turnips, oats, grass-seeds, peas, wheat. In all cases, too, he must remember in what small proportion some of the essential ingredients of his crops are at first existing in this peaty soil, and how valuable even a slight dressing of clay or marl will be found in supplying such deficiencies.

And, again, it is here that the services of the manure-drill are available to an invaluable extent in applying bone-dust, or any kind of organic or even earthy manure, especially to the young land's earliest crops. For the natural results of the progress of cultivation, the gradual decomposition of the soil and tough vegetable remains, the accumulation of more easily decomposable vegetable matters, the application of the ordinary farm-yard compost, finally sufficiently enrich the ground with those salts of lime and of potash which form the essential ingredients of all fertile land.

To expedite the accumulation of decomposing soluble matters in the soil, several expedients may be adopted. For instance, if the farmer has access to night-soil, an admirable compost may be made by mixing this seven or eight weeks previous to its employment with the peat itself. I know of no other compost so powerful on peat soils as a compost of well-putrefied peat and night-soil: 4 or 5 cubic yards of the night-soil is an ample dressing per acre with 12 or 15 cubic yards of peat. If the farmer has not access to night-soil, let him substitute farm-yard compost with the peat in a rather larger proportion, or even urine, or the drainage from his farm-yard. This plan, first, I believe, successfully adopted by the late Lord Meadowbank, is well described by Mr. Dixon, of Heathershow, in an essay for which a prize was awarded to him, in 1839, by the Royal Agricultural Society of England.

The farmer must, to derive the maximum benefit from this plan, avoid certain errors, which will else materially deteriorate the richness of the compost. He must be careful to have the peat he intends to use dug for some time previously, and exposed in spits to the drying influence of the sun and winds. The peat, in fact, can hardly be employed too dry; and the farmer will find that, if he makes the compost in the dry, warm weather of summer, he may then use more peat in proportion to his farm-yard dung or night-soil, than if he makes the mixture when the temperature of the air is less. In the warm weather of the spring and summer months, the cultivator will find 1 cubic yard of fresh, good farm-yard compost sufficient for 3 or 4 cubic yards of peat; but in colder weather the proportion of peat must be decreased. The farmer will find that the fresher and richer the animal manure, the larger will be the proportion of peat with which it may be successfully mixed. Thus, with the rich semi-fluid mixture from the slaughter-houses of London, with 1 cubic yard of this, 6 or 7 cubic yards of peat may be mixed; and I have found, on several occasions, every reason to agree with Lord Meadowbank and others who have employed peat in this way, that it is very desirable not to mix more than half the intended proportion of peat

at first, but to wait until the fermentation of the mass is somewhat advanced, and the temperature of the peat increased, before the last half is added to the heap. Some persons recommend the addition of a portion of lime to this compost; but this is a plan I do not consider either advantageous or harmless: for the lime combines with, and even partially decomposes, some of the richest portions of the animal matters of the manure; and I have on some occasions suspected, from certain appearances, that it retarded, when thus used, the dissolution of the peat. In 8 or 9 weeks the compost will be ready for use; the peat and dung will be thoroughly mingled together, and the whole heap will have the colour of a dark garden-mould. Of the nourishing quality of this mixture of peat with night-soil or yard-manure, or urine, the farmer will readily convince himself by the fertile effects which it produces; and, when drilled with turnip-seed, the roots of the young plants will be found to encircle the lumps of it, just as they do in the case of crushed bones.

If the possessor of a peat soil cannot well prepare a compost of either night-soil or farm-manure with the peat, he may still furnish his soil with a valuable dressing, by mixing hot lime and peat together, at the rate of 1 cubic yard of the former with 3 or 4 cubic yards of the latter. In this case it is not necessary to dry the peat previously, for the lime readily absorbs the water contained in it, and in the course of 7 or 8 weeks the entire mass is reduced to the state of mould. From some experiments which I have made on a small scale, I have found that the addition of a portion of common salt to the lime, not exceeding 1 part of salt to 3 parts of lime, will still more increase the fertilizing powers of this peat compost; but my experiments on this head require repetition before I can confidently recommend this plan for the farmer's adoption.

When once the peat is well drained, a very thin covering of earth will produce much greater effects in forming a solid soil than the farmer may imagine possible: the facility with which roads are made across the extensive deep Scotch peat-mosses and the great Irish bogs, in some degree illustrates the same fact: the bog, when once dried, is found to require only a thin layer of gravel to make an excellent road. It is true that these are apt to tremble pretty considerably under the feet of the plough-horses, but they bear the heaviest carriages with perfect safety, even in places where the bog of peat is of a depth of from 20 to 40 feet.

Peat-moss lands are commonly divided by the deep ditches or channels by which they are drained.

A valuable account of the practice of English farmers in the improvement of peaty ground, by Ph. Pusey, Esq., more especially those of Lincolnshire, is contained in the *Journ. Roy. Agr. Soc.* vol. ii. p. 390.

PECK. A measure of capacity containing 2 gallons, or the fourth of a bushel. The imperial peck contains 554.55 cubic inches. Besides the standard peck, there are in England

local pecks, which are extremely various: thus the Lancashire peck contains six gallons; but in other counties it is much less.

PEE-TSEE. A species of water chestnut, which grows in the southern provinces of China, in shallow rivers and ponds, with leaves like a bulrush, and hollow like the stalk of an onion. Its fruit is in the capsule of the root, like the husk of a chestnut.

PENNYROYAL (*Mentha pulegium*). English pennyroyal. This well known perennial plant is found growing wild in England on wet commons, and about the margins of small brooks. It has a strong acid, and very peculiar smell, and is stimulant and tonic, but less grateful than peppermint. The stems are somewhat procumbent, or quite prostrate. Leaves ovate, scarcely half an inch long, full of pellucid dots. Flowers whorled. Flower-stalks purplish, clothed entirely with very short, dense, hoary pubescence.

Pennyroyal is cultivated in Europe for its use in culinary and pharmaceutical preparations. There are two varieties—the trailing, which is usually cultivated, and the upright. These plants are best grown on a tenacious soil: even a clay is more suitable to them than a light silicious one. It should be moderately fertile, entirely free of stagnant moisture, and consequently on a dry subsoil, or well drained. A wet soil makes them luxuriant in summer, but insures decay in winter.

They are propagated by parting the roots in February or March, September or October, and by slips or offsets at the same season. The mints likewise may be increased, by cuttings of the annual shoots in May or June, as well as by cuttings of the roots either in spring or autumn. For production of green tops throughout the winter and early spring, the spearmint is often planted in a hot-bed; and more rarely pennyroyal, every three weeks during October and three following months.

The pennyroyal indigenous to North America is the *Hedeoma pulegioides*, an aromatic annual plant, very different in its habits from the European pennyroyal. It grows in all parts of the country, preferring dry grounds and pastures, where it often scents the air to a considerable distance. (*Flora Cestricea*.)

PEPPER-BRAND. A disease in grain. See MILDEW.

PEPPER-GRASS (*Lepidium sativum*). Tongue-grass. A kind of cress, possessing very pleasant and refreshing qualities, and generally cultivated in the United States for the table. The Virginia lepidium, or wild pepper-grass, is an annual commonly found in fields and along road-sides. One or two other species are known in the United States. (*Flora Cestricea*.)

PEPPERIDGE. An appellation improperly applied by the descendants of the Dutch in New York, to the tupelo or black-gum. The name more appropriately belongs to the common barberry.

PEPPERMINT (*Mentha piperita*). This species differs from the common spear or green mint chiefly in the intensity of its taste and dark colour of its foliage. It is only cultivated for distillation; the essential oil or distilled

water enters into various cordial and medical preparations.

PEPPERS. See CAPSICUM.

PEPPER-SAXIFRAGE (*Cnidium*, the ancient name of orach). These are worthless herbaceous plants.

The meadow pepper-saxifrage (*C. silaus*) is an indigenous perennial species, with smooth dark-green herbage. The root is spindle-shaped; stem erect, furrowed, solid, tough, from 1 to 2 feet high. Flowers yellowish or greenish-white, blowing in August and September. The whole plant being fetid when bruised, is supposed, in some parts of Norfolk, Eng., to give a bad flavour to milk and butter; but cattle certainly do not eat it, except accidentally or in small quantities. When this herb abounds in pastures, it may be found partially cropped, though generally left almost entire.

PEPPER, THE WALL. See STONECROP.

PEPPERWORT (*Lepidium*, from *lepis*, a scale, in allusion to the shape of the pods, which appear like little scales). Most of these plants are uninteresting, and none of them are pretty. *L. sativum* is the well-known garden cress. There are, in England, four indigenous species.

PERCH. In land measure is the fortieth part of a rood, or equal to 30¼ square yards. Perch is also sometimes used as a denomination of long measure, when it signifies the same thing as a rod or pole, being 5½ yards or 16½ feet.

PERENNIALS (Lat. *perennes*, lasting throughout the year). In botany, those herbaceous plants, the roots of which remain alive more years than two, but whose stems flower and perish annually. Gardeners generally call them herbaceous plants.

PERIWINKLE (*Vinca*, probably from *vinculum*, a band; in allusion to the suitability of the shoots for making bands). These plants are well adapted for covering naked ground in shady situations. Any common soil suits them, and they are readily increased by separating the rooted trailing shoots. The two species indigenous to England are called the greater and the lesser periwinkles.

PERSIMMON (*Diopyros Virginiana*). This American tree grows in the Southern and Middle States to the height of 60 or 70 feet. The French call it *Plaqueminier*. It produces an abundance of excellent fruit, abounding in sugar, and somewhat resembling the date.

PHLEUM PRATENSE. See *Cat's-tail*.

PHOSPHATES. Substances in which phosphoric acid is united with some other matter, such as lime, magnesia, potash, soda, iron, &c. See ACIDS. Within a few years past, a class of manures in which phosphate of lime is the most active fertilizing agent, have acquired very great agricultural importance. It includes bones, and the superphosphate of lime prepared from them, urate, guano, &c., among organic substances, and a mineral called *apatite*. Phosphoric acid is found in some soils but not in others, its deficiency corresponding with different degrees of sterility. In three specimens of soil analyzed by Mr. Gyde, he detected in 1000 parts of one fertile without manure, 4½ parts; in another fertile with manure only 1¼ parts, whilst in the

third specimen, from a naturally barren soil, he could not detect any phosphoric acid.

Under the heads of BONES and ACIDS, will be found much valuable information relative to the important influence exercised by phosphoric acid upon the growth and fullest development of plants, with statements of the proportions in which phosphates exist in different grains and other agricultural crops. The extent of the demands made upon the soil for the phosphate of lime, by growing animals kept upon it, have been estimated by Mr. Hayward, a skilful chemist. He calculates the amount of phosphoric acid annually abstracted by the live stock from a farm of 100 acres, to be equal to 413 lbs., requiring to produce it 1491 lbs. of bones. His estimate is as follows:—

	Acid.	Bones.
In the bones and flesh of 110 lambs, of 25 lbs. each, at 6 weeks old	145	537
In 40 year-old sheep, of 90 lbs. each	210	777
In 4 calves, at 5 weeks old, weighing together 500 lbs.	21	77
In 4 young cows, forming 135 lbs. flesh and 35 lbs. of bone each per annum	16	23
In 2 young horses, gaining the same as the last	21	77

Phosphate of lime consists of 59 parts phosphoric acid, and 47 parts lime. The phosphates of magnesia, potash, and soda, are found much less extensively in agricultural products than the phosphate of lime, which last seems indispensable to fertility. The chief modes in which the farmer has long been accustomed unconsciously to return this salt to the soil has been, by the use of oil cake for his stock and of crushed bones for manure. In a more recent period the use of guano, of urate, &c., has been in fact a similar operation. It has been found by Professor Johnston (*Trans. High. Soc.* 1845, p. 470), that turnips grown upon land dressed with guano contained a considerably larger proportion of phosphate of lime than the turnips grown in the adjoining soil, dressed in the ordinary way, the ashes of the turnips grown with the ordinary farm-yard dung containing 7.73 per cent. of phosphoric acid, whilst the turnips produced on the land manured with guano yielded 19.39 per cent.

Perhaps the most economical plan by which phosphoric acid can be introduced into the soil is through the application of superphosphate of lime, the process of preparing and applying which will be found described under the head of BONES. Of bone-dust, 40 lbs. to an acre, Liebig considers sufficient to furnish the necessary supply of phosphates to 3 crops of wheat, clover, &c.

Oil or linseed cake is not only valued by English farmers as food for stock, but, as we have previously stated, as a dressing for land. It has been usual to attribute its good effects in promoting the growth of plants mainly to the oil; but as this exists in small proportion, and as the effects of oily manures, such as blubber, fish, &c., only last a single year, whereas those of linseed cake endure for several years, its fertilizing effects must depend upon some other ingredient. In 3 specimens of linseed cake analyzed by Mr. Gyde, he found respectively 12.4, 10.5, and 8 per cent. only of fatty matters. The ashes or solid portions of 3 varieties of oil cake, examined by Mr. Fromberg, were found to contain per cent. of earthy phosphates: 1st, Gold of pleasure, 40.56; 2d, English cake, 47.67; and 3d, American cake, 38.28, (the ashes constituted of the

1st cake 6.89, of the 2d 7.25, and of the 3d 6.35 per cent. of the entire cake.)

The phosphates of lime, magnesia, soda, &c., which abound in the urine of man, the swine, and other omnivorous and carnivorous animals, are not met with in that of the ox or horse, which last discharge all their phosphates with the solid excrements. The *superphosphate* of lime, as prepared for sale, ought to contain, when genuine, in 100 parts, according to Mr. Pusey, phosphate and biphosphate of lime 35 to 40; Sulphate of lime or gypsum 20 to 25; animal matter 20; water 20 parts. It has often, however, other substances mixed with it which reduce its value, and of these plaster of Paris is one of the most common. Its price in England is about 7 shillings, or \$1.75, for 112 lbs.

In an experiment where about 6 cwt. of superphosphate of lime was applied to wheat, ploughed in at the time of sowing, the produce on the acre was over 53 bushels of 61 lbs. each; whilst an acre sown with 400 lbs. Peruvian guano, the ensuing spring yielded 40 bushels, and the soil without any dressing, about 29 bushels per acre. Hence it appears probable, that weight for weight, it is fully equal as a fertilizer to the best guano.

PIGEON (*Columba*). All the numerous varieties of this domestic bird, such as tumblers, carriers, pouters, &c., come from one common species—the stock-dove—which derives its name from building in the stocks of trees.

PIGEON'S DUNG. See DOVE-COTE and GUANO.

PIGGERY. A collection of small sties where hogs or swine are lodged. See SWINE.

PIKE. A word of various signification in different districts. In some counties it is applied to a prong, or what is generally called a fork, used for carrying straw, &c., from the barn, cocking of hay, &c. In others it signifies a sort of stacklet or load, cock of hay, &c. In the midland districts of England it means to glean.

PILE. A sharpened beam of wood driven down into the ground to protect the banks of rivers, or for other similar purposes. Pile is also provincially applied to the breaking off the awns of thrashed barley, and to a blade of grass.

PILING-IRON. A tool used in breaking off the awns of barley, and sometimes the tails of oats, an operation which with the farmers is called piling barley. See HUMMELLER.

PILEWORT CROWFOOT. See CROWFOOT.

PILLWORT (*Pilularia*, from *pilula*, a pill; shape of the heads containing the reproductive organs). The creeping pill-wort, or pepper-grass (*P. globulifera*), is in England an obscure little plant, found in dark meadows among grass, especially where they have been overflowed with water during winter. It is perennial in habit, putting forth brown flowers in June and July.

PIMPERNEL (*Anagallis*). A genus of very pretty, interesting plants, of easy culture.

PINE TREE (*Pinus*, from *pinos*; a Greek word used by Theophrastus, to designate a pine tree; and some authors derive it from the Celtic *pin* or *pyn*, a mountain or rock, alluding to the habitat of the tree). This much-esteemed and well-known genus, belonging to the gymnospermous division of exogens, contains some of the trees of most universal use in civilized society, and which form a very important article

commerce, both in Europe and America. The genus *Pinus* is distinguished from the firs, by the leaves being needle-shaped and grouped in pairs, or in three, four, or five together; held, if it were, together by a sheath at their base. Most, if not all of the species, are highly deserving of culture, being very ornamental and beautiful in every stage of their growth. They will succeed on almost any kind of soil, but to bring the timber to its greatest state of perfection, a somewhat loamy surface soil and a cool subsoil are requisite. Young plants may be obtained by a variety of methods. All the species may be propagated by layers, by inarching nearly allied kinds, and by herbaceous grafting; many may also be increased by cuttings, but the speediest way is by seed, and which process I shall briefly notice. In some of the species the cones attain their full size the first year, but in most not till the end of the second autumn. The cones of the Scotch pine (*P. sylvestris*), and those allied to it, open of themselves shortly after being gathered from the tree, and spread out in the sun; but the cones of *P. pinaster*, *P. pinea*, and similar kinds, do not, though treated in the same manner; and when their scales only after several months. The seed should be sown on a finely-prepared sandy soil, in March or April. The seeds of the most common kinds are always sown in beds, and after being gently beaten down are slightly covered with light soil.

There are upwards of fifty species of pines, and the appearance of the tree, as well as the quality of the timber, varies with the species and with the situation in which each grows. Generally speaking, the timber is hardest and best in exposed cold situations, and where its growth is slow. See FIR TREE.

PINE, THE GROUND. See BUGLE.

PINK (*Dianthus*; from *dios*, divine; and *thos*, a flower, in reference to the fragrance of the blossoms and the unrivalled neatness of the flowers). A truly beautiful and ornamental genus, containing some of the most prized flowers we possess, on account of the beautiful fragrance of their blossoms, and their foliage, which is as green and vivid in winter as in summer. The genus is divided into those with *solitary* and those with *aggregate* flowers.

PIP. A disease among poultry, consisting in a white thin skin, or film, growing upon or under the tip of the tongue, which hinders the feeding. It is supposed to arise from the drinking of foul water, or eating filthy meat; it is usually cured by pulling off the film with the fingers, and washing the part with a solution of common salt.

PIPE-CLAY. A species of clay abounding in Devonshire and other parts of England, employed in the manufacture of earthenware. See MIXTURE OF SOILS.

PISTIL. In botany, the columnar body in the centre of a flower, consisting commonly of three parts; viz., the ovary, styles, and stigmas. It is one of the essential parts of the flower; and when it is absent the flower is sterile. It receives the pollen, and communicates its stimulus to the ovules; without which the seeds are imperfect, and do not germinate.

PITCH (Ger. *pech*). In commerce, the resi-

duum which remains on inspissating tar, or boiling it down to dryness. It is a black solid substance, with a shining fracture, softens at 90°, and becomes liquid in boiling water. It is extensively used in ship-building, and for other purposes. Large quantities are manufactured in Great Britain, but not sufficient to supply the great demand. The duty on importation is 10*d.* per cwt. In husbandry, pitch signifies a fork-full of hay, corn, or straw, or as much as is raised to the load, stack, or mow, at one time.

PLANER TREE (*Planera ulmifolia*). "Kentucky, Tennessee, the banks of the Mississippi, and the Southern States, are, says Michaux, the only parts of the American republic where my father and myself have found the planer tree.

"I have more particularly observed the planer tree in the large swamps on the borders of the river Savannah in Georgia. It is a tree of the second order, and is rarely more than 35 or 40 feet high, and 12 or 15 inches in diameter. Its bloom is early and not conspicuous. Its minute seeds are contained in small, oval, inflated, uneven capsules. The leaves are about 1½ inch long, oval-acuminate, denticulated, of a lively green, and a little like those of the European elm, to which this species bears the greatest analogy.

"The wood of the planer tree is hard, strong, and seemingly proper for various uses; it is probably similar in its characters to the analogous species in the north of Asia, the *Siberian elm*; but the tree is rare and the wood is neglected." (*N. A. Sylva*.)

PLANKS (Ger. *plancken*; Dan. *planker*; Fr. *planches*). Thick strong boards cut from various kinds of wood, especially oak and pine. Planks are usually of the thickness of from one inch to four. They are imported in large quantities from the northern ports of Europe, and from several ports of North America. Those employed for making sheds or farm out-houses should be tarred, or steeped in corrosive sublimate.

PLANT. In natural history. See ACCLIMATION, BOTANY, EARTHS, GASES, ORGANIC CHEMISTRY, TEMPERATURE, WATER, &c.

PLANTS IN CLOSELY GLAZED CASES. By the recent discovery of Mr. Ward, of London, that certain plants will grow when enclosed in glazed cases, the most forbidding local circumstances may be overcome, and any person, whether inhabiting the most humble or the most splendid dwelling, provided they are exposed for a few hours every day to the sun's light, has it in his power to rear and cultivate a miscellaneous collection of plants, to enjoy the beauty of their appearance, and to watch their progress through all the stages of their growth, at an expense so insignificant as to be within the means of every one, even in very moderate circumstances; in short, to enjoy, even in rooms heated with anthracite coal, a *parlour green-house*.

To do this an apparatus must be provided, consisting of a box and a glass roof, such as are used for raising cucumbers, for instance, or more ornamental, as may be desired. The box should be lined in the bottom with zinc to prevent leakage. The whole should be close, to

prevent evaporation, and may be painted to represent any description of wood; a hole or holes should be left in the bottom, through the zinc and board, to carry off any extra water, if you find there is too much for the health of the plants enclosed. At the upper edge of the box a groove is sunk to receive the lower edge of the glass roof, which rests tightly upon it.

The frame-work cover should be glazed with good glass, with a door on one side made to fit close, and which may be opened to remove dead branches, for trimming, and the addition or subtraction of plants. Along the top of the roof, hooks or brass rods may be placed, from which small pots may be suspended with brass wires; twine will soon decay in the continued dampness. The whole of the frame-work should be well fitted, so as to preclude, as far as possible, all interchange between the air in the case, and that in the room.

Lay the bottom of the box with pieces of broken earthenware, as an open subsoil. Next lay a stratum of turfy loam, one inch deep, and fill in the remainder of the space with soil, composed of equal portions of peat and loam, mixed with about one-twentieth part of rough white sand, free from iron. The artificial garden plot is now ready to receive the plants. Plant these in the usual manner, and then shower over them, with a fine rose watering-pot, sufficient water to saturate the soil, till the liquid begins to run off by the opening in the bottom. After draining thus for 24 hours, cork up the hole or holes, place the glass case on the box, and the operation will be finished.

The most remarkable part in the economy of the case, thus closed up, is the preservation of atmospheric purity. To all who reflect, for the first time, on this subject, it will seem incomprehensible how the plants can possibly thrive and blossom, without the occasional interchange of fresh air with the atmosphere. This certainly does appear extraordinary, yet it is ascertained by experiment, that no such reinvigoration is requisite; to account for the phenomenon it will be necessary to explain the constitution of atmospheric air, and the means adopted by nature for its purification.

Air consists of three gases in close mechanical union, nitrogen, oxygen, and carbonic acid, in the proportions of about 79 of nitrogen, 20 oxygen, and 1 of carbonic acid, in 100 parts of pure air. In this mixed composition, the essential element for the support of respiration in both animals and plants, and also for combustion, is the oxygen, the nitrogen being little else than a diluent to modify the strength of the oxygen. It was long believed by men of science, that plants possessed the power of exuding oxygen, and so formed a prime agent for restoring vitiated air to purity. Later investigations, however, by French chemists, have made it evident that plants have no such power, unless when placed under the influence of the sun's rays, or, in other words, that solar light is the grand cleanser of the atmosphere, and without which, both plants and animals languish and die. With respect to plants in particular, it is ascertained, that while inhaling oxygen, and expiring carbonic acid, their leaves possess the remarkable property, in conjunction

with the sun's light, of retransforming the carbonic acid into oxygen. At night, when light of day has departed, the expired carbonic acid may be detected in the neighbourhood of plants, and hence, one cause of injury to health by breathing night-air; but when the morning sun again bursts upon the scene, a great chemical process commences in the atmosphere, the carbonic acid is decomposed, oxygen evolved, and all nature rejoices in re-creation of its appropriate nourishment.

A question will here readily occur—What species of plants are best adapted for these domestic green-houses? This has been answered by Mr. Ellis, in a paper read before the Edinburgh Botanical Society in 1839. According to this gentleman's statement, the plants most suitable are "those which partake largely of a cellular structure, and possess a succulent character, and especially those which have fleshy leaves; whilst on the contrary, the continued humidity is unfavourable to the development of flowers of most exogenous plants, except such as naturally grow in moist and shady situations." Plants, therefore, which grow naturally, and bloom in cavernous and moist situations, or in moist and warm climates, are best adapted for these cases; within this class of vegetables there are many beautiful and luxurious plants, which it would be a small pleasure to contemplate. We name a few which have eminently succeeded. A specimen of this mode of culture may be seen in the possession of Mr. J. J. Smith, Jr., Librarian of the Philadelphia Library, which is eminently successful.

Crocuses, and winter aconite; joy; lycodium; the various cactuses; aloes; primroses; the fairy roses; begonias; all the ferns; a mone; musk plants; myrtles; jasmines, &c.

All the vacant spaces in the case may be employed in raising salads, radishes, &c. "and I think," says Mr. Ward, "that a man would be a bad manager who could not, in the course of a twelvemonth, pay for his case out of its proceeds."

Sir W. J. Hooker, in a letter to Mr. Ward, says, "Splendid as is the hot-house and greenhouse collection at Woburn Abbey, I doubt whether that gives more pleasure to the proprietors and their numerous visitors than the beautiful little collection in Mr. Ward's case, that occupies a table in the library, and flourishes without requiring the skill of a gardener in its cultivation." Once properly watered, these cases have remained for several years without any additional moisture.

The uses to which this discovery of Mr. Ward's has led, are important to man; especially so in the transmission of plants from one country to another by sea. So admirably does it answer to thus enclose plants for sea voyages, that few instances of failure have occurred in their transmission, where care has been taken to renew the glasses, if broken, and to expose the cases to the action of the sun's rays on deck in fine weather. But, even more important than this, it will enable the chemist to make observations strictly comparative of the effects of different soils, manures, &c.; to determine the powers possessed by plants

orbing, and selecting various substances by their roots; to ascertain the existence and nature of the deleterious excretions from the plants; the poisonous character of these excretions, if they exist, being rendered very pronatal by the circumstance of plants, in a variety of nature, occupying the same situations and ages; to prove the effects of poisons on plants; to test the influence of light in producing plants from the effects of low temperatures; and, lastly, by means of these cases the scientific naturalist will be assisted in exploring that debatable ground on the confines of the animal and vegetable kingdoms, where it is often impossible to determine the point at which one ends and the other begins.

PLANTAIN (*Plantago*; derived from *planta*, sole of the foot; resemblance in the leaves). Genus of plants, the greater number of species of which are mere weeds: they are generally almost stemless, and for the most part perennial. There are in England five native species:—

1. Greater plantain, or way-bread (*P. major*), which is very common in meadows, pastures, waste and cultivated ground, perennial, in flower all summer. The root consists of many long, stout fibres. The leaves are radical, numerous, broad, with seven or nine ribs, on channelled, ribbed stalks, often longer than themselves; margins wavy or toothed. Flowers on long spikes, small, whitish, with yellowish anthers, very numerous; the spikes, when on a simple, naked, radical stalk. The leaves, which are angular, in a membranous sheath, are the food of small birds. The rose-crested variety and the paniced one are often cultivated in gardens for the sake of curiosity, and afford remarkable instances of vegetable transformation. This species, like the whole genus, in general, is mucilaginous, and somewhat astringent, qualities which render it not together a useless rustic medicine. Cows and horses do not relish this plant, but it is relished by sheep, goats, and swine. This perennial-rooted plant is extensively naturalized in the United States, and is remarkable, says Dr. Wright, for accompanying civilized man, following along his foot-paths, and flourishing around his settlements. From this circumstance, the American Indians call it by a name which signifies "the white man's foot."

2. Hoary plantain (*P. media*). This species grows abundantly in chalky or gravelly hills. The root is rather woody. The leaves are radical, downy, all pressed close to the ground, entire, with five or seven ribs. The hoary plantain, a great and lasting nuisance in the grass-plats, is best killed by a drop of vitriolic acid on the crown of the root, which it never long survives. Its medical qualities are the same as the former.

3. Ribwort plantain, or rib-grass (*P. lanceolata*), is also a very common species in meadows and pastures. Pl. 9, i. The leaves are numerous, erect, deep-green, acute, each tapering at the base into a broad, flat, ribbed foot-stalk, accompanied at its insertion with large masses of soft, white, woolly fibres. Flower-stalks taller than the leaves, likewise woolly at the base, five-angled, with intermediate fur-

rows, nearly smooth, twisted. Spike ovate, an inch long, with black imbricated bractes, occasionally leafy at the base. This species makes a part of most meadow hay, and has been cultivated as a crop, but seems to be now disused. Cattle are said not to eat it willingly, at least by itself. The total absence of rib-grass in marshy lands is a certain criterion of their indifferent quality; and in proportion as such soils are improved by draining, this plant will flourish and abound.

4. Sea plantain (*P. maritima*). This grows in muddy salt-marshes, and about the mouths of large rivers. It is perennial, and flowers in August and September. The root is long and cylindrical; herb various in luxuriance. The leaves are all radical, numerous, from four to twelve inches long, dull-green, linear, channelled, hairy, nearly entire. Flower-stalks round, longer than the leaves, erect, smooth. Spikes cylindrical, slender, many-flowered, dense, with fleshy keeled bractes, not longer than the calyx. Sheep appear to be very fond of this species.

5. Buck's-horn plantain, or star of the earth (*P. Coronopus*). This is an annual species, which flourishes on dry, sandy, or gravelly ground, flowering from June to August. The root is tapering; leaves pale, hairy, in pinnatifid, pointed segments. Spikes numerous, dense, cylindrical, varying greatly in length, on spreading hairy stalks.

The White, or Virginia Plantain, is a native of the United States, where it is commonly found in barren old fields and stony hills. It has a biennial root, leaves 2 or 3 inches long and from 1 to 2 wide, the whole plant being covered with a gray pubescence or down. Nine or ten additional species of plantain are enumerated in the United States.

PLANTAIN, WHITE, see **CUDWEED**.

PLANTATION. In England this term is applied to a piece of ground planted with trees for the purpose of producing timber or coppice wood; and the term is also applied to a collection of trees or shrubs placed in the ground for their beauty or usefulness.

For the correct consideration of the best mode of forming plantations of timber trees, several circumstances must, of necessity, be taken into the planter's account, of which the principal are—1st, The composition of the soil; 2dly, The trees to which that soil is best adapted; 3dly, The elevation, or inclination of the land: an inattention to these three primary questions has been the source of much waste of time, of labour, and of capital.

In this, as in all researches where vegetation is concerned, nature is ever our best guide and instructor. We find indigenous on the chalks, the beech, the birch, and the ash; the oak tenants the clay formation, the elm delights in rich alluvial bottoms, and in warm, sheltered situations. To the sand is left the fir tribe, the ash, and the birch, which last most picturesque tree will endure a climate, and vegetate on soils, far too cold and too barren for any other to exist in. On the warm gravels, and on deep, light loams, we find the Spanish chestnut located; and if, on even the peat, we only occasionally meet with a few straggling

mountain ash and Scotch firs, it is not because the composition of the soil is too poor to sustain a better description of timber tree, but that the soil is usually saturated with water, too much impregnated with the salts of iron for any plants to be successfully planted till that corrosive moisture is removed.

Then, again, as regards the temperature best adapted to the tree, much too little attention is commonly paid. The fir tribe are found to delight in dry, cool elevations, whilst attempts to make the larch grow in warm, rich bottoms, generally fail.

These facts should be more carefully attended to by the planter: he should consider the inequalities of his land and the habits of his trees, and distribute them accordingly. Leaving the natives of a temperate climate to the southern and western slopes, he should devote to the northern declinations the natives of a colder climate; to them consign the larch and the Scotch fir, the ash and the birch.

This last-mentioned tree will, in fact, grow at a greater elevation above the sea, and in a more northern latitude, than any other. As we approach the Arctic regions, it is the last tree that remains to us. Long after all others have departed it still flourishes: in Greenland there is no other tree.

Then, again, as in all other questions where plants of any kind are to be made to vegetate, the chemical composition of the soil is a tolerably certain criterion, when compared with that of the wood of trees, to guide us in our selection of the species to which that land is the best adapted: the earths found in them by the chemist are sure to indicate the soils on which they will flourish. Thus, the ashes of the perfect wood of the oak contain more than 38 per cent. of soluble salts, and only 2 per cent. of silica (flint); that of the fir (*Abies*), grown on granite, only 16 per cent. of soluble salts, and 19 per cent. of silica. Now the fir flourishes very well on the poorest silicious sands, but the oak will not grow on such soils without a dressing of other earths. Carbonate of lime (chalk), when in excess in soils, is less prejudicial to the growth of trees than an excess of any other earth. Now the carbonate of lime is precisely that earth which is most commonly found in timber trees, and in the largest proportions. The ashes of the wood of the oak, for instance, contain about 22 per cent. of the earthy carbonates, the poplar 29, the hazel 22, the hornbeam 26 per cent.; and that of the beech a still larger proportion. And so almost universally does carbonate of lime and silica exist in wood, that M. Einhof, an able Prussian chemist, came to the conclusion that the plant had the power of forming these earths when growing on soils that did not contain them: they certainly, however, are found to absorb the largest proportion of carbonate of lime and silica on soils in which those earths abound. Thus M. Saussure found in the ashes of the fir, growing on a soil which contained 1.74 per cent. of carbonate of lime, 16.34 per cent. of this earth; but in the ashes of the same wood, produced from a soil containing 93 per cent. of carbonate of lime, he found 63 per cent. of that earth. And when the

soil contained 75.25 per cent. of silica, the timber growing on it contained 13.49 per cent. but when the soil was entirely free from the earth, it was equally absent from the wood.

The observations of the planter confirm entirely those of the chemist. Thus, on the poor hungry, heath lands, such as those of Norfolk, Surrey, and the north, which contain hardly a trace of carbonate of lime, they find that by dressing land intended for planting with chalk or marl, the growth of the trees is very materially increased; and more recently, as in the forest of Darnaway, in Scotland, the planter have found the greatest advantage from placing only a handful of lime (about four bushels per acre is sufficient) in the soil under the plants: by this means the young trees, they say, are *forced forward*, that is, they are supplied with the carbonate of lime at the very period of their growth when their roots, from want of extension and vigour, are least able to absorb from the soil the portion of this earth so essential for their healthy growth. And it is precisely such heath soils as those to which I have alluded as being so materially benefited by the application of lime, chalk, or marl (which also contains chalk), that are found when examined, in their natural state, to be nearly destitute of carbonate of lime.

It is for the same reasons that, in the early state of their growth, timber plantations are benefited so materially by being manured with organic matters, a fact well known to those who plant for merely ornamental purposes; and it is because all timber trees contain phosphate of lime in very considerable proportions, that crushed bones are found to be so excellent a fertilizer for them; and hence one reason why it has been long a well-known fact, that by burying dead animals under trees nearly exhausted for want of nourishment, those trees will almost invariably be considerably revived, and send out their shoots with unusual vigour, and how essential the presence of phosphate of lime is to their growth, may be judged of from the fact, that this salt constitutes 4.5 per cent. of the ashes of the oak, 35 in those of the hazel, 16.75 of the poplar, 23 in the hornbeam, 12 per cent. in those of the fir.

These chemical examinations naturally support the conclusions to which I have long come in my own experiments, that in all plantations of timber trees, both on the score of profit and of ornament, it is in almost all situations desirable to assist the growth of the young trees by a small addition of manure. On a large scale this must be chiefly confined to the use of the earths, either lime, chalk, or marl, according to their respective local value; and for this purpose a smaller proportion per acre of any kind of manure is of much greater value than is commonly supposed. In Scotland they have found about 4 bushels of lime an abundant addition, since they merely mix a handful of this earth in the soil under each plant; and in the fine woods produced by Mr. Withers, of Holby spreading a poor marl over his hungry, black, heath soil, and then ploughing them in very deeply, he merely added about 20 cubic yards per acre.

In preparing the land for plantations, the

same chemical examination of its composition well illustrates the advantage derived by the plant from merely previously stirring the soil, since it is evident that when the constituents of the young trees are contained in it in only very limited proportions, in such case the more easily their roots are enabled to penetrate in search of that necessary nourishment, the more rapid will be their growth. Previous trenching of the soil also conduces to the healthy growth of trees in more ways than one. It renders them less subject to injury from want of moisture in the heats of summer; the atmosphere more freely finds access to their roots, and not only yields its watery vapour in the warmest weather for their service, but its gases, so essential to their very existence, are also in a similar manner more readily absorbed.

I have had many occasions to notice the advantages of deeply stirring the land for timber trees. In my early plantings, my larch and other timber trees made but little progress, for I merely placed them in holes dug in the soil; neither manured, nor in any way prepared the soil. An experiment, however, which I made some years since—in which, by merely trenching the soil with the fork in a clump of larch, Scotch firs, and birch, to the depth of about 20 inches, the growth of the trees, which had for several years been extremely slow, was in the succeeding years exceedingly vigorous—convinced me of the truth of the observations made by Sir Henry Steuart, Mr. Withers, and others, of the great advantages of trenching the soil, either by the spade or by the common or the subsoil plough.

The opinions and explanations given by the labouring woodmen of the cause of the occasional very luxuriant patches in extensive young plantations accord with these conclusions. They tell you that those favoured trees are on a *deep, tender* piece of land.

The last branch of the investigation—that of the best mode of planting and of expense—is now to be considered. Too little attention is usually paid by planters in the choice of their plants, the manner in which they have been reared, and in the care of their removal: instead of attending to the acquired habits of the tree, it is a very common practice for the plants to be bought of some nurseryman, who has reared them in a warm, rich bottom, and then, as a natural consequence, when the trees are transplanted to a cold, poor, hungry, exposed soil, a large portion of them are sure to perish, or, if they live, many become stunted or stagg-headed. That all these evils may be avoided with only ordinary care, is proved by the experience of the best planters, who are careful to procure their seedlings from land at least not better than that on which they are intended to be placed; and is further evidenced by the fact that, when the soil is prepared by either deep digging or manuring, or both, then the mortality amongst the plants is very small indeed,—they need no further attention, they usually set at defiance the extremes of heat and cold, are very rarely diseased, and shoot with uncommon vigour. This attention to the early acquired habits of the plant is not entirely a modern observation—the early Italian plant-

ers were careful in replacing the tree in the same position as regards the cardinal points that it occupied in its early growth. (*Virgil, Geo. ii. 269.*)

There are other very common errors, of which I have long noticed the ill effects; for instance, the want of care with which the roots of the young trees are deposited in the earth, and the unnecessary length of time which is suffered to elapse between the period when the plant is taken from the nursery and replanted. I have always found the after good effect of causing the roots of the young plant to be carefully arranged, and spread out before the earth is thrown in upon it; the usually heedless way in which the roots are thrust into the hole, and perhaps broken or materially bruised in the act of treading in the earth upon them, is of necessity very prejudicial to the young plant; and then, again, a still more negligent practice, that of *ploughing in* the young trees, is too often adopted on a large scale, by which the plants are still more hastily deposited in the soil, and are neither fixed with sufficient firmness in the ground, nor even placed in an upright position. From these causes I have witnessed some very decided failures; and there is certainly no economy in this hasty mode of planting; the trees perish in great numbers; they linger for years without vigour; have to be replaced at a considerable expense; and in the mean time the owners lose all the advantages which might have been insured from a more skilfully obtained rapidity of growth.

The grouping or mixture of trees is a question which rarely engages the attention of the planter, although it is certain that, like the commonly cultivated crops of the farmer, some trees grow better when mixed with other kinds than when vegetating in plantations of the same species; that they have certain secretions, and excrete matters, both by their roots and leaves, which are noxious to other trees, is certain. Thus the ash, and more particularly the locust, are very obnoxious to most trees. Then, again, the grouping together of certain trees is particularly grateful to them all. Thus, the larch is a very good neighbour; the Scotch fir, the birch, and the Spanish chestnut grow very luxuriantly with it; the oak, the elm, the hazel, and the hornbeam are evidently good neighbours. The Roman planters had remarked this habit of trees. Thus, they believed that the elm was particularly grateful to the vine; and they were so convinced of the existence of what they called the sympathy between them, that they called the elm the husband of the vine. It was invariably their custom to plant them near each other; and as we are indebted to them for the introduction of the vine into England, so hence, in all probability, came with them our first elm trees.

The expense of these different modes of planting is next to be ascertained; it is an inquiry which will well repay the planter. The favourite mode, that of digging a small hole and inserting the tree, is, apparently, attended with the least outlay of money; in some instances it has been done for 4*l.* or 5*l.* per acre, or even less; but such plantations are very rarely profitable,—the plants die, or bare!

vegetate for years, have to be renewed again and again, and the general appearance of the plantation, overrun with weeds, or heath-moss, or furze, is very melancholy. About 40s. per acre more, bestowed in deep ploughing or subsoiling, will make a strange difference in the rapid growth and consequent early profit of the plantation, and, moreover, save materially the expense of the trees; for the number of them which perish in land thus prepared for their reception is very small.

In a still greater degree are these good results obtained by the addition of say 20 cubic yards per acre of marl, or clay, or a still less quantity of chalk, according to the nature of the soil, or lime, which may usually be procured for an outlay of less than 30s. per acre; or of 2 or 3 tons of well putrefied farm-yard manure, a shovelful under each tree, in the manner I have before described. Now, supposing that even all these preparations of the soil are made, the expense per acre will then, in many situations, stand as follows,—

	£	s.	d.
Ploughing deeply - - - - -	2	0	0
20 cubic yards of marl or clay, or 10 of chalk -	1	10	0
3 cubic yards of dung, at 6s. - - - - -	0	18	0
Trees, ploughing, &c. - - - - -	6	0	0
	10	8	0

Subsoil ploughing will cost from 24s. to 30s. per statute acre.

If the manure is omitted, as well as the earth and the ploughing, the outlay of 5s. per acre in lime, in the way I have noticed, will not be without decided advantage. I am quite convinced, therefore, that if all planters were to confine their operations to a less extent of land, and prepare and plant that ground well, they would reap a much earlier and richer harvest from the money expended than they now do from a much greater extent of ill-planted, exhausted soil. Such are the facts which I have noticed, in my own practice and that of others, as most necessary to be attended to in rearing profitable, luxuriant plantations of timber trees, on the poorest lands of England; hardly any of whose soils, however, are so barren or so elevated as not to be able to produce, with only reasonable care and expense, an ample return for the capital of the planter. It is a pursuit which is, in more respects than one, worthy of the attention of the landed proprietor, since he not only by his plantations adds to the beauty and income of his own estates, but at the same time yields to the community at large great and important services; its barren wastes are made to produce timber and underwood, the soil is gradually rendered fertile, profitable supplies of labour are afforded, its health is promoted, the very climate by a general system of plantations is ameliorated, for its bleak hills are clothed, its stagnant swamps are drained.

There is an excellent paper "On collecting and preparing the seeds of Forest Trees, and mode of sowing them," &c., by Mr. Adam, and other planters. (*Trans. High. Soc.* vol. iii. p. 329.) He advises Scottish planters to collect the seed of the white larch (*Pinus larix*) in November, from trees of 20 to 40 years of age, at an elevation not exceeding 400 feet; that the seed-

bed should be manured with cow dung, well mixed with the soil for some time previously to sowing the seed, which should be in April and May; the beds to be 42 inches in breadth, with intervals of 18 inches. The seed should be sown so that each square yard of ground may produce 2000 plants, which in the first year should reach to a height of 5 or 6 inches. One-third of the plants may be drawn and pricked out in rows at a distance of 10 inches, and the remainder left for another year. The autumn, Mr. Adams thinks, is the best time for forming plantations.

The seed of the Scotch fir (*Pinus sylvestris*) is gathered in the same way, and, to separate the seeds from the cones, it is necessary to kiln-dry them; about 11½ quarters of cones produce about 112 lbs. of seed. The Scotch fir must stand 2 years in the seed-bed. Oaks are to be sown early in February: the best acorns are to be had in Kent, the brightest and heaviest being the most valuable; they keep very well spread on a deal floor; and may be placed in drills a foot apart, 2 inches deep, to be planted out when 2 or 3 years old. Ash keys are gathered in December or January, and laid in heaps mixed with one-third of their bulk of sand under cover; they should be turned over once or twice in the following year, and thus, after resting for 12 or 14 months, are ready for sowing in March, in drills a foot from each other, and 1¼ inches deep. The seed of the Scotch elm is ripe in June, and should be sown soon after; that of the beech is gathered in September, and sown in the following March or April, in drills 1½ inches deep. The seeds of the Spanish chestnut are best procured from Spain: they may be sown in February, in drills 4 inches deep. The horse-chestnut seeds are to be sown in October: those of the weeping birch should be sown as soon as gathered, and covered with earth half an inch deep. Those of the lime should be gathered and sown in October. Poplars are propagated by cuttings.

For a description of the advantages of preparing the land for plantations, I would advise the young planter to consult the works of Mr. Withers, the excellent *Planter's Guide* of Sir Henry Steuart, and the *Journal of the Royal Agricultural Society of England*. And for those who wish to plant in the most simple way at an expense of only 10s. per acre, see a paper by Mr. Grigor. (*Trans. High. Soc.* vol. iii. p. 363.)

By this mode, which consists of merely making a hole, or raising the turf of the ground sufficiently to put in the plants, the estimate is for a Scotch acre (which is equal to 6150 square yards)—

500 one-year transplanted larches - - -	1	9
1500 two-year seedling, do. - - -	3	0
500 one-year transplanted Scotch firs -	0	9
1000 two-year seedling, do. - - -	1	0
Carriage of plants to the moor - - -	1	2
Expenses of planting 3,500 - - -	2	4

Total expense per Scotch acre - - - 10 0

PLANT-LICE.

and gardening. As in the preceding article I have gone very fully into the particulars of planting trees, I shall only add in this place the following useful table, showing the number of plants required for one acre of land, from 1 foot to 21 feet distance from plant to plant.

Distance.		Number.	Distance.		Number.
Ft.	In.		Ft.	In.	
1	0	43,560	8	6	602
1	6	19,360	9	0	538
2	0	10,890	9	6	482
2	6	6,960	10	0	436
3	0	4,840	11	0	361
3	6	3,556	12	0	302
4	0	2,722	13	0	258
4	6	2,151	14	0	223
5	0	1,742	15	0	194
5	6	1,440	16	0	171
6	0	1,210	17	0	151
6	6	1,031	18	0	135
7	0	889	19	0	121
7	6	775	20	0	109
8	0	680	21	0	99

PLANT-LICE. See APHIDIANS.

PLASHING. A mode of repairing or modifying a hedge by bending down a portion of the shoots, cutting them half through near the ground, to render them more pliable, and twisting them among the upright stems, so as to render the whole effective as a fence, and at the same time preserve all the branches alive. For this purpose the branches to be plashed or bent down must not be cut more than half through, in order that a sufficient portion of sap may rise up from the root to keep alive the upper part of the branches. Where hedges are properly formed and kept, they can very seldom require to be plashed; but this mode of treating a hedge is most valuable in the cases of hedges abounding with hedge-row trees, when from neglect, or from any other cause, the hedge has become of irregular growth. See HEDGES.

PLASTER OF PARIS, or GYPSUM. One of the common names of the sulphate of lime or plaster stone, which is found abundantly near Paris. When burnt and reduced to powder, and then mixed with water, it forms a firm, sonorous substance, admirably adapted for forming models and casts.

PLASTER OF PARIS OF GYPSUM, AS A MANURE. It is useless to search in the works of the early agricultural writers for any notice of the employment of gypsum as a manure. It is true that Virgil speaks of the value of a very impure variety of it, when he is commending the use of ashes to the Roman farmers. The early inhabitants of Britain thus used it; the farmers of Lombardy did the same; but ages elapsed before even chemists were able to distinguish this salt from limestone, or other calcareous matter. Its uses, in its simple state as a manure, were first noticed, according to Kirwan, about the middle of the 18th century, by a very able German clergyman, of the name of Meyer, who tried with success various experiments with a mineral substance found in his neighbourhood, which was long afterwards shown to be an impure sulphate of lime. The name of plaster of Paris, by which this substance is commonly known, arose from its abounding in the neighbourhood of that capital, where it was burnt into a powder, and used as a stucco. The composition of sulphate of lime, when pure, is—

PLASTER OF PARIS.

	Parts
Sulphuric acid	43
Lime	33
Water	24
	<hr/> 100

But the gypsum of commerce is usually united with a portion of silica and carbonate of lime. It is thus combined in its native state. According to Chaptal and Buchholz, gypsum consists of—

	Parts.
Sulphuric acid	32 or 43
Lime	30 or 33
Water	38 or 21

There is, perhaps, no artificial manure so decided in its effects upon some soils, so readily obtainable by the farmer, and so plentiful, as gypsum. Its mode of action, too, is now easily understood. It acts as a direct food for some plants. There are five commonly cultivated crops which contain gypsum in sensible proportions, and to which, in consequence, it is a direct food, viz., lucern, sanfoin, red clover, rye-grass, and turnips. Now, these are precisely the crops to which the farmer finds, on most soils, gypsum to be a fertilizing top-dressing. Wheat, barley, oats, beans, and peas, do not contain a trace of this salt; and the farmer tells you that gypsum is of little or no service to these crops, however the application may be varied. That it does not operate by its attraction for atmospheric moisture, I some time since determined by my own experiments; for 1000 parts, previously dried, when exposed to air saturated with moisture for 3 hours, only gained 9 parts, while under the same circumstances a good arable soil, worth 2 guineas per acre, gained 14 parts; and when compared with other manures, the disproportion is still greater: thus soot gained 36 parts, and horse-dung 145 parts. That it is not a promoter of putrefaction, I have ascertained by mixing this salt with various animal and vegetable substances; it seemed, in every case, rather to retard than promote the spontaneous decomposition of them all. The housewives consider *hard* water, which commonly owes its properties to the presence of this salt, to be a greater sweetener of tainted food than soft water. Davy, also, in some experiments with minced veal, thought that the addition of the gypsum rather retarded putrefaction.

There is no reason to believe that the proportion of sulphate of lime found in certain plants is as essential to their growth as the presence of the other earthy salts and pure earths. Thus, those plants which yield this salt never grow well on lands which do not contain it; those in which carbonate of lime is found never flourish in soils from which this salt is absent. Plants which abound with nitrate of potash (saltpetre), such as the sunflower and the nettle, always languish in soils free from that salt; but when watered with a weak solution of it, their growth is very materially promoted, and the saltpetre is then found in them, as shown, upon analysis, in very sensible proportions. The same remarks apply to the growth of those plants which contain common salt, or phosphate of lime; the effect is the same, the result invariable.

Liebig contends that the nature of gypsum consists in its giving a fixed constitution to the nitrogen, or ammonia, which is brought into the soil, and is indispensable for the nutrition of plants. He says, that 100 lbs. of gypsum give as much ammonia as 6250 lbs. of horses' urine would yield it: 4 lbs. of gypsum, he affirms, increase the produce of the meadow 100 lbs. The decomposition of gypsum is slow, which, he says, explains the reason why the action of gypsum lasts for several years. See AMMONIA.

I have noticed, in applying gypsum to grasses, that the weather, at the time of spreading it, has a very material influence upon the result of the experiment. Its effects are never soon apparent when it is sown in dry weather; but if the season is damp, so that the white powdered gypsum adheres to the leaves and stalks of the young grass, the good effect is then immediate. This observation was made many years since by Arthur Young, by Mr. Smith, and by the American farmers: it is a well-known fact with the sainfoin growers, of the Berkshire and Hampshire chalk formation; the clover cultivators of the gravels and loams of Surrey and Kent; and on the lucern grounds of the alluvial soils of Essex and Middlesex. The farmers of the United States, when dressing their clover or turnips with gypsum, always found it answer best when spread in rainy weather.

The result of the analysis of the clover and sainfoin grasses shows that an ordinary crop of these usually contains from $1\frac{1}{2}$ to 2 cwt. per acre of sulphate of lime. Now, this is precisely the proportion of gypsum which the best cultivators find to be attended with the maximum benefit; those of Kent and Hampshire find it useless to apply more; but then they all agree that the annual repetition of the dressing, as long as the grass is suffered to remain on the ground, is attended with renewed benefit. It is here again that the experiments of the chemist and the farmer mutually confirm and illustrate each other; the very quantity of sulphate of lime which the first shows to be carried off the land in the clover, is precisely that which the latter returns to it in his dressings with gypsum.

One of the chief reasons why gypsum has not been universally employed by all cultivators of the artificial grasses, arises perhaps from the fact that many good soils naturally contain sulphate of lime in sufficient abundance for the service of the plant; and, in consequence, to such lands the application of gypsum is useless—it is an attempt to supply a deficiency which does not exist. I have invariably found in those soils to which gypsum is not a manure an abundance of this salt. It is not, however, necessary for the farmer to have his soil analyzed to determine the probable advantages of applying gypsum to his clover and other grasses; there are several easy observations which will readily indicate to him the nature of the case. Thus, when he finds that those fields which once produced luxuriant crops of red clover or sainfoin will no longer yield them in abundance; if he notices that the young plants spring up very numerous, but

die away, as the summer advances; if he finds that his fields will only grow clover successfully once in 8 or 12 years, and that his neighbours tell him his land is tired of clover, or "clover-sick;" if he notices that even the application of farm-yard compost hardly adds to the luxuriance of his grasses; he may then safely conclude that his crops have gradually exhausted his land of sulphate of lime; and he may, with every confidence of success, apply a dressing of gypsum, at the rate of 2 cwt. per acre, taking care to choose a wet morning for the application; and this may be done at any season of the year, but it is best either in April or the first days of May. These facts I can attest from the results of my own observations and experience. In an old grass paddock, of about 70 acres, in the vale of Kennett, in Berkshire, the grass had for many years gradually become less and less productive, and this in spite of all kinds of applications; the earths (such as clay and chalk), farm-yard compost, &c., had been liberally and repeatedly spread, without producing any thing like a luxuriant crop: but it was found at last that the peat ashes of the banks of the Kennett, when spread at the rate of about 40 bushels per acre, produced the very best results, an excellent crop, both in weight and in colour; certainly more than a ton of hay per acre beyond what the soil yielded before. The fact was now evident that it was gypsum that the soil needed; for as these peat ashes contain about $12\frac{1}{2}$ per cent. of sulphate of lime, more than 2 cwt. of gypsum was conveyed into the land in them; it constitutes, in fact, by far the chief fertilizing ingredient in these peat ashes, the remainder being about 40 per cent. of sand, and the rest chalk, red oxide of iron, and a small quantity of common salt.

If this conclusion, therefore, was correct, as to the gypsum being the only valuable portion of the peat ashes, it was certain that an application of 2 cwt. per acre of gypsum to the same land would produce similar beneficial results; and, upon a trial, it was found that benefits fully equal to any yielded by the application of the peat ashes resulted. 2 cwt. per acre of gypsum, in fine powder, was spread on a portion of the grass with the most excellent effect: the grass not only grew with greatly increased vigour, but a quantity of white clover and other grasses made their appearance on the portion dressed, in so marked a manner as to attract the attention of the tenant to the fact. The soil on which these experiments were tried consists of—

Organic matter, chiefly vegetable	-	-	3.5
Soluble matters	-	-	3
Carbonate of lime and magnesia	-	-	19
Oxide of iron	-	-	2.75
Alumina	-	-	8.5
Sand and gravel	-	-	62

98.75

This is about 10 inches deep, and it rests on a thin stratum of gravel and thin chalk.

There is another fact which clearly supports these conclusions, viz., the great use of common coal-ashes as a top-dressing to clover, sainfoin, and lucern; there is no manure uni-

versally in the possession of the farmer, in fact, equal to them for immediate effect upon those grasses. Now, coal-ashes usually contain about 10 per cent. of sulphate of lime; and, therefore, a dressing with 50 bushels of coal-ashes per acre is equal to an application of about 5 bushels of gypsum; the remaining portion of the ashes consists principally of about 10 per cent. of lime and sand, and a small portion of red oxide of iron and alumina: so that the gypsum is here again evidently the active ingredient—the other constituent parts being nearly inert substances. My own experiments and observations have been confirmed by many others within the last two years, for gypsum is evidently creeping gradually into use as a manure for the grasses.

In England, the expense of the application of the gypsum is about 7s. per acre; this substance being usually sold in London for about 2l. 10s. per ton—at Reading and Southampton at 1s. 9d. per bushel. In the midland counties it may be had at a still more reasonable rate; thus, in Derbyshire, it is so plentiful that the farmers' cheese-room floors are commonly formed with it; it abounds, too, in the north of England. The comparative produce of the gypsumed over not-gypsumed land is very great; it of course varies in amount. I have seen it double the produce of clover hay, and give an equally copious crop of lucern; but this last I invariably cut green for soiling.

Mr. Smith, of Highstead, found still greater benefit from the use of gypsum to his clover leys; for where the simple soil produced 1 ton only per acre of hay, the portion of the same soil to which 5 bushels per acre of gypsum had been applied yielded 3 tons; the first yielding only 20 lbs. of seed, while the latter produced 105 lbs. Mr. Smith, too, first noticed—what my own observations have confirmed—that cattle, horses, &c., always prefer the grass growing on the gypsumed portion of the field to any other. The same remark is made by those who spread coal-ashes on their grass leys: the peat-ashes of Berkshire produce the same effect.

The general introduction, then, of gypsum, as a top-dressing for the artificial grasses which I have mentioned, is certainly an object of no mean interest to the farmer, especially if he cultivates the poor inland soils of England, where artificial manures are scarce, and the carriage of even the most portable is expensive; for gypsum possesses, in this respect, two advantages combined, which do not belong to any other, even of the saline manures: its first cost is trifling, and its carriage light, since a wagon will convey sufficient gypsum to dress 30 acres of grass.

PLASTER FOR TREES. See **CANKER**.

PLASTIC CLAY. Clay used in the manufacture of pottery.

PLATYPHYLLUM CONCAVUM, or **KATY-DID**. A kind of grasshopper found in the United States. Dr. Harris, who was the first to give a scientific description, has called it *Platyphyllum concavum*. The front of its head is obtuse, body of a pale-green colour, the wing-covers and wings being somewhat darker. Its thorax is rough like shagreen. The musi-

cal organs of the male consist of a pair of taborets, formed by a thin, transparent membrane, stretched in a strong half-oval frame in the triangular overlapping portion of each wing-cover. During the daytime these insects are silent, and conceal themselves among the leaves of trees; but at night, they quit their lurking-places, and the joyous males begin the tell-tale call with which they enliven their silent mates. This proceeds from the friction of the taboret frames against each other when the wing-covers are opened and shut, and consists of two or three distinct notes, almost exactly resembling articulated sounds, and corresponding with the number of times that the wing-covers are opened and shut; and the notes are repeated, at intervals of a few minutes, for hours together. The mechanism of the taborets, and the concavity of the wing-covers, reverberate and increase the sound to such a degree, that it may be heard, in the stillness of the night, at the distance of a quarter of a mile. At the approach of twilight the katydid mounts to the upper branches of the tree in which he lives, and, as soon as the shades of evening prevail, begins his noisy babble, while rival notes issue from the neighbouring trees, and the groves resound with the call of "katy did, she did," the live-long night. From the head to the end of the wing-covers, this insect measures rather more than $1\frac{1}{2}$ inch, the body alone being 1 inch in length. The piercer is broad, laterally compressed, and curved like a cimex; and there are, in both sexes, two little thorn-like projections from the middle of the breast between the fore-legs. It is found in the perfect state during the months of September and October. (Harris.)

PLEASURE-GROUND. That portion of ground adjoining a dwelling-house in the country; and which is exclusively devoted to ornamental and recreative purposes. In the ancient style of gardening, the pleasure-ground was laid out in straight walks, and regular or symmetrical forms, commonly borrowed from architecture; but in the modern style, it is laid out in winding walks, and in forms borrowed direct from nature. A portion of lawn or smooth grassy surface may be considered as essential to the pleasure-ground under both styles. See **GARDENING, LAWN, and PARTERRE**.

PLOUGH. (Sax. *Plou*; Dan. *Ploegh*.) A well-known, perhaps the most ancient, certainly the most valuable of all agricultural implements. There are traces of it in even the earliest of all written authorities, and, judging of its importance in agriculture, we can hardly imagine it possible to carry on extensive systems of cultivation in any period or country without its assistance. By consulting the sacred records, we find, that in very early times they ploughed with two oxen (*Deut.* xxii. 10), that their plough had a coulter and plough-share (*1 Sam.* xiii. 20), and that they were early aware of the advantages of a winder's fallow (*Prov.* xx. 4). It is certain that their ploughs were long since furnished with wheels; a fact which is proved by the drawings on the early Greek ploughs which have escaped to us.

Hesiod (*Works and Days*, p. 50—441) advised the Greek farmers to have a spare plough, that

an accident might not interrupt the work; and he also enforces the advantages of careful and skilful ploughing.

The ploughs of Rome were of the most simple form, as may be inferred from ancient drawings. See AGRICULTURE.

Rivalling these in simplicity and rudeness of form, are the never altered or improved ploughs of the Hindoos and the Chinese, from whose implements it is probable the shape of those of Rome was borrowed.

The object sought to be effected by means of the plough, is exactly the same as that accomplished in the primitive ages by the spade. The addition of cattle to force the plough in the operation of breaking up the ground, leads to complexity. But although the spade is an implement of such great simplicity, the act of digging with it exacts a great deal of individual exertion, almost every muscle of the body being called into play in alternately pushing and lifting. In this respect the modern improved plough possesses great advantages in being propelled by animals and directed with very little individual muscular exertion.

It is curious to trace the progress of plough-making in England. Those of the early cultivators were of necessity rude and imperfect, for in those days the ploughman made his own plough. A law of the early Britons in fact directed that no one should guide a plough until he was able to make one. The driver was, by the same law, to make the traces by which it was drawn, and these were to be formed of withes of twisted willow; a long-exploded custom; many of the olden terms of which, however, are still retained by the rustic ploughmen. Thus the *womb-withy* is yet called the *wambtye* or *wantye*. *Withen* trees are denominated *witten trees*, or *whipple trees*, &c.

It is uncertain whether the early British ploughs had wheels; some of those of the Saxons were certainly furnished with them. Yet it is pretty certain that they used ploughs of a form rivalling those of modern India in simplicity; a rude sketch of one of these is given in a Saxon MS. (*Harl. MS. 603*), from which it would seem that our Saxon forefathers were wont to fasten their horses to the plough by their tails; a barbarous custom, which certainly was formerly practised in Ireland to such an extent that the legislature interfered in 1634, and declared by the 11 & 12 Car. II. c. 15 (Irish Parl.), entitled "An act against ploughing by the Tayle, and pulling the Wool off living Sheep," that "in many places of this kingdome there hath been a long time used a barbarous custome of ploughing, harrowing, drawing, and working with horses, mares, geldings, garrans, and colts by the taile, whereby (besides the cruelty used to the beasts) the breed of horses is much impaired in this kingdome. And also divers have and yet do use the like barbarous custome of pulling off the wool yearly from living sheep, instead of clipping or shearing of them." These wretched practices are then declared illegal, and to be punishable with fine and imprisonment.

The Norman plough was also furnished with wheels, and it was usual for the ploughmen to carry a hatchet to break the clods, as is de-

icted in an ancient picture from whence the sketch at page 41 is engraved.

It is pretty certain that the ox was at first, and for a lengthened period, the only animal employed to draw the plough. Thus, although the plough and oxen are so frequently mentioned in conjunction in the Bible, the horse is never alluded to for such an occupation: an old British law forbade the use of any animal except the ox for this purpose. The first representation, of which I am aware, observes Mr. J. A. Ransome, of a horse employed in the plough, is that given (A. D. 1066) in the tapestry of Bayeux.

There are evident traces in the early English agricultural authors of the importance which they ascribed to the improved construction of the plough. This implement, however, was long drawn entirely by oxen in Britain.

Fitzherbert, in his *Boke of Husbandrye* (1532), speaks in a manner that shows that even in his day plough-horses were not generally employed; he observes, "a husbände may not be without horses and mares, and especially if he goe with a horse-plough." Worlidge, in his *Mystery of Husbandry*, describes (A. D. 1677) very clearly the first rude attempt to construct a sub-soil plough: he tells us, p. 230, "of an ingenious young man of Kent, who had two ploughs fastened together very firmly, by the which he ploughed two furrows at once, one under another, and so stirred up the land 12 or 14 inches deep. It only loosened and lightened the land to that depth, but doth not bury the upper crust of the ground so deep as is usually done by digging." When Heresbach wrote (1570), it was not uncommon in some of the warmer parts of Germany and Italy to plough during the night, "that the moisture and fattness of the ground may remain shadowed under the clodde, and that the cattell through overmuch heate of the sunne be not diseased or hurt." (31 b.) Jethro Tull, more than a century since, paid considerable attention to the plough; he had even searched into the early history of this implement, and concluded that it was "found out by accident, and that the first tillers (or ploughers) of the ground were hogs." (*Husb. p. 131.*) The ploughs which he describes, and of which he gives drawings, were evidently (although rudely and heavily constructed) superior in several respects to all that had preceded them.

It is not necessary to do more than thus slightly advert to the various notices which are to be found in the early histories and pictures of this invaluable implement; for, in fact, for ages the plough was little more than a rude, clumsy instrument, which served only to rake the surface, instead of making furrows in the land sufficiently deep for the seeds to be buried. It was not brought to any thing like a perfect tool for the purposes required till the close of seventeenth century.

The plough, being the fundamental implement of agriculture, common to all ages and countries, its primitive form is almost everywhere the same. The forms used by the Greeks and Romans (see AGRICULTURE) seem to have spread over Europe, and undergone no change till probably about the sixteenth century, when

they began to be improved by the Dutch and Flemish. In the seventeenth century the plough underwent further improvement in England; and it was greatly improved in that following, in Scotland. There are now a great variety of excellent forms, the best of which, for general purposes, is, in Britain, universally allowed to be what is called the Scotch plough, and in Scot. and the improved Scotch plough. In speaking of the implement we shall adopt the latter term, because the unimproved Scotch plough differs little from some old forms of the implement common to Europe from the time of the Romans. As the operation of ploughing, like many other operations in practical husbandry, must often vary in the manner of its being performed, it is evident that no one particular sort of plough can be superior to all others, in every season, and under every variety of soil or inclination of surface. The Scotch plough, however, and the variations of which it is susceptible, render it perhaps the most universal tillage implement hitherto invented or used.

In Britain ploughs are classed into two kinds: those fitted up with wheels, and called wheel-ploughs; and those without wheels, called swing ploughs. The latter are the lightest of draught, but require an experienced and attentive ploughman to use them; the former work with greater steadiness, and require much less skill in the manager: some sorts, indeed, do not require holding at all, excepting at entering in, and turning on and off the work at the ends of the ridges. On the whole, taking ploughmen as they are, and ploughs as they are generally constructed, it will be found, that a district ploughed with wheel-ploughs will show greater neatness of work than one ploughed with swing ploughs: but, on the other hand, taking a district where the improved form of swing ploughs is generally adopted, the ploughmen will be found superior workmen, and the work performed in a better manner, and with less expense of labour, than in the case of wheel-ploughs.

In the construction of ploughs, whatever be the sort used, there are a few general principles that ought invariably to be attended to; such as the giving the throat and breast, or that part which enters, perforates, and breaks up the ground, that sort of long, narrow, clean, tapering, sharpened form that affords the least resistance in passing through the land; and to the mould-board, that kind of hollowed-out and twisted form, which not only tends to lessen friction, but also to contribute greatly to the perfect turning over of the furrow-slice. The beam and muzzle should likewise be so contrived, as that the moving power, or team, may be attached in the most advantageous line of draught. This is particularly necessary where a number of animals are employed together, in order that the draught of the whole may coincide.

Land, when properly ploughed, must be removed from a horizontal position, and twisted over to a certain angle, so that it may be left in that inclining state, one furrow leaning upon another, till the whole field be completely ploughed. The depth and width of the furrows

which is most approved of by farmers, and commonly to be met with in the best-ploughed fields, are in the proportion of 2 to 3; or, if the furrow be 2 deep, it must be 3 wide, and left at an angle of 45 to 46 degrees.

Various forms have been given to the different parts of the plough, by ingenious persons, according to their different fancies, in order to diminish the weight of the draught, and to turn over the furrow, and leave it in its proper position, without tearing or breaking it.

To have the line of draught at right angles to the horses' shoulders is of great importance in the formation of a plough; a circumstance of which the greatest part of the plough-makers are totally ignorant, although it is well known to every one that has the least knowledge of mechanics. If we take the angle that the horses' shoulders make with a perpendicular from the horizon, and continue another line at right angles to it, or parallel to the draught chain; the length of this line from the horses' shoulders to where it meets or crosses the coulter, at half the depth of the furrow, will be 13 feet 2 inches for ordinary sized horses.

Length of beam.—If the plough be properly made, the line of draught should pass through the middle hole of the plough bridle at the point of the beam. This requires the beam to be 7 feet long, to give it a proper height at the bridle.

Left side plane.—That part of the plough next the solid land should be made a perfect plane, and run parallel to the line of draught; whereas some of the common ploughs are completely twisted in that part, and deviate more than 2 inches from the line of draught; this throws the plough to the left, and causes the hinder part of the mould-board to press hard against the furrow, and crush and break it, besides increasing the labour of the cattle.

The position of the coulter must not deviate much from an angle of 45 degrees: for, if we make it more oblique, it causes the plough to choke up with stubble and grass roots, by throwing them up against the beam; and, if less oblique, it is apt to drive the stones or other obstacles before it, and make it heavier to draw.

The *mould-board*, for all free soils, and for working fallows, is generally most effective when it has a considerable concavity; but for breaking up clover leys, pasture, or any firm surface, and also for clayey soils, it is found to clean itself better and make neater work when it approaches nearer to a plane, and in very stiff clays, is formed with a concave surface. The lower edge of the mould-board, on the most improved forms, is in a separate piece, which, when it wears, can be taken off and renewed. The technical name of this slip of iron is the *wearing-piece*.

The *materials* with which ploughs are constructed is, generally, wood for the beam and handles, cast iron for the head, side-plates, mould-board, and sole, and wrought iron for the share, coulter, and muzzle. But of late years, in consequence of the dearness of timber, and the cheapness of iron in Britain, they have been constructed wholly of the latter material, and with considerable advantage in point of

strength and durability, and some also in point of convenience. Among the conveniences may be mentioned, the facility which they afford of bending the left handle to the right of the straight line first introduced by Mr. Wilkie of Uddingston (who, if not the inventor, may certainly be considered the greatest improver of iron ploughs,) by which means the ploughman is permitted to walk with ease in the bottom of the furrow. The stilts or handles may also be joined to the body of the plough, in such a way as to admit of taking off and packing for a foreign country, or raising or lowering the points of the handles according to the size of the ploughman, as in Weatherley's plough.

A wooden Scotch plough with iron mountings, says Mr. Stephens, usually weighs 13 stones imperial, and an iron one for the same work 15 stones. The cost of a wooden one is 3*l.* 16*s.*, capable of being serviceable, with repairs, for the currency of a lease of 19 years; that of an iron one 4*l.* 4*s.*, which will last a lifetime, or at least many years. Some farmers, however, still prefer the wooden one, alleging that it goes more steadily than the iron. Whatever of prejudice there may be in this predilection for the wooden plough, it must be owned that the iron one executes its work in a satisfactory manner. There is, I believe, no great difference of economy in the use of the two kinds of ploughs. (*Stephens.*)

Of *swing ploughs*, says Loudon, by far the best is the implement known in England as *the Scotch plough*. It is almost the only plough used in Scotland, and throughout a considerable part of England; it is drawn with less power than wheel-ploughs, at least, those of the old construction, the friction not being so great; and it probably admits of greater variations in regard to the breadth and depth of the furrow-slice. It is usually drawn by two horses abreast in common tillage; but for ploughing between the rows of the drill culture, a smaller one drawn by one horse is commonly employed. A plough of the swing kind, having a mould-board on each side, is also used both in forming narrow ridges for turnips and potatoes, and in laying up the earth to the roots of the plants, after the intervals have been cleaned and pulverized by the horse and hand-hoe. This plough is sometimes made in such a manner that the mould-board may be shifted from one side to the other when working on hilly grounds; by which means the furrows are all laid in the same direction.

Swing ploughs, similar to the Scotch plough, have been long known in England. In Blythe's *Improver Improved* we have engravings of several ploughs; and what he calls the "plain plough" does not seem to differ much in its principal parts from the one now in use. Amos, in an *Essay on Agricultural Machines*, says, that a person named Lummis (whom he is mistaken in calling a Scotchman) "first attempted its construction upon mathematical principles, which he learned in Holland; but having obtained a patent for the making and vending of this plough, he withheld the knowledge of these principles from the public. However, one Washley, plough-wright to Sir Charles Turner

of Kirkleatham, having a knowledge of those principles, constructed upon them a vast number of ploughs. Afterwards his son established a manufactory for the making of them at Rotherham. Hence they obtained the name of the Rotherham plough; but in Scotland they were called the Dutch or patent plough." Plate 17, *a*, represents a Rotherham plough constructed chiefly of wood. The Americans have claimed the priority of the invention; and President Jefferson, of the United States, presented the principles for the construction of a mould-board, first to the Institute of France, and next to the Board of Agriculture in England.

The *Scotch plough* was little known in Scotland till about the year 1764, when Small's method of constructing it began to excite attention (*Small's Treatise on Ploughs and Wheel Carriages*, 1784; and *Lord Kaimes's Gentleman Farmer*). This ingenious mechanic formed the mould-board upon distinct and intelligible principles, and afterwards made it of cast iron. His appendage of a chain has been since laid aside. It has been disputed, whether he took the Rotherham, or the old Scotch plough, for the basis of his improvements. The swing plough has been since varied a little, in some parts of Scotland, from Small's form, for the purpose of adapting it more completely to particular situations and circumstances. Since 1810, this plough has been very generally made entirely of iron. In Northumberland, the mould-board is made less concave than in Berwickshire, and in Berwickshire it is even less concave than in Small's plough. Different degrees of concavity in the mould-board suit different soils: soft and sandy soil requires most, and a loamy or clayey soil least concavity. The following are the principal varieties of the improved Scotch plough at present in use in the most improved districts of the north, and among scientific farmers in all countries.

Small's plough.—The mould-board is more concave than in most other varieties, and this may be considered its characteristic as compared with these varieties. It is sometimes drawn by a chain proceeding from the muzzle to the head; in order to lessen the strain on the draught-beam, and in that case it is called Small's chain-plough. It is commonly made of wood and iron. Pl. 17, *b*. For a design of the East Lothian plough, or Small's improved, see Pl. 17, *c, d*, the figures representing two views.

In this plough the proper lines of the body on the land-side lie all in one plane, which, in working, should be held in the vertical position, or very slightly inclining to the left. The coulter slightly oblique to the land-side plane, the point standing towards the left, the rake of the coulter varies from 55° to 65°. In the mould-board the vertical sectional lines approximate to straight lines, giving the character of apparent concavity, and it is truncated forward. Share pointed, with a feather or cutter standing to the right, having a breadth of at least $\frac{2}{3}$ the breadth of the furrow, the cutting edge of the feather lying nearly as low as the plane of the sole. The neck of the share is prolonged backward, joining and coinciding with the curve of the mould-board, which curvature is also carried forward on the

back of the feather. The character of this plough is to take a furrow of 10 inches in breadth by 7 inches in depth, cut rectangular, leaving the sole of the open furrow level and clean. The resistance to the draught is generally below the average of ploughs, and this plough is employed for every kind of soil. The improved English swing plough, as made by Ransom, is represented in Pl. 17, e.

The *Northumberland plough*, and the *Berwickshire plough*, are very nearly the same implement; differing from Small's plough in having the mould-board less concave.

Wilkie's swing plough, which Loudon says is the best iron swing plough in Scotland, is formed entirely of iron, except the points of the handles. Its characteristic, in point of form, is a longer mould-board with a greater twist in it, the object of which is to reverse the furrow more completely in light or highly pulverized soils.

Finlayson's iron ploughs are, as he informs us (*British Farmer*, p. 9), constructed in imitation of those of Wilkie, but with improvements and modifications adapted for particular circumstances.

The *heath or self-cleaning plough*, or *rid plough*, is formed with the beam so curved vertically, or divided and curved horizontally, as to leave no resting-place for stubble, heath, or other vegetable matter, at the top of the coulter, where in rough grounds, with ploughs of the ordinary construction, it gets entangled and stops the work.

Finlayson's Kentish skeleton self-cleaning plough (Pl. 17, f) is intended as a substitute for the common Kentish turn-wrest plough. "The soil, in great part of Kent, is of a peculiarly adhesive clay. When this soil is between the wet and dry, it adheres to the body of the plough like glue, by which the draught is increased probably double or treble." By substituting 3 or 4 iron rods for the mould-board, the soil is prevented from adhering, while the operation of ploughing is at the same time performed in an equally perfect manner with two horses as with four. This is accounted for "by the whole surface of this plough not being more than one-third or one-fourth the surface of other ploughs." In like manner, when it is necessary to dig or trench very strong clayey soil between the wet and the dry, the operation is performed with much greater ease by a two-pronged fork. It is important to agriculturists to know the opinion and experience of a man of so much science and extensive practice as the late Mr. Finlayson, who says, "from my own experience I have no hesitation in saying that the most adhesive land may, with ease, be ploughed by the skeleton plough and one pair of good horses."

Finlayson's line plough is characterized by a rod which proceeds from the sheath of the plough to the muzzle, which is put on when the plough is drawn by horses in a line—a very disadvantageous manner, but yet common in many parts of England.

The *Somerville swing plough* is known by its mould-board, a part of which is rendered movable by hinges; the advantage of this is, that the furrow can be laid more or less flat at

pleasure. This plough, however has been but little used, and does not seem to meet the approbation of the best cultivators.

Turn-wrest swing ploughs are such as admit of removing the mould-board from one side to another at the end of each furrow, for the purpose of throwing the earth removed always to one side. Their principal use is in ploughing across steep declivities, in order that the furrow-slice may always be thrown down. Wherever it is practicable, however, it is best to plough obliquely up and down such declivities; because the other practice soon renders the soil too rich and deep at bottom, and too thin and poor at top.

Gray's turn-wrest swing plough is one of the most scientific implements of the kind. The beam, head, and sheath, must always be placed in the direction of a line passing along their middle; and the two handles must be placed equidistant on each side of that line. There are two mould-boards and two coulters, and a mould-board is produced on either side, at pleasure, by moving a lever between the plough handles from the one side to the other. The line of draught can be shifted with equal ease and expedition, and at the same time one of the coulters raised up clear of the land, and placed along the side of the beam, whilst the other is put down, and placed in a proper position for cutting off the furrow-slice from the furrow-ground. All this is performed at once, without the ploughman changing his position, by means of two levers.

A *skim-coulter* (Pl. 17, m, m) may be added to any plough, and may be useful in turning down green crops and long dung, as well as in trench ploughing. But in most instances it is thought a preferable plan, where the soil is to be turned to an unusual depth, to make two common swing ploughs follow each other in the same track; the one before taking a shallow furrow, and the other going deeper, and throwing up a new furrow upon the former.

The *double share plough* is distinguished by having one share fixed directly over the other. It is made use of in some of the southern districts of England with advantage, in putting in one crop immediately after ploughing down another; as by it a narrow, shallow furrow is removed from the surface, and another from below placed upon it, to such depth as may be thought most proper,—it being capable of acting to 10 inches or more. In this manner many sorts of crops, such as rye and other green crops that have much height of stem, may be turned down without the inconvenience of any of the parts sticking out through the seams of the furrow-slices, by which the farmer has a clean surface of mould for the reception of the grain.

The *mining plough*, or *trenching plough*, is sometimes employed for the purpose of loosening the soil to a great depth, without bringing it up to the surface; a mode of operation which is particularly useful for various sorts of tap-rooted plants, as well as for extirpating the roots of such weeds as strike deep into the ground. For these purposes it may be employed in the bottom of the furrow after the common plough. It is constructed in a very

strong manner, having a share, but no mould-board. The share raises the earth in the bottom of the furrow, and, passing on under what it has raised, leaves the soil where it was found, but in a loosened state. See **SUBSOIL PLOUGH.**

Somerville's double-furrow plough is obviously advantageous in performing more labour in a given time, with a certain strength of team, than other sorts of ploughs, as producing two furrows at a time. It has been found useful on the lighter sorts of land, where the ridges are straight and wide, though some think it more confined in its work than those of the single kind. The saving of the labour of one person, and doing nearly double the work with but little more strength in the team, in the same time, recommend it for those districts where four-horse teams are in use. This plough has been brought to its present degree of perfection by Lord Somerville, especially by the introduction of movable plates at the extremities of the mould-board, as in his lordship's single plough. But, as observed by an excellent authority, "with all the improvements made by Lord Somerville, it can never come into competition, for general purposes, with the present single-furrow ploughs." Lord Somerville admits, that it would be no object to invade the system already established in well-cultivated counties; though, where large teams are employed, with a driver besides the ploughman, it would certainly be a matter of importance to use this plough, at least on light, friable soils. "Their horses," he says, "will not feel the difference between their own single furrow, working one acre, and the well-constructed two-furrow plough, with two acres per day; here is no system deranged, and double work done." This plough is also of particular value for ploughing up and down steeps.

The Argyleshire plough differs from Small's, or any single swing plough, in having no coulter fixed in the beam, but, in lieu of this, a fin or knife rising from the left side of the share, which serves the purpose of slicing off the furrow as well as a coulter. This fin or feather must be placed at the same angle as the coulter, and should terminate in a lance-like shape, in order to furnish the least obstruction to stubble, weeds, or stones. This plough is not liable to be choked by stubble, or thrown out by catching small stones between the points of the coulter and sock. In point of draught it is precisely the same as the common plough.

The double mould-board plough is a kind of plough often used with advantage in clearing out furrows, in setting potatoes, cabbages, and other similar crops, and in earthing up such as are planted in wide rows. Those whose mould-boards move on hinges, and may be set wide or narrow at pleasure, are the most convenient. A variety of this plough, made by Weir of London, admits of removing the mould-boards, and fixing in curved coulters and hoes, for cleaning between drilled turnips and similar crops.

The binot is almost the same thing as the double mould-board plough, and the one is commonly sold for the other, with no loss to the

purchaser. It has two mould-boards, one on each side of the beam. It is used in some soils in forming a ribbed or ridged bed for wheat or other grains; by which means, when the grain is sown over the ribs or ridgelets in the broad cast manner, as it falls for the most part into the furrows, or is harrowed into them, it comes up in rows. It is also used in earthing up crops; and sometimes in Flanders, but never by the best cultivators in England, in giving the first furrow to stubbles.

The marking plough is used in straightening and regulating the distance of ridges where the drill system is practised. Any plough with a rod fixed at right angles to the beam, and a short piece depending from this rod, will trace a line parallel to the furrow drawn by the plough, which line will serve for a guide as to the width of ridges, &c.

Clymer's plough is a recent modification of the implement, formed entirely of iron, and chiefly remarkable for the absence of the coulter, or rather its attachment to the breast, and for the share, mould-board, and other parts which move under ground, being composed of distinct pieces of cast-iron. This is considered as cheaper to commence with and easier to repair, because any one part may be renewed of the same material without deranging the rest; whereas renewing or repairing wrought-iron shares, mould-boards, or coulters, is found in many districts both difficult and expensive. It has never come into use in England.

Stothard's plough is characterized by a perforated mould-board. The holes may be in any form or dimensions; and their object is to allow the air to pass through, and thereby prevent the adhesion of wet earth, which it is contended adheres in ordinary ploughs with such a degree of tenacity as greatly to increase the friction, and diminish the speed of the horses.

Morton's trenching plough has two bodies, the one working 4 or 6 inches deeper than the other. The first cuts or pares off the surface to the required depth, say 5 inches, and turns it over into the furrow, 10 or 12 inches deep, made by the main body. The second body generally works from 10 to 12 inches deep, but might be made to work to the depth of 13 or 15 inches; upon its mould-board is formed an inclined plane, extending from the back part of the feather of the sock or share to the back part of the mould-board, where it terminates about 6 inches above the level of the sole. This inclined plane raises the soil from the bottom of the furrow, and turns it over on the top of that which has been laid in the bottom of the previous furrow, by the body going before.

Draining ploughs are of various kinds, but none of them are of much use; the work can always be done better, and generally cheaper, by manual labour.

Wheel ploughs are of two kinds: by far the most common, are those where the wheel or wheels are introduced for the purpose of regulating the depth of the furrow, and rendering the implement more steady to hold; those less common are where a wheel is introduced for the purpose of lessening the friction of the sole or share. This last description of wheel plough

is scarcely known, but it promises great advantages. The former is of high antiquity, having been used by the Romans.

Ploughs with wheels for regulation and steadiness vary considerably in their construction in different places, according to the nature of soils and other circumstances; but in every form, and in all situations, they probably require less skill in the ploughman. Wheels seem, indeed, to have formed an addition to ploughs, in consequence of the want of experience in ploughmen; and in all sorts of soil, but more particularly in those which are of a stony and stubborn quality, they afford great assistance to such ploughmen, enabling them to perform their work with greater regularity in respect to depth, and with much more neatness in regard to equality of surface. From the friction caused by the wheels, they are generally considered as giving much greater resistance, and consequently demand more strength in the team that is employed; and, besides, are more expensive in their construction, and more liable to be put out of order, as well as more apt to be disturbed in their progress by clods, stones, and other inequalities that may be on the surface of the ground, than those of the swing kind.

With regard to wheel ploughs, those more especially in which the wheel is placed in the heel of the plough, the following extract from Mr. Stephens's *Book of the Farm*, will explain both the philosophy and practical effect:

The application of a wheel in the heel of a plough, does not come under the same mode of reasoning as that under the beam, the former becoming a part of the body, from which all the natural resistance flows; but in viewing it as a part of that body only, we can arrive at certain conclusions which are quite compatible with careful experiments.

The breadth of the whole rubbing surface in the body of a plough, when turning a furrow, is on an average about $17\frac{1}{2}$ inches; and supposing that surface be pressed nearly equal in all parts, we shall have the sole-shoe, which is about $2\frac{1}{2}$ inches broad, occupying $\frac{1}{4}$ part of the surface; and taking the entire average resistance of the plough's body, as before, at 336 lb., we have $\frac{1}{4}$ of this, equal to 48 lb., as the greatest amount of resistance produced by the sole of the plough. But this is under the supposition that the resistance arises from a uniform degree of friction spread over the whole rubbing surface of the body; while we have seen, on the contrary, that the coulter, when acting alone, presents a resistance equal to the entire plough. It is only reasonable, therefore, in absence of further experiments, to conclude, that the fore-parts of the body, the coulter and share, yield a large proportion of the resistance when turning the furrow-slice; but since we cannot appreciate this with any degree of exactness, let the sole have its full share of the resistance before stated, namely, 48 lb. If a wheel is applied at or near the heel of a plough, it can only bear up the hind-part of the sole, and prevent its ordinary friction, which, at the very utmost, cannot be more than half of the entire friction due to the entire sole. A wheel, therefore, placed here, and acting under every

favouring circumstance, even to the supposed extinction of its own friction, could not reduce the resistance by more than 24 lbs., being the half of that due to the entire sole, or it is $\frac{1}{16}$ of the entire resistance. But we cannot imagine a wheel so placed to continue any length of time, without becoming clogged in all directions, thereby greatly increasing its own friction; and when it is considered that the necessarily small portion of any wheel that can be so applied will sink into the subsoil, to an extent that will still bring the sole of the plough into contact with the sole of the furrow. It will thus be found that the amount of reduction of the general resistance will be very much abridged, certainly not less than one-half, which reduces the whole saving of draught to a quantity not exceeding 12 lb., and even this will be always doubtful, from the difficulty of keeping such wheels in good working condition. This view of a wheel placed at the heel has been confirmed by actual experiments, carefully conducted, wherein Palmer's patent plough with a wheel in the heel, as patented many years ago (but in this case it was applied on the best principles), gave indications of increased resistance from the use of the wheel, as compared with the same plough when the wheel was removed; the difference having been $1\frac{1}{2}$ stone in favour of no wheel. I hesitate not, therefore, to say, that in no case can wheels be of service towards reducing the resistance of the plough, whether they be placed before or behind, or in both positions, and the chances are numerous that they shall act injuriously. That the use of wheels may, under certain circumstances, bring the implement within the management of less skilful hands than is required for the swing plough, must be admitted; but, at the same time, there may be a question whether, even with that advantage, the practice is commendable. I should be wanting in candour if, for myself, I answered otherwise than in the negative.

Having, says Mr. Stephens, in a general way described the construction of the frame-work and the acting parts of the wheel plough, there remains for me to say a few words on the wheels with which it is furnished. I have already adverted to wheels, as they appear to me to affect the draught of ploughs, and have expressed myself in sufficiently distinct language to show that, in my opinion, they must in all cases be injurious, and tend to increase the resistance of the plough to which they are appended, whether they be applied within the body, or under the front, or any other part of the beam. That wheels may be of advantage for the working of a plough in the hands of an unskilful ploughman may be true; but if this advantage is acquired by a certain additional expenditure of horse-power, which, however much the proprietor of the team may blind himself to, will ultimately, though probably unheeded, tell on his profit and loss account, there will be no gain, but an ultimate loss. It must be admitted, even by the advocates of the wheel plough, that though they may be handled with perfect regularity in ploughing along ridges, whether the holder be an experienced ploughman or not, yet in cross-ploughing they

cannot by any means be brought so handily to follow the undulations of the surface. In leaving one ridge, the share will pass too shallow, and in entering on the brow of the next, it will go too deep, or at least deeper than the average of the ploughing. There is also the element of time, which in all farming operations is an important one; and here wheel ploughs are found to come short by about 25 per cent. as compared with swing ploughs. Mr. Pusey, in his paper on the draught of ploughs, incidentally observes: "While the work of our ploughing teams is at best but $\frac{3}{4}$ of an acre upon strong ground (and sometimes as much as one acre upon the lightest), the daily task performed by 2 Scotch horses upon strong land is $1\frac{1}{4}$ acre." This deficiency of effect cannot be attributed to want of power in the horses, for English horses are at least not inferior to those employed in Scotland for agricultural purposes, neither can it be from unskilfulness in the ploughmen, for even the most skilful seem to come short in this respect, by not being able to plough more than $\frac{3}{4}$ of an acre in a day, while with the swing plough almost any ploughman will turn over his acre a day. From the remarks of the same writer, it is to be inferred that a Scotch swing plough was incapable of being drawn through a certain clay soil by 2 horses, while the wheel ploughs were found to perform the work with tolerable ease, though still a heavy draught. There may be such cases; but from the conditions of this particular case, where the draught that baffled the horses in the swing plough seems not to have exceeded 52 stones, there is an ambiguity in the matter that leads to doubts of the accuracy on the part of the observers of the experiment. We know well that in working the Scotch swing plough in an 8 or 9-inch furrow on stiff land, the draught is not infrequently as high as 7 cwt. or 56 stones; but 2 good horses never shrink from the task; and how a less draught, whatever be the soil, should have baffled the exertions of 2 good horses in a swing plough, even in the Oxford clay, requires some further investigation to be satisfactory.

Among agricultural writers, it seems, says Mr. Stephens, to be a prevalent opinion, that land when ploughed receives a curvature of surface; whereas, correct ploughing, that is, making the furrow-slices on the same ridge all alike, cannot possibly give the surface any other form than it had before it was ploughed. If the former surface were curved, then the newly ploughed surface would also be curved; but if it were flat, the new surface will be flat also. A thoroughly good ploughman, and I have known a few, but only a few of such valuable men, avoids so objectionable a practice, and ploughs always a true, sound furrow, making it larger or smaller as the particular state of the work may require.

Without putting much value on the information, it may serve as a fact to refer to, in case it should be wanted, to state the weight of earth turned over in ploughing. If 10 inches are taken as a fair breadth for a furrow-slice, there will be 18 such slices across a ridge of 15 feet in breadth; and taking 7 inches as a proper depth for such a furrow-slice, a cross section

of the slice will have 70 square inches. A cubic foot of earth is thus turned over in every $24\frac{1}{2}$ inches and a little more of length of such a slice; and taking 2.7 as the specific gravity of ordinary soil, every $24\frac{1}{2}$ inches and a fraction more of such a slice will weigh 12 stones 1 lb. imperial.

The usual speed of horses at the plough may be ascertained in this way. A ridge of 5 yards in breadth will require a length of 968 yards to contain an imperial acre; and to plough which at 9 bouts, of 10-inch breadth of furrow-slice, counting no stoppages, will make the horses walk $9\frac{7}{8}$ miles, which in 10 hours gives a speed of $1742\frac{1}{2}$ yards per hour. But as ridges are not made of 968 yards in length, and as horses cannot draw a plough that distance without being affected in their wind, and as allowance must be made for time lost in turning at the ends of the ridges, as well as for affording rest to the horses, that speed will have to be considerably increased to do that quantity of work in the time. By experiment it has been found, that 1 hour 19 minutes, out of 8 hours, are lost by turnings while ploughing an acre on ridges of 274 yards in length, with an 8-inch furrow-slice. Hence, in ploughing an acre on ridges of 250 yards in length, which is the length of ridge I recommend as the best for horses in draught, in 10 hours, with a 10-inch furrow-slice, the time lost by turnings is 1 hour 22 minutes. I presume that the experiment alluded to does not include the necessary stoppages for rest to the horses, but which should be included; for however easy the length of ridge may be made for draught, horses cannot go on walking in the plough for 5 hours together (one yoking) without taking occasional rests. Now 250 yards of length of ridge give nearly 4 ridges to the acre, or 36 bouts; and allowing a rest of 1 minute in every other bout, 18 minutes will have to be added to the 1 hour 22 minutes lost, or very nearly $1\frac{1}{2}$ hour of lost time, out of the 10 hours, for turnings and rest. Thus 18,000 yards will be ploughed in $8\frac{1}{4}$ hours, or at the rate of 1 mile 422 yards per hour. I think this result is near the truth in regard to the ploughing of lea in spring; it is too little in ploughing red land in summer, and perhaps too much in ploughing stubble land in winter; but, as lea-ploughing is the criterion by which all others are estimated, this result may be taken as a near approximation to the truth.

The comparative time lost in turning at the ends of long and short ridges may be seen from the following table, constructed from data furnished by the experiment above alluded to:

Length of ridge.	Breadth of furrow-slice.	Time lost in turning.	Time devoted to ploughing.	Hours of work.
<i>Yards.</i> 78	<i>Inches.</i> 10	<i>h. m.</i> 5 11	<i>h. m.</i> 4 4	<i>h.</i> 10
149	—	2 44	7 16	—
200	—	2 1	7 59	—
212	—	1 56½	8 3½	—
274	—	1 28	8 32	—

Thus it appears that a ridge of no more than 78 yards in length requires 5 hours 11 minutes of time to turn at the landings, to plough an acre in 10 hours, with a 10-inch furrow-slice; whereas a ridge of 274 yards in length only re-

quires 1 hour 28 minutes for the same purpose, making a difference of 3 hours 43 minutes in favour of the long ridge in regard to saving of time. Consequently, in the case of the shortest ridge, only 4 hours 49 minutes out of the 10 can be appropriated to ploughing, whereas in that of the long ridge, 8 hours 32 minutes may be devoted to the purpose. Hence, so very short ridges require double the time of long ones to plough, and are thus a decided loss to the farmer. This is a subject well worth your experimenting on, by ascertaining the time usually taken in ploughing and turning and resting on ridges of different lengths, in the different seasons, and in different soils. A watch with a good second-hand to mark the time will be required, and the observations should be made unknown to the ploughmen, at their usual rate of work; for if you be constantly in the presence of the men, more than the usual work will be done, and less than the usual rests taken.

The whole value of ploughing, scientifically speaking, depends upon its having the effect of loosening the texture of the soil, and thus permitting a free circulation of air and moisture through its interstices, for the double purpose of increasing the rapidity of the disintegration of its stony portions, and of re-reducing to powder what had formerly been pulverized, but which, from the joint action of pressure, and the binding effect of root-fibres, had become agglutinated together.

However well you may manure your land, however thoroughly you may drain it, you will never obtain the crops it is capable of yielding, unless you pulverize it; nay, so important did Jethro Tull think this, that he felt firmly persuaded that if you pulverized your soil well, you need not manure at all. I need hardly tell you, that we shall prove hereafter Jethro Tull to have carried his conclusions too far; but still so direct and unqualified a statement, from such a writer, should have its full influence upon all who wish to learn thoroughly the art of agriculture. Always bear in mind that the impalpable powder is the active part of soil, and that no other portion has any direct influence upon vegetation, and you will then, at all times, be sufficiently impressed with the necessity of thorough ploughing, harrowing, &c.; indeed, you may rest assured that, except upon some few very light sands, you cannot pulverize the soil too much—economy alone must fix the limit of this useful operation.

Tempering, &c.—A good ploughman will have his plough so “tempered,” or its different parts so regulated or adjusted, that it will neither have a tendency to *take more or less earth*, or, in other words, go deeper or more shallow than is necessary. The width of the furrow-slice will be at the same time regulated, so that neither *more nor less land* be taken than is requisite. Some ploughmen, says Mr. Stephens, habitually make the plough lean a little over to the left, thus giving it in effect less land than it would have, were it made to move upon the flat of the sole; and to overcome the consequent tendency of the plough to make a narrower furrow-slice than the proper breadth, they move the draught-bolt a little to the right. The ploughing with

a considerable lean to the left is a bad custom, because it makes the lowest side of the furrow-slice, when turned over, thinner than the upper side, which is exposed to view, thereby deluding you into the belief that the land has all been ploughed of equal depth; and it causes the horses to bear a lighter draught than those which have turned over as much land in the same time, with a more equal and therefore deeper furrow-slice. Old ploughmen, becoming infirm, are very apt to practise this deceptive mode of ploughing. The plough should always move flat upon its sole, and turn over a rectangular furrow-slice; but there are certain exceptions to this rule, depending on the peculiar construction of parts of certain forms of ploughs.

None assume the habit of leaning the plough over to the right, because it is not so easy to hold it in that position as when it moves upon the sole along the land-side.

Other ploughmen, especially tall men, practise the habit of constantly leaning hard upon the stilts, or of steeping; and as this practice has the tendency to lift up the fore-point of the plough out of the ground, they are obliged, in order to keep it in, to put the draught-bolt farther from the ground than it should be. A little leaning of the hands upon the stilts is requisite at all times, in order to retain a firm hold of them, and thereby have a proper guidance of the plough.

A good ploughman will use none of these expedients to make his plough go steadily, nor will he fall into any of these reprehensible habits. He will temper the irons so as there shall be no tendency in the plough to go too deep or too shallow into the ground, or make too wide or too narrow a furrow-slice, or cause less or more draught to the horses, or less or more trouble to himself, than the nature of the work requires to be performed in the most proper manner. If he have a knowledge of the implement he works with—I mean, a good practical knowledge of it, for a knowledge of its principles is not requisite for his purpose,—he will temper all the parts, so as to work the plough with great ease to himself, and, at the same time, have plenty of leisure to guide his horses aright, and execute his work in a creditable manner. I have known such ploughmen, and they invariably executed their work in a masterly way; but I never yet saw a ploughman execute his work well, who had not acquired the art of tempering the irons of his plough. Until he learns this art, the best-made plough will be comparatively worthless in his hands.

The state of the irons themselves has a material effect on the temper of the plough. If the cutting edge of the coulter, and the point and cutting edge of the sock, are laid with steel, the irons will cut clean, and go long in smooth soil. This is an economical mode of treating plough-irons destined to work in clay-soils. But in gravelly and all sharp soils, the irons wear down so quickly, that farmers prefer irons of cold iron, and have them laid anew every day, rather than incur the expense of laying them with steel, which perhaps would not endure work much longer in such soil than iron in its ordinary state. Irons are now seldom

if ever steeled; but whether they are steeled or not, they are always in the best state when sharp, and of the proper lengths.

An imperfect state of the mould-board is another interruption to a perfect temper of the plough. When new and rough, it accumulates the loose soil upon it, whose pressure against the turning furrow-slice, causes the plough to deviate from its right course. On the other hand, when the mould-board is worn away much below, it is apt to leave too much of the crumbled soil in the bottom of the furrows, especially in ploughing loose soils. Broken side-plates, or so worn into holes that the earth is easily pressed through them into the bosom of the plough, also cause rough and unequal work; and more or less earth in the bosom affects the balance of the plough, both in its temper and draught. These remarks are made upon the supposition that all ploughs are equally well made, and may, therefore, be tempered to work in a satisfactory manner; but it is well known that ploughs sometimes get into the possession of farmers, radically so ill-constructed, that the best tempering the irons are capable of receiving will never make them do good work.

When all the particulars which ploughmen have to attend to in executing their work,—in having their plough-irons in a proper state of repair, in tempering them according to the kind of ploughing to be executed, in guiding their horses, and in ploughing the land in a methodical way—when all these particulars are considered, it ceases to surprise that so few ploughmen should be first-rate workmen. Good ploughmanship requires greater powers of observation than most young ploughmen possess, and greater judgment than most will take time to exercise, in order to become familiarized with all these particulars, and to use them all to the best advantage. To be so accomplished, implies the possession of talent of no mean order. The ship has been aptly compared to the plough, and the phrase “ploughing the deep” is as familiar to us as ploughing the land: to be able to put the ship in “proper trim,” is the perfection aimed at by every seaman; so, in like manner, to “temper a plough” is the great aim of the good ploughman; and to be able to do it with judgment, to guide horses with discretion, and to execute ploughing correctly, imply a discrimination akin to sailing a ship. (*Stephens.*)

Plough Handles.—The handles should be sufficiently wide apart to allow the ploughman to walk in the furrow, and long enough to give him a full command of the plough, so that he can lift or depress it readily in work, guide it to the right or left hand, and swing it round at the land's end out of the furrow into another.

Plough-beam.—The beam should be of such a length, that its end, commonly called its head, shall cut at the point of draught, upon a line drawn from that part of the collar to which the traces are attached, to the share or that part of it where it first raises the soil. On the right arrangement of the point of draught in the structure of the plough depends much of its steady working at its proper depth. It is from

the principle of balancing from a point adjusted to the line of draught, that the plough takes its name of *swing*, in contradistinction to the names of *foot* and *wheel* ploughs.

The beam should be curved upwards at the coulter and throat of the plough, to clear itself of rubbish which sometimes accumulates, and should be inclined slightly from the land, or, in other words, towards the furrow, because its tendency is to yield towards the loosened land, and it therefore requires this counteraction in the line of draught to keep it in a right line. This is supposing a pair of horses to be harnessed abreast; if they be harnessed at length, the beam should be still more inclined; for as neither horse then walks on the “land,” the direction of the force towards the land-side is still further decreased.

Plough-head.—The cross-head of the plough forms a ready means of increasing or decreasing the inclination last spoken of, and the hake, or draught-iron, which moves in the arc of a circle along the cross-head, has notches by which the depth of the plough can be regulated in unison with the line of draught. There are various contrivances for these purposes, most of which involve the use of a screw as a means of adjustment; but the plan of pins and notches is sufficiently accurate, and not liable to be out of order. Sketches of two, the one English, *h*, the other Scotch, *i*, are given in Pl. 17.

Plough-share.—The plough-share is the apex of the sole, as the hind part is called the heel. It varies in shape for different purposes. On stony lands it is best with a point, as figured Pl. 17, *k*. But where the land is free from stones, the wing is best when angular, and the cutting edge in a line, or nearly so, as figured in Pl. 17, *l*.

For different work, “hard lands” and “summer lands,” shares of a greater “dip” or “pitch” are requisite. A common plan is to use new shares on hard lands, and to wear them a day or two, and then lay them aside for summer lands.

Mould-board.—The upper part over the box of the share should form the first part of the rise of the mould-board. After the coulter and share have made the vertical and horizontal cuts for the depth and width of the furrow-slice, the mould-board has to complete the work by turning it over and leaving it in its proper position. On the precision with which this part of the plough performs its work, much, indeed nearly all, of the beauty of the ploughing depends: hence the importance of discovering its true form for the land on which it has to be used. Desirable, however, as this is, there does not as yet appear to be any precise rule for the formation of the mould-board, that has met with so uniform an approval under the test of practice, as would lead us to speak with entire confidence of it. We have looked at the mechanical principles laid down by Small, Bailey, Gray, Amos, Jefferson, Clymer, and others, but are not aware of any plough-makers of the present day who strictly adhere to either the one or the other; and so long as the mould-board cannot be used on even the same farm

under circumstances always similar, as its operation will necessarily be affected by the weather, the state of the land, with the varying depth and width of the plough, it is not an easy matter to determine which form is best for general purposes. It is clear that different soils, as, for instance, light sand and heavy clay, require mould-boards almost the opposite of each other; and such they are. The Norfolk mould-board is short, with rather a hollow or concave surface, whilst that used in the hundreds of Essex is long and convex.

Lord Western, many years ago, improved upon the form of the heavy land mould-board in use in that part of the county of Essex where he resides, by cutting away a considerable portion of the lower and hinder part of the figure, and by making it in a straight line lengthwise from the nose to the hind part.

Were the circumstances always the same, there can be no question but that one mathematical form of the mould-board would be preferable to all others; but, under circumstances so various, the plan hitherto adopted has been to prove, by experience and from practical operation, the forms best suited to different lands under an average depth and width of work, keeping as nearly as possible to the principle of the wedge, as necessary for the proper lifting, turning, and laying over the soil. Provided the mould-board be made so that the work, while in operation, goes on as it should do, a good practical criterion as to its figure will be found in the evidence of friction it has undergone, and this, with the fine cast metal now in use, can be determined to a nicety. If, on a given soil, the mould-board becomes brightened uniformly—if the mould appears to slip with light friction and with the same pressure from one end of it to the other, it cannot be far, if any thing, out of its proper shape for the purpose intended. And yet, if the same mould-board be used on some other lands, it will immediately show its inapplicability to them by the soil adhering to it in parts, not slipping well through it, and thus evidencing a want of uniformity in its general friction. Therefore, considering that neither depth nor width of furrow is always the same, and that scarcely one circumstance affecting its use is unvarying, it is difficult to find a rule which shall aptly suit these changes. At the same time it is not presumed that such will not or cannot be found; and the theory which most accords with our view, is one which has recently been laid down by the Rev. W. L. Rham, rector of Winkfield, Berkshire, a gentleman whose scientific and agricultural knowledge entitles his opinion to considerable deference. His theory is, that the mould-board should be composed of straight lines in the direction of its length, with continually increasing angles to the line of the furrow: these last lines being either straight, convex, or concave, horizontal sections of the mould-board.

Coulter.—Simple as the coulter may appear to be, it is a very important part of the plough, and much depends upon its being properly formed and fixed for the work it has to perform in the operation of ploughing. It should be

made of iron and steel, and of sufficient substance to stand firmly to the position in which it is set for its work, not bending either to the right hand or to the left. The blade or cutting part should be about $2\frac{1}{2}$ inches wide, and formed by the meeting of two curves, as this shape cuts the land easier than when the edge is either in a straight line or curved forward. The land side of the coulter should be flat, and the opposite side a gradual taper from the edge to the back: the thickness must be determined by the strength of the work it has to perform.

The angle at which the coulter is usually set, is about forty-five degrees from the plane of the ground; but in summer lands it requires to be placed in a more slanting position, and to take the lead of the share about three-quarters of an inch, to prevent the grass or rubbish driving in a heap, as it otherwise might do. On the contrary, when used for ploughing up hard fallows, it requires to be fixed in a more upright position, and rather more backward than the point of the share. It should be placed about half an inch above the share, and a quarter of an inch to the land side of it. Every good ploughman has his own notions on the subject of setting the coulter, but the above directions are given from practical observation.

The usual mode of fixing the coulter in the socket of the frame or beam, is by means of wood or iron wedges driven above or below the socket, or by a coarse cut screw-bolt, which turns into the side of the socket and presses against the coulter-stalk. Each of these modes is defective, there being a complication in the details of all that appears not quite adapted to the class of workmen who have to use them.

Skim Coulters.—Skim coulters are sometimes used for the purpose of burying the surface-grass or rubbish. Sketches of two kinds are given in pl. 17, *m, m*. The usual plan is to fix the skim about six inches before the common coulter.

Wheel Coulters are used in the fen lands, and are useful when ploughing up turf. One of these coulters is represented in pl. 17, *n*. The cutting-disk should be made of steel, with a nave sufficiently long for it to be steady, and the box should be bored true, and revolve on a well-fitted steel pin, as on the perfect fitting of the box and axle the correct working of the disk, and consequently the effective operation of the plough, depends.

Swing Ploughs.—The advantages attributed by Mr. Ransome to the swing plough are as follows:—

1. It admits of being set into its work at a given depth, either shallower or deeper, by the alteration of the draught iron at the point of draught, or by increasing or decreasing the distance at which the power of the horses is applied.

2. The ploughman has also the power of regulating, in some degree, the depth of the work, by either lifting or bearing upon the handles.

3. It is a plough of more simple construction than any other, and less expensive in its first cost.

4. A skilful workman can plough across a ridge and furrow at very nearly a uniform

depth; he can work with it on almost all lands, and in all weathers when ploughing can be done at all.

The Wheel Plough (with high Gallowses).—This derives its name from having the appendage of a carriage and wheels. The body of the plough is essentially the same as that of the swing plough, and notwithstanding the different form of its beam, the point of draught should be the same as that of the swing plough, namely, to cut a line drawn from the horse's shoulder to the share or point of resistance.

In the *Report to the Board of Agriculture* from the county of Leicester, published in 1808, it is stated, "that more than thirty years ago, wheels were first applied to the fore-end of the beam, and it was found by 'pitching' the plough a little deeper, and setting the wheels so as to prevent its drawing too deep, the wheels were a sufficient guide, and the plough required no one to hold it except in places of difficulty." If properly adjusted, a lad of 14 years of age can manage it easily; and the writer of this article once saw, at a ploughing match, a lad having a plough of this sort—the only one in the field—walking leisurely beside it, to the great astonishment of the other competitors, and from whom, to their still greater astonishment, he carried away the prize. This lad had been taught ploughing only a few months.

When one wheel only is attached to the plough, some persons give the preference to a small one to run upon the unploughed land, as it is less likely to clog up, and requires no alteration towards the end of the furrow; but others prefer a larger wheel which runs in the furrow, as it has an even bottom to travel over, and correctly regulates the width of the furrow-slice. It also more effectually facilitates the turning round at the headland, particularly if the horses have to go to the right hand. The larger wheel to run in the furrow, therefore, is best for general purposes, and, with a lever attached to it, is rendered very easy of adjustment.

In the use of a gauge for the depth of ploughing, whether of two wheels, one wheel, or a foot, the plough should be so regulated as to press but lightly on the ground when passing over it; thus admitting as little of the counter-acting force between the wheel and share as possible.

In the Prize Essay by Henry Handley, Esq., the advantages of wheels are clearly set forth, and his arguments in favour of their use have since been very strikingly confirmed by the trials made under the directions of Philip Pusey, Esq.

The silver medal of the Royal Agricultural Society of England was awarded to John Clarke, of Long Sutton, Lincolnshire, for the invention of a plough (see *Jour. of Roy. Agr. Soc.*, vol. i. p. 66) for the purpose of ridge culture; by an easy transition of shape, which is accomplished in a very simple manner, this implement becomes,

1. A double tom or ridge plough.
2. A moulding plough.
3. A horse-hoe, or cleaning plough.
4. A skeleton, or broad-share plough.

Subsoil Ploughs.—At the thought of a subsoil

plough, says Mr. Ransome, our minds turn at once to James Smith, of Deanstone, as the gentleman who has opened a very interesting and important view of tillage, by the system of subsoil ploughing, and thereby breaking the under soil without turning it up to the surface. His practical knowledge has long been devoted to the interests of agriculture, and the results have been most beneficial. The plough he invented for the purpose is too well known to need a description, though we should consider our Essay incomplete without a sketch of it. See pl. 17, *o*; also *g*.

Following the invention of James Smith, of Deanstone, was another of a different and much lighter description, the invention of Sir Edward Stracey, Bart., Rackheath, and the plough is called by the latter name. It answers the purpose of deep ploughing, that is, from 10 to 16 inches below the surface, and when preceded by the common plough, which is plan recommended, the depth below the surface-ground is just as much again as the ... plough effects.

This plough answers admirably for under-ploughing grass lands, and is made into a sub-turf plough by changing the wheel gear in front, to that of a carriage and two wheels.

P. Pusey, Esq., in an interesting paper in the *Eng. Agr. Soc. Journ.* (vol. i. p. 434), gives an account of a plough, made to his order by Charles Hart, of Wantage; at the hinder part of this plough was fixed a strong tine, something like those on Biddel's scarifier, for the purpose of under-ploughing the soil. This tine was made to rise or lower at pleasure; and from the description of its use and operation, given in the above paper, we should think it a valuable invention, as it may be easily attached to a plough of the common sort, and removed when not wanted.

Skeleton, or Cleaning Ploughs, are often the transformations of common ploughs for that purpose, by taking the mould-boards and shares off, and substituting for the shares subsoil or cleaning shares, with prongs. See Pl. 17, *f*.

The plan of laying furrows in one direction, so as to have neither ridge nor water furrows, has within the last year attracted more than common attention in Britain. It has led to a careful inquiry into the the system of ploughing pursued in Kent, and there seems to be a disposition among many first-rate agriculturists to try the plan, provided lighter implements can be furnished for the purpose, not exceeding the power of two horses' draught. To this object some eminent practical farmers have turned their attention, and a plough, made under the direction of Mr. William Smart, a farmer of great respectability and experience at Rainham, in Kent, bids fair to open a new and very important view of the mechanical principles of the turn-rest plough, which he has remodelled; and it may be made equally applicable to the power of two or four horses.

This gentleman, after many trials, arrived at the conclusion that, inasmuch as the work of the turn-rest plough depended on its wedge-like construction, its form could only be correct in proportion to its approach to the perfect wedge; and this form, obtained by straight

lines in the direction, first, from the point of the share to the throat of the plough, to produce the effect of elevating the furrow-slice; and, second, from the edge of the coulter to the heel of the rest, to effect the turning of the flag, is that which he has adopted; making these lines tend to an angle of 15 degrees. With the assistance of an ingenious ploughwright in his own neighbourhood, several ploughs on this principle were constructed, and these have been the basis upon which still further improvements in the detail have been carried out. They are now so constructed that the ploughman can readily shift his coulter by means of a lever, which reaches the bottom of the handles, and also his rests or mould-boards from side to side, without leaving his station between the handles of his plough, they being so arranged that, by withdrawing a small pin and pressing the projecting rest towards the body of the plough, the mould-boards on either side become alternately the land side when not in work.

Ploughs for the purpose of turning the furrows all in one direction, and laying the slices at an angle with the horizon, as is done by the common plough, have been within the last year or two brought before the public, but we cannot learn that they have been generally adopted.

In going thus at length into the subject of the plough, we have shown the present state of agricultural mechanics as respects those in general use. To have gone more fully into the description of those out of the common routine of farming, would have carried us beyond what we imagine to be the proper limit of this portion of the work. At the same time it must be observed, that there are a variety of purposes for which ploughs of a particular form, different from any already described, are required; such as paring ploughs, draining ploughs, drill ploughs, &c. &c. On each, indeed on all of which, a considerable amount of judgment and ingenuity has been expended.

Ploughs even for common purposes have been long in arriving at their present state; and there are doubtless many improvements that may yet be accomplished.

In the construction of ploughs, the first object to be borne in mind is the proper performance of the work to be done; the next, that this should be effected with the least expenditure of animal power, and with the greatest economy; and, lastly, that they should be made as simple as possible in reference to the ploughman who will have to use them. The circumstance of repairs, which will be continually required as the parts wear out, should also be kept in view, and the whole require to be made on an accurate plan, so as to insure every part fitting properly; the workman may then fix them on the spot as readily as a mechanic at his manufactory. Nor should it be forgotten that quality of materials and workmanship are main points in economy, and that to dispense with either is to pave the way to dissatisfaction and trouble to all parties concerned.

It is difficult to suggest alterations on the present implements, which appear adapted

to the purpose, and likely to agree with the description of the requisites just given; but there is no doubt that the plough, in its various forms, is capable of great improvement; and amongst the points to which attention may be usefully directed are the following:—

Amount of draught that different forms of mould-boards and shares require, in order to determine those best suited to the purpose.

A mould-board that will best turn the work on either side of the plough, so as to admit of its being changed from one to the other, after the plan of the Kent turn-rest.

A ready means of altering the depth or pitch of the swing plough while in motion, without stopping the horses, so that it may be accommodated to any difference in the nature of the soil, or inequalities on its surface, which the plough may meet with.

The same as respects the wheel plough, without placing any of its forces in opposition to each other.

Many papers on ploughs and ploughing are contained in the best modern agricultural periodicals. Wilkie's turn-rest plough is described in the *Trans. High. Soc.* vol. vi. p. 484. Mr. Heathcote's steam plough, *Ibid.* p. 72. Mr. Laidlaw "On the general advantages of Two-horse Ploughs," *Quart. Journ. of Agr.* vol. ii. p. 712. "On the Plough of Palestine," *Ibid.* vol. iii. p. 373. "On Small's Plough as a Drill Plough," *Ibid.* p. 854. "On the Mathematical Construction of the Plough," by Mr. Amos, *Com. Board of Agr.* vol. vi. p. 437. "On Wheel and Swing Ploughs," by Mr. Handley, *Journ. Roy. Agr. Soc.* vol. i. p. 140. "On Draught in Ploughing," by Mr. Pusey, *Ibid.* p. 219. "On Subsoil Ploughing," by Sir James Graham, *Ibid.* p. 245. "On the Rackheath Subsoil Plough," by Sir E. Stracey, *Ibid.* p. 253. "On the Charlbury Subsoil Plough," by Mr. Pusey, *Ibid.* p. 433. "On the Rackheath Subturf Plough," by Sir E. Stracey, *Ibid.* vol. ii. p. 37; and "On a Light Subsoil Plough, adapted for two Horses," by Mr. Gabell, *Ibid.* p. 421.

The Plough in the United States.—Whilst in Europe, and particularly in Great Britain, the plough has been so much improved, American intelligence and ingenuity have been rewarded with great success in the same pursuit. The implement which the pioneer is obliged to make use of in first stirring and partially turning up the soil filled with roots and stones, is necessarily very rude, sometimes almost equal in this respect to those of the primitive ages of husbandry. One of these rough contrivances is, in New England and the Northern States, familiarly called the *Bull plough*. The several improvements on the plough in the United States seem to have progressed, for the most part, with little or no reference to European plans or models, and to have been almost exclusively confined to swing-ploughs, wheel-ploughs being scarcely ever seen. Simplicity and economy seem to have been kept in view by all who have undertaken to improve or modify the implement. As the various sections of the Union present varieties in the conditions of the soil, the ploughs are constructed with reference to these conditions, so that

the Northern, Eastern, Middle, and Western States, different ploughs are vaunted for their excellence. It has been observed as a singular circumstance, that to the celebrated author of the Declaration of Independence the United States should be also indebted for the first theory of the plough formed on mathematical principles. President Jefferson's letter to Sir John Sinclair, president of the British Board of Agriculture, addressed in 1798, is published in the *Transactions of the Am. Philosophical Society*, vol. iv. p. 314. It describes the mould-board, and the principles upon which it is properly constructed. (See *American Farmer*, vol. ii. p. 185, and *Domestic Encyclopedia*, vol. iii. p. 113.)

In England the most complete set of experiments yet made to ascertain the particular merits of different ploughs, are those instituted by Mr. Pusey, president of the Royal Agricultural Society, and described by him in the 3d No. of the *Journal* of that Society. A condensed view of the objects and results of these experiments may be found in the *Cultivator*, (vol. viii. p. 10), together with the results obtained with American ploughs at the Worcester ploughing match in 1840.

The points embraced in the English experiments were :

1. The comparative lightness in draught, of wheel and swing ploughs.
2. The lightest plough absolutely, of whatever kind.
3. The effect of different soils upon the qualities, and chiefly on the draught of the plough.
4. The comparative tenacity of different soils.
5. The power of two horses to plough the strongest or clay soil.

Ten ploughs, embracing some from the most celebrated makers in England, the highly famed Scotch swing plough, and several of those in common use in the different districts of the kingdom, were selected by Mr. Pusey for his experiments, and he was aided by the presence and advice of some of the most distinguished agriculturists in the country. The ploughs were worked by skilful ploughmen; and, as much interest was attached to the experiment on the Scotch ploughs, a Clydesdale span of horses and a ploughman accustomed to the plough were sent up by Lord Moreton to manage that part of the trial. The Scotch plough has obtained considerable celebrity from the strong praise bestowed upon it by Mr. Loudon, who declares the improved Scotch plough to be superior to any similar implement known in England. They are constructed on the principles laid down by Mr. Jefferson, in his celebrated *Report* on the true shape of the mould-board, addressed to the French Institute, which, he showed from mathematical data, should be in the form of a gentle hollow curve; other ploughs constructed more full and short, not raising the earth gradually like a wave, but throwing it over at once. In condensing Mr. Pusey's experiments, we shall select, as sufficient for the present purpose, from the list given by him, three ploughs—1st, the improved Scotch plough made by Fergu-

son, and entirely of iron—2d, a one-wheeled plough of wood, with an iron breast, by Mr. Hart, but commonly known as the improved Berkshire plough; and 3d, an old-fashioned plough made of wood, and such as is in general use in many parts of England, where it is called the old Berkshire plough. Some previous experiments had convinced Mr. Pusey that the Hart plough was of easy draught, and the ones now instituted showed that his impressions were correct.

The Clydesdale horses were much admired in their work; and it was the opinion of the bystanders that such land, usually worked with four horses in line, might be ploughed with two such horses abreast; though it was said it would cost as much to keep two horses in that condition, as to support the four in their usual working state. On this ground, where the horses had a firm footing, they worked with perfect ease.

In summing up the trials, Mr. Pusey remarks that the plough requiring the least draught was Hart's, though in the last trial it was beat by Ransome's two-wheel plough; and that of all modern ploughs the Scotch swing plough was the heaviest, "out of the question on a light soil, and by no means the best on a heavy one." The following table shows the average draught of all the ploughs on the several soils in which the experiments were made :

Trial 1. Sandy loam	- - - -	17½	stone.
2. Clay loam	- - - -	47½	"
3. Loamy sand	- - - -	16½	"
4. Strong loam	- - - -	31½	"
5. Clay loam	- - - -	28½	"
6. Moory soil	- - - -	20	"

A drawing of Hart's improved Berkshire one-wheel plough is given in the *Cultivator*, (vol. viii. p. 10.)

The trials at the Worcester ploughing match in 1840, were made to determine the award of two premiums offered by the Massachusetts Agricultural Society, of \$100, and \$75, for the best ploughs, one for lapping furrows and the other for laying them flat. The following remarks by the reporting committee will enable the reader to understand the experiments, whilst the list of ploughs will show the number of inventors and improvers whose implements have acquired most celebrity in the eastern portion of the United States.

The power required to turn over a given quantity of earth by a plough is a very important consideration. This power can be measured with great accuracy; greater than many of the committee supposed, before they witnessed the operation. The dynamometer, inserted between the plough-beam and the chain, measures with great accuracy the strength exerted by the team. Suppose the strength applied be the same that would be required to raise 336 lbs. over a single pulley; suppose also that the depth of the furrow is 6½ inches with a width of 13 inches. Multiply 13 by 6½, and you will have 84 with a fraction. Now, if 336 lbs. of power will take up and turn over 84 inches of earth, then 112 lbs. will turn 28 inches. Tried in this way, the ploughs exhibited showed the following results. The power in each case is 112 lbs.

ENGLISH AND SCOTCH PLOUGHS

FIRST TRIAL.—Ploughs for lapping furrows.

By Charles Howard	-	-	20½ inches.
Ruggles, Nourse & Mason	-	-	24 "
John Wilson	-	-	21½ "
Stephens' plough	-	-	20 "
James Stewart (Scotch plough)	-	-	19½ "
Cornelius Bergen	-	-	18 "
Barnaby & Mooers	-	-	17½ "
E. G. Whiting	-	-	18 "

SECOND TRIAL.—For flat furrows.

Prouty & Mears	-	-	27½ "
Charles Howard	-	-	25 "
Ruggles, Nourse & Co.	-	-	24 "
Barnaby & Mooers	-	-	18½ "
E. G. Whiting	-	-	14 "
Another plough by Prouty & Mears	-	-	26 "
Do. do. Charles Howard	-	-	25 "

The terms used in this experiment are different from those adopted in the English one; but those who choose may easily compare them with each other by remembering that 112 lbs. is 8 stone, and making the furrow-slice to correspond, which in the American experiment was 84 inches, and in the English one 45; or 6½ by 13, to 5 by 9. When this is done, the experiments will be found to correspond remarkably well, and the general results of both may be considered as establishing many important truths, some of which have been already pointed out. Thus it will be seen that in the same soil, and under the same circumstances, one plough will work 100 per cent. easier than another, or that one horse will perform the work of two, or two that of four, with the same ease. Could horses speak, they would doubtless direct a vote of thanks to the men who have invented, and the farmers who use, implements by which one-half of the severest labour the horse performs is done away. We very much question whether our farm-horses on our heavy wheat lands do not often perform much more severe labour than the highest rate named by Mr. Pusey (52 stone, or 728 lbs.), as we have seen them day after day showing more exertion and evident distress in ploughing than when drawing a ton a day over hard roads. Whatever may be the obduracy or tenacity of the soil, or the toughness of the sward; only one pair of horses is used, where, under the same circumstances, four would be used abroad, and the question is

never asked whether the plough is of a construction so defective as to require 5 cwt. to move it, or whether it works with ease, with a force of 2 cwt. applied. Mr. Pusey estimated the fair draught of the Clydesdale horse at 168 lbs. or 12 stone, and that of a common English farm-horse at 112 lbs. or 8 stone.

At a fair held by the New York Agricultural Society, at Syracuse, in 1841. the first of the regular premiums, \$30, was awarded to the plough made by Howard Delano of Mottsville, the second premium of \$20 to E. G. Holliday, for his plough, favourably known as the Laughlin plough. The Wisconsin and other ploughs attracted considerable notice; but the double mould-board plough of Barnaby and Mooers, from the excellence and novelty of its construction, the facility with which it would operate on side hills as well as on level land, and its ease of draught, rendered it deservedly a favourite implement, and the honorary premium was deemed well awarded. It was supposed by many very good judges of ploughing, that the resistance offered by the land-side share would increase the draught sensibly, but the result showed that such was not the case.

The trial of ploughs which took place under the direction of a committee of the American Institute, at New York, was very well conducted; and although the number of ploughs on the ground was not as great as at Syracuse, the trials with the dynamometer were more satisfactory. It is to be regretted that some of the favourite Massachusetts ploughs had not been present for competition, as a full investigation and understanding of the matter requires repeated and careful comparison of ploughs in the same soils, and as near as possible under the same circumstances. We believe that such will hereafter be the case. The manner in which the report of the trials of ploughs last year at Worcester was presented, renders a comparison of the actual draught used there and at New York, difficult; but as the mode was adopted at New York that English experimenters have used, a comparison between the ploughs of England and Scotland, and those of this country, is more easily made. The following table, which we find prepared at our

Name of Plough.	Weight of Plough.	Draft by dynamometer.	Remarks.
Hart's English	140 lbs.	400 lbs.	Furrow not well taken out.
Ransome's wheel, do.	168	480	Between furrow not well laid up.
Yester, No. 1, Scotch	170	380	Clean furrow.
" " 2, English	136	440	" "
Scoular's swing, do.	150	446	" "
Hunter's English	190	560	Furrow not well laid up.
Currie's Scotch	170	500	" " "
Coltman's do.	176	500	Second best furrow.
Hadden's do.	180	510	Third "
Neill's do.	185	500	Good furrow.
Wilkens's English	175	540	" " "
Ransome's swing	160	462	" "
Palmer's wheel, English	230	560	Good work.
New spring, Scotch	189	560	" " "
Sussex, English	189	680	" "
The following ploughs were tried at Sing Sing, 14th October :			
Barnaby & Mooers	142	350	Best work of any American
Wisconsin	170	438	Second best rate.
Beebe's swing	-	451	Good furrow.
Minor, Horton & Co.'s	-	460	" "
Cornelius Bergen's	-	472	" "

hand in an account of the New York trials, given in the *Brooklyn Star*, we transfer to our columns with pleasure, merely remarking that we have verified the correctness of the foreign results, by reference to the reports in the Journals of the English Royal Agricultural Society, and the Scotch Highland Agricultural Society, from which they were taken. The reader will see that the best British plough, Yester No. 1, weight 170 lbs., draught 380 lbs., removed a furrow-slice of only 10 inches by 6, while the best American, Barnaby and Mooers' double mould-board side-hill plough (the same that received the premium at Syracuse), weight 142 lbs., draught 350 lbs., removed a furrow-slice of 12 inches by 8, or nearly twice as large. We are gratified to learn that this plough, which received the premiums at Syracuse and New York, has been presented by the Institute to the Royal Agricultural Society, and that doubtless it will be subjected to comparison with the ploughs of that country. In examining the list of English agricultural implements, we have often remarked the fact, that English ploughs range in prices from \$20 to \$30, while the best improved American ones do not cost more than from \$10 to \$15. The table will be understood without further explanation.

In a report of a committee appointed to superintend a trial of ploughs near Baltimore, in 1842, the following results are stated.

Plough.	Depth of furrow.	Width of furrow.	Force.
1. Barnaby & Mooers'	5 2-0 in.	12 in.	350 lbs.
2. Mott's Wiley plough	6 6-9	13 1-6	562
3. Prouty & Mears' centre-draught plough, Boston	5 1-9	12 1-6	500
4. Howard Plough, Boston	5 7-9	14	550
5. The Davis Plough. This plough worked well, but was withdrawn before trial with the dynamometer.			

The committee remark, "the task to the committee, of deciding where such excellence was to be found in each of the implements contending, was one of difficulty, and would have been more so, but for the various purposes to which the Barnaby and Mooers' plough is adapted, it being in fact a plough of all work, and from the fact of its executing its work with so much less draught than either of the others."

In commenting on the qualities of the several ploughs submitted to trial, the committee say of Barnaby and Mooers' side-hill plough, the one used:—"There is a peculiarity about this plough which is worthy of note. On the bottom of the furrow, and on the land side, it cuts out fully 12½ inches of the earth, so as to reduce resistance to the turning of the succeeding furrow, thereby facilitating, not only that operation, but insuring the exactitude with which it is performed, leaving a clean and broad furrow behind, in which the furrow-horse can walk, and preventing the treading of the ground in turning."

Although the trials made at the various exhibitions have thus far resulted so much in favour of the double mould-board plough of Barnaby and Mooers, still has this been less extensively adopted than it would appear to deserve. Associated with its great merits, there may yet remain some obstacle to its general use, of easy removal. The objection from great

weight requiring unusual exertion in throwing out and turning, might possibly be obviated by the addition of a wheel or some other device.

The price of this plough varies from \$4 for No. 3, a 7 inch seeding plough, to \$10 for No. 8½, a heavy two or three horse, 12 inch plough.

The following is a summary notice of the ploughs best known to the farmers of the Middle States. The order in which they are mentioned is not intended to express the precise dates of their invention or their relative merits.

Beech's Self-sharpening Plough has a concave mould-board. Its price varies with the size, from \$6 to \$10, the average price being \$8.

Miles's Plough, known also by the name of *Dickson's*, has the bar-share, land-side, and lock-coulter of wrought iron. They cost about \$13. This plough still retains precedence in the old counties of Pennsylvania, its execution being excellent, and its strength enabling it to contend successfully against obstacles met with in stony ground and tough swards.

Peacock's Plough.—This has been long known and is still extensively used. It has a bar-share and lock-coulter, and is best adapted to soils of a light texture, where shallow work will answer. It does not turn a sod so well as is desirable.

Wiley Plough.—One of the oldest of the cast-iron ploughs still in use is that of B. H. Wiley. The share of this has two points capable of being turned once. It is adapted to stubbles, but does not perform so well in tough sward.

Woodcock's Plough.—For the last few years this has been in extensive use in Lancaster county, Pennsylvania, and Newcastle county, Delaware. It is a self-sharpening implement, with a slightly concave mould-board. A cast-iron angular cutter supplies the place of a coulter. It is sometimes constructed so as to have the mould-board on either the right or left side, thus adapting it to the habits of a few old farmers who retain a partiality for ploughs turning the furrow-slice to the left hand.

Prouty and Mears's Centre-draught Plough.—One of the chief late improvements on American ploughs consists in lengthening or extending the mould-board, and still retaining the *centre-draught principle*, a construction which enables the instrument to turn a sod or furrow-slice so as merely to lap, or to lie completely flat, at the discretion of the ploughman. The cost of these ploughs, which possess high merits, varies, according to size, from \$7 to \$12. The larger sizes are provided with a small wheel to each, attached near the beam, a rare thing in America, but which in the present instance serves to render it more easy for the plough to follow the horses with proper steadiness, thus serving to ease the ploughman as well as the horses, the tendency to sink too deeply into the soil being completely checked. With regard to the wheel to ploughs, it is worthy of remark that there is a disposition beginning to be manifested in the United States in favour of at least one such appendage.

Subsoil Ploughs, now so extensively used in

Great Britain, are rapidly coming into use in the United States, where various sizes are made, the largest being a heavy tug for four horses, whilst the smallest may be worked by two mules or one stout horse. Those made by Prouty and Mears are very efficient implements, the prices varying from \$8 for the single horse, and \$10 to \$12 for the larger sizes. A more simple and cheaper subsoil plough, which has proved very successful on trial, has lately been made in the city of New York, adapted to one or more horses. These consist of a common plough from which all the upper portion of the mould-board has been cut away, so as to leave the mere skeleton, which strikes deep and stirs up the subsoil very effectually. The price of these varies from \$4 to \$6, according to size, &c. They may be had in New York at most of the agricultural implement stores, and in Philadelphia, of E. Chandler, agricultural implement maker, 196 Market street. See SUBSOIL PLOUGHING.

PLOUGHING. The art of turning over the soil by means of the plough. There are various kinds of ploughing. Trench ploughing is effected by the plough passing twice along the same furrow: the first time for the purpose of throwing the surface soil into the bottom of the furrow, and the second time for raising a furrow-slice from under that which had been already turned over, and raising it up, &c., turning it upon the first furrow-slice, by means of which the surface soil is entirely buried, and a stratum of subsoil laid over it: thus effecting in the field what trenching with the spade does in the garden. Trench ploughing can only be employed with advantage where the subsoil is naturally dry and of good quality, or where it has been rendered so by draining and subsoil ploughing; for bad subsoil brought to the surface, unless considerably altered in composition and texture, would be unfit for receiving seeds or plants.

To excel in the art of ploughing, the ploughman should take a pleasure in his work, and not rest satisfied till he can make his furrows in a straight line, and lay the slices as much as possible at the same angle from the bottom of the furrow. He should open his first furrow in a uniform manner, and proceed with regularity of width and depth of the furrow-slice, and "shut up" clean at last.

Ploughing matches, which of late years have been so general, have given a very increased interest to ploughmen and ploughboys. The face of the country is in many parts strikingly improved by the change which sound ploughing has effected, and much of this may be traced to the lively interest which has been paid to this part of tillage by agricultural societies and by practical farmers. I never knew a ploughing-match meeting established in any rural district without very beneficial effects being produced on the character of the peasantry. It never fails to elevate the ploughman in his own opinion; it induces him to strive to excel in his honourable vocation, to please his employer, and to stand well in the estimation of his richer neighbours. The very assemblage of the neighbouring farmers and gentry to wit-

ness the trial of skill, brings out all the latent pride of the roughest ploughman. The flowers in his horses' bridles, the network on their ears, the new, gay-coloured tape with which their manes and tails are braided, betray the little feelings of honest pride in the ploughman's bosom. When at a recent meeting I noticed the air of triumph with which the victor in the field of Langley, in Buckinghamshire, after having had the queen's prize of five guineas awarded to him, marched his sleek, well-fed plough-horses off the field, with a sprig of laurel in their bridles, I could not but admit that the effect of that meeting would be felt, not only amongst the contending ploughmen there assembled, but through the adjoining hundreds. The triumph, too, was not confined to the ploughman; his master, nay, his parish, shared in the honour; and I will engage that many an honest ploughman, between one year's meeting and the next, as he ploughs "his acre," thinks of the field of meeting, and of the best means of securing a prize. Such meetings, moreover, teach even the most ignorant the importance of such affairs; that there is a great difference in the neatness, style, and profit to the farmer where the ploughmen execute their work properly; and they are pretty sure to convince even the most listless that there is more skill required in a ploughman than many persons would readily believe.

I believe it admits of no doubt, says Mr. Stephens, that, since the institution of ploughing matches throughout the country, the character of our farm-servants as ploughmen has risen to considerable celebrity, not but that individual ploughmen could have been found before the practice of matches existed as dexterous as any of the present day, but the general diffusion of good ploughing must be obvious to every one who has been in the habit of observing the ploughed surface of the country. This improvement is not to be ascribed to the institution of ploughing matches alone, because superior construction of implements, better kept, better matched, and superior races of horses, and superior judgment and taste in field labour and in the farmer himself, are too important elements in influencing the conduct of ploughmen, to be overlooked in a consideration of this question.

But be the primary motive for improvement in the most important branch of field labour as it may, there cannot be a doubt that a properly regulated emulation amongst workmen of any class, proves a strong incentive to the production of superior workmanship, and the more generally the inducement is extended, the improvement arising from it may be expected to be the more generally diffused; and on this account the *plough medals* of the Highland Agricultural Society of Scotland, being open for competition to all parts of Scotland every year, have perhaps excited a spirit of emulation among ploughmen, by rewarding those who excel, beyond any thing to be seen in any other country. Wherever 15 ploughs can be gathered together for competition at any time and place, there the ploughman who obtains the first premium offered by those interested in the

exhibition, is entitled to receive, over and above, the Society's plough medal of silver, bearing a suitable inscription, with the gainer's name. About 40 applications are made for the medals every year, so that at least 600 ploughmen annually compete for them; but the actual number far exceeds that number; as, in many instances, matches comprehend from 40 to 70 ploughs, instead of the minimum number of 15. The matches are usually occasioned by the welcome which his neighbours are desirous of giving an incoming tenant to his farm, and its heartiness is shown in the extent of the assistance which they give him in ploughing a field or fields at a time when he has not yet collected a working stock sufficient for the purpose.

Ploughing matches are generally very fairly conducted in Scotland. They usually take place on lea ground, the ploughing of which is considered the best test of a ploughman's skill, though I hold that drilling is much more difficult to execute correctly. The best part of the field is usually selected for the purpose, if there be such, and the same extent of ground, usually from 2 to 4 ridges, according to the length, is allotted to each portion of ground to be ploughed. A pin, bearing a number, is pushed into the ground at the end of each lot, of which there are as many marked off as there are ploughs entered in the competition. Numbers corresponding to those on the pins are drawn by the competing ploughmen, who take possession of the lots as they are drawn. Ample time is allowed to finish the lot, and in this part of the arrangements I am of opinion that too much time is usually allowed, to the annoyance of the spectators. Although shortness of time in executing the same extent of work is not to be compared to excellency of execution, yet it should enter as an important element into the decision of the question of excellence. Every competitor is obliged to steer his own lot, guide his own horses, and do every other thing connected with the work, such as assorting his horses, and trimming his plough-irons, without the least assistance.

The judges, who have been brought from a distance, and have no personal interest in the exhibition, are requested to inspect the ground after all the ploughs have been removed, having been kept away from the scene during the time the ploughs were engaged.

The primary objects of the institution of ploughing matches must have been to produce the best examples of ploughmanship; and by the best must be understood that kind of ploughing which shall not only appear to be well done, but must be thoroughly and essentially well done. In other words, the award should be given to the plough that produces not only work of a proper surface finish, but which will exhibit, along with the first, the property of having turned up the greatest quantity of soil and in the best manner. (*Book of the Farm.*)

The following will be found a useful table, showing the distance travelled by a horse in ploughing or scarifying an acre of land; also the quantity of land worked in a day, at the rate of 16 and 18 miles per day of 9 hours.

Breadth of Furrow—slice or Scarifier.	Space travelled in ploughing an acre.	Extent ploughed per day at the rate of	
		18 Miles.	16 Miles.

PLUM (*Prunus*, from *prune*, its Greek name) A genus of trees and shrubs, several of which are indigenous to Britain. Having already noticed the bird cherry (*P. padus*), the wild cherry tree (*P. cerasus*), the wild bullace tree (*P. insititia*), the black thorn or sloe (*P. spinosa*),

under their several heads, it only remains to speak in this place of the wild and cultivated species of plum tree. The wild plum tree (*P. domestica*) is a moderate sized tree, without thorns, found growing sometimes in woods and hedges, flowering in May. The fruit is rather oblong, seldom quite globular, its colour and flavour very variable. "Whether all our cultivated plums have originated from this species, or from the wild bullace tree" (*P. insititia*), says Sir J. E. Smith, "its thorns having disappeared by culture like those of the pear tree, is a question which perhaps no botanist can ever solve." As to its varieties, Gerarde declares that "to write of plums particularly would require a peculiar volume, and yet the end not be attained unto, nor the stock or kindred perfectly known, neither to be distinguished apart." He adds that each country has an abundance of its own peculiar varieties. All the kinds of plum grow well in any common soil, and are increased by seeds or suckers, or by grafting or budding to perpetuate the particular kinds. There are 274 varieties named in the catalogue of the Horticultural Society. As a choice selection for a small garden, Mr. Nicol recommends the following twelve varieties: Jaune Hâtive, Wilmot's Orleans green gage, red magnum-bonum, white ditto, Coe's golden drop, Caledonian, mussel, damson, wine-sour, white bullace, blue impératrice.

The best plums for cultivation may be thus classed—

a. **PURPLE ROUND.**—*Shoots smooth.*—Purple gage; nectarine plum; Kirkes; virgin; queen-mother.

Shoots downy.—Royal native; Orleans; early Orleans; Coxe's fine late red; wine-sour.

b. **OBLONG.**—*Shoots smooth.*—Blue impératrice; Inkworth impératrice; Cooper's large red.

Shoots downy.—Blue perdrigon; Shropshire damson.

a. **PALE ROUND.**—*Shoots smooth.*—Green gage; Knight's large green drying; Lucombe's nonsuch.

Shoots downy.—Drap d'or; Mirabelle; Washington.

b. **OBLONG.**—*Shoots smooth.*—Coe's golden drop; St. Catherine; White magnum bonum.

Shoots downy.—Gumaraen; White perdrigon.

If plum trees are much pruned, they grow too luxuriant to produce fruit, and often gum and spoil. The choice varieties of plums are much esteemed for the dessert; the more common sorts are used for pies, tarts, preserves, &c. The wood is employed for turnery and cabinet work, and for the manufacture of musical instruments.

The following information relative to the cultivation and management of plum trees, is from a communication made by Mr. S. Reeve, of Salem, N. J., to that valuable American work, Hoffs's Orchardist's Companion.

Plum trees, like other fruit trees, when first transplanted, and for a few or several subsequent years, should be managed and cultivated alike; but when the plum tree has arrived to maturity and ready to bear, the soil around it

should be thrown into a hard texture, for instance, of the consistency of a gravel walk.

A pig and poultry yard which remains uncultivated, and never suffered to become a sward, is also very appropriate, from the circumstance of its being promenaded over constantly by bipeds and animals so as to preclude the possibility of grass growing.

In a soil of this description, owing to its being compact and consequently remaining drier, the trees do not grow so fast as in cultivated grounds, the beneficial result is, that the sap centres itself more in the fruit; whereas, when the sap is too abundant, it is more apt to flow past the fruit into the branches, and thus ultimately, from a want of nourishment, the plums drop off in profusion, owing to their starved condition, and not so much, as it is often supposed, from the bore or sting of the curculio, of which it is frequently found divested when picked from the ground.

From a compact position or nature of soil as before described, another important advantage arises: although not operating as a perfect antidote to the attacks of the curculio, it is nevertheless a great preventive to its depredations, from the circumstance that this insect, when the fruit does fall, not meeting with a surface or soil such as sward, garden ground, &c., in which to take shelter until the following spring, when it hatches and assumes the winged form, and again commences its destructive attacks upon the fruit.

Mr. Reeve submits it therefore as his opinion, that it would fully repay any person for his trouble or expense in removing (which should only be done when vegetation is checked) from the plum tree, when it has arrived to the age of 8 to 10 years, all the rich subsoil from around the tree in a circumference of from 10 to 12 feet down to the clay soil, and fill up the space again with poor earth, sand, or gravel, so as to check the growth of the tree for the benefit of the fruit, in accordance with the first principles stated in this article.

PLUM TREE WEEVIL. It is now well known that the falling of unripe plums, apricots, peaches, and cherries, is caused by little whitish grubs, which bore into these fruits. The loss of fruit, occasioned by insects of this kind, is frequently very great; and, in some of our gardens and orchards, the crop of plums is often entirely ruined by the depredations of grubs, which have been ascertained to be the larvæ or young of a small beetle of the weevil tribe, called *Rhynchænus* (*Conotrachelus*) *Nenuphar*, the Nenuphar or plum-weevil. "I have found the beetles," says Dr. Harris, of Boston, "as early as the 30th of March, and as late as the 10th of June, and at various intermediate times, according with the forwardness or backwardness of vegetation in the spring, and have frequently caught them flying in the middle of the day. They are from three-twentieths to one-fifth of an inch long, exclusive of the curved snout, which is rather longer than the thorax, and is bent under the breast, between the fore-legs, when at rest. Their colour is a dark-brown, variegated with spots of white, ochre-yellow, and black. The thorax is un-

even; the wing-covers have several short ridges upon them, those on the middle of the back forming two considerable humps, of a black colour, behind which there is a wide band of ochre-yellow and white. Each of the thighs has two little teeth on the under side. They begin to sting the plums as soon as the fruit is set, and, as some say, continue their operations till the first of August. After making a suitable puncture with their snouts, they lay one egg in each plum thus stung, and go over the fruit on the tree in this way till their store is exhausted; so that, where these beetles abound, not a plum will escape being punctured. The irritation arising from these punctures, and from the gnawings of the grubs after they are hatched, causes the young fruit to become gummy, diseased, and finally to drop before it is ripe. Meanwhile the grub comes to its growth, and, immediately after the fruit falls, burrows into the ground. This may occur at various times between the middle of June and of August; and, in the space of a little more than three weeks afterwards, the insect completes its transformations, and comes out of the ground in the beetle form. The history of the insect thus far is the result of my own observations; the remainder rests on the testimony of other persons."

In an account of the plum-weevil, by Dr. James Tilton of Wilmington, Delaware, published in the *Domestic Encyclopædia*, (article *Fruit*,) and since republished in the "Georgical Papers for 1809" of the Massachusetts Agricultural Society, and in other works, it is stated, that peaches, nectarines, apples, pears, quinces, and cherries are also attacked by this insect, and that it remains in the earth, in the form of a grub, during the winter, ready to be matured into a beetle as the spring advances. These statements, says Dr. Harris, I have not yet been able to confirm. It seems, however, to have been fully ascertained by Professor Peck, Mr. Say, and others, in whose accuracy full confidence may be placed, that this same weevil attacks all our common stone-fruits, such as plums, peaches, nectarines, apricots, and cherries; Dr. Burnett has recently assured me that he has seen this beetle puncturing apples; and it is not at all improbable that the transformations of some of the grubs may be retarded till the winter has passed, analogous cases being of frequent occurrence. Those that are sometimes found in apples must not be mistaken for the more common apple-worms, which are not the larvæ of a weevil. The Rev. F. V. Melsheimer remarks in his catalogue, that this insect lives under the bark of the peach-tree. Professor Peck raised the same beetle from a grub found in the watery excrescence of a cherry tree, and from this circumstance named it *Rhynchænus Cerasi*, the cherry-weevil. The plum, still more than the cherry tree, is subject to a disease of the small limbs, which shows itself in the form of large irregular warts, of a black colour, as if charred. Grubs, apparently the same as those that are found in plums, have often been detected in these warts, which are now generally supposed to be produced by the punctures of the beetles, and the residence of the grubs. Professor

Peck says, that "the seat of the disease is in the bark. The sap is diverted from its regular course, and is absorbed entirely by the bark, which is very much increased in thickness; the cuticle bursts, the swelling becomes irregular, and is formed into black lumps, with a cracked, uneven, granulated surface. The wood, besides being deprived of its nutriment, is very much compressed, and the branch above the tumour perishes." The grubs found by Professor Peck in the tumours of the cherry tree, went into the ground on the 6th of July, and on the 30th of the same month, or 24 days from their leaving the bark, the perfect insects began to rise, and were soon ready to deposit their eggs in healthy branches.

In speaking of the difference between the grub of the plum-weevil and apple tree caterpillar, Dr. Harris observes, "It must be borne in mind that this plum-weevil, an insect unknown in Europe, when arrived at maturity, is a little, rough, dark-brown or blackish beetle, looking like a dried bud, when it is shaken from the trees, which resemblance is increased by its habit of drawing up its legs and bending its snout close to the lower side of its body, and remaining for a time without motion and seemingly lifeless. In stinging the fruit, before laying its eggs, it uses its short curved snout, which is armed at the tip with a pair of very small nippers; and by means of this weapon it makes, in the tender skin of the young plum or apple, a crescent-shaped incision, similar to what would be formed by indenting the fruit with the finger-nail. Very rarely is there more than one incision made in the same fruit; and in the wound, the weevil lays only a single egg. The insect hatched from this egg is a little whitish grub, destitute of feet, and very much like a maggot in appearance, except that it has a distinct, rounded, light-brown head. By means of the microscope I have satisfactorily ascertained that the grubs from the fruit and from the warts were exactly alike, and that both were without feet. It appears, furthermore, that the tumours on plum and on cherry trees are infested not only by these insects, but also by another kind of grub, provided with legs, and occasionally by the wood-eating caterpillars of the *Ageria exitiosa*, or peach tree borer. When the grubs of the plum-weevil are fully grown, they go into the ground, and are there changed to chrysalids of a white colour, having the legs and wings free and capable of some motion; and finally they leave the ground in the form of little beetles, exactly like those which had previously stung the fruit. Further observation seems to be wanting before it can be proved that the cankerous warts on plum and cherry trees arise from the irritating punctures of the plum-weevils, and of the other insects that occasionally make these warts their places of abode; although it must be allowed that the well-known production of galls by insects on oak trees and on other plants, would lead us to suppose that those of the plum tree have a similar origin. In addition to the means already recommended for preventing the ravages of plum-weevils, I would observe that wall-fruit can be perfectly secured by a screen of millinet or close netting, which should be put on as

soon as the fruit is formed, and should remain till it begins to ripen.

The following, among other remedies that have been suggested, may be found useful in checking the ravages of the plum-weevil. Let the trees be briskly shaken or suddenly jarred every morning and evening during the time that the insects appear in the beetle form, and are engaged in laying their eggs. When thus disturbed they contract their legs and fall; and, as they do not immediately attempt to fly or crawl away, they may be caught in a sheet spread under the tree, from which they should be gathered into a large, wide-mouthed bottle or other tight vessel, and be thrown into the fire. All the fallen wormy plums should be immediately gathered, and after they are boiled or steamed, to kill the enclosed grubs, they may be given as food to swine. The diseased excrescences should be cut out and burned every year before the last of June. The moose plum tree (*Prunus Americana*), which grows wild in Maine, seems to escape the attacks of insects, for no warts are found upon it, even when growing in the immediate vicinity of diseased foreign trees. It would, therefore, be the best of stocks for budding or engrafting upon. It can easily be raised from the stone, and grows rapidly, but does not attain a great size. For further suggestions and remarks, the account of this insect by Dr. Joel Burnett, in the 18th volume of the *New England Farmer*, may be consulted. (Harris.)

Plums, nectarines, and apricots have been saved after being stung, by extracting the stung part. This may be done with the point of a knife or nippers properly adapted to the purpose. The wounds heal and the fruit grows and attains to perfect maturity.

POA (From *poa*, signifying grass or herbage). The meadow-grass. A genus of grasses of considerable extent, and very abundant in the pasturages of Europe. This genus contains some valuable hay and pasture grasses, succeeding well in rich loamy soil; some of the species are aquatic, growing only in water, or in very moist situations; and increased by seeds or divisions of the roots. *Poa annua*, pl. 6, c, is the most common of all grasses. *P. trivialis* and *P. pratensis* are sown extensively as a part of the artificial grasses for pastures and lawns, which are now commonly made with picked grasses instead of "hay seeds." In general these grasses appear to be nutritious and agreeable to cattle. There are, in England, nine indigenous species, besides several varieties.

1. Flat-stalked meadow-grass (*P. compressa*), pl. 7, h. This is a very common species in dry, barren ground, flowering from June to September.

The root is moderately creeping, with downy fibres; stems obliquely ascending in the lower part, then erect and often crowded together, from 1 to 1½ foot high, remarkably compressed, by which this species may readily be known, as also by a sudden contraction where the panicle begins. Leaves short, narrow, roughish, especially at the edges, with long compressed sheaths, and a short obtuse stipule. The whole plant is more or less glaucous.

Florets from three to eight or nine, connected at the base by a mass of white folded threads, as fine and soft as a spider's web, which may be drawn out to a considerable length. This grass, though not succulent, is eaten by all cattle, but cannot be cultivated in moist or manured ground. It never forms a close turf, and although it possesses superior nutritive powers, its produce anywhere is far from abundant.

A variety of this species (*P. c.* var. *erecta*) is mentioned by Sinclair, which differs from the last, in having culms more upright, less compressed, and produced in greater quantities. It grows closer, forms a pretty good sward, and the roots are less inclined to creeping. But it is nevertheless inferior in point of early growth, and the produce of the foliage. See BLUE GRASS.

2. Alpine meadow-grass (*P. alpina*), pl. 6, l. This species is chiefly confined to alpine regions and lofty mountains.

3. Wavy meadow-grass (*P. laxa*). This species grows in some of the Highlands of Scotland. It possesses no agricultural merit.

4. Bulbous meadow-grass (*P. bulbosa*). This species tenants the sandy sea-shore, and other dry, barren ground. It is perennial, and flowers in April and May.

5. Roughish meadow-grass (*P. trivialis*), pl. 5, i. This is a very common species, in meadows and pastures, especially such as are rather moist. Perennial, flowering from June to October. The root is fibrous, and tufted; the stems several, about eighteen inches high, erect, leafy, with several knots, the naked part cylindrical, roughish to the touch, as are the edges and backs of the flat, slightly spreading, lax, linear, deep-green leaves. In their long compressed sheaths also a slight roughness is sometimes perceptible. Panicle large, spreading with half-whorled, horizontal, wavy, angular, rough-compressed, unequal branches. Mr. Curtis, deeply versed in the practical economy of grasses, declares this to be one of the most valuable for pasturage and hay, yielding abundantly, though not particularly early; and of the most excellent quality. Mr. G. Sinclair, another practical authority on the grasses, also observes, "The superior produce of this *Poa* over many other species, its highly nutritive qualities, the seasons in which it arrives at perfection, and the marked partiality which oxen, horses, and sheep have for it, are merits which distinguish it as one of the most valuable of those grasses which affect moist, rich soils and sheltered situations: but in dry, exposed situations it is altogether inconsiderable; it yearly diminishes, and ultimately dies off, not unfrequently in the space of four or five years. Its produce is always much greater when combined with other grasses than when cultivated by itself; with a proper admixture, it will nearly double its produce, though on the same soil, so much does it delight in shelter. Those spots in pastures that are closely eaten down, consist for the most part of this grass."

6. Smooth-stalked meadow-grass (*P. pratensis*), pl. 5, h. This is a very common species in all meadows and pastures. It is perennial, flowering in May and June. The root is strong and creeping, with horizontal runners. The

general aspect of the plant is very like the last, with which it has usually been confounded; but the stems and leaves betray no roughness when drawn through the hand. Spikelets four-flowered; florets lanceolate, ribbed, connected by a web. But the clear and essential mark of this species, compared with the last, consists in its very short, abrupt, pointless stipule, which in every leaf of every variety proves constant and invariable.

As an object of agriculture, this species is not less valuable than the *P. trivialis*, especially for permanent pasture. It is earlier in leaf, and will thrive with less moisture, though the rough-stalked meadow-grass produces, at last, a better crop. Mr. Curtis, and several other able botanists, have rendered great service to the farmer in directing his attention to such objects; and it is undoubtedly worth his while to be select in seeds for grass lands. But, after all, Nature is supreme in the accommodation of particular grasses to certain soils and situations, and whatever we may sow, unless we have well studied her laws, she finally triumphs. The great objection to this grass is the property of the creeping roots to scourge the soil.

Mr. Sinclair notices, in his experiments on the grasses, two varieties, the short blue meadow-grass (*P. pratensis subcærulea*) and the narrow-leaved meadow-grass (*P. pratensis angustifolia*), pl. 6, e, which requires some notice here.

The discriminating characters of the first-named are as follows:—Panicle diffuse; spikelets oval, generally three-flowered; the culms shorter, and somewhat glaucous; and the leaves much shorter and broader than those of the *Poa pratensis*. It may be further distinguished by its delicate sky-blue or glaucous colour. From its creeping roots and other demerits, this is evidently one of the inferior grasses. Although the botanical characters of the narrow-leaved meadow-grass (*P. angustifolia*) are not sufficient to constitute it a distinct species, its agricultural merits cause it to differ from *P. pratensis*, to which it is much superior. Its spring produce is considerable, and its properties of early growth and great nutritive matter would rank it with the most valuable grasses, but for its powerful creeping root. The culms are most valuable for the manufacture of the finest straw-plait, in imitation of the celebrated "Leghorn." See BLUE GRASS.

7. Annual meadow-grass, Suffolk-grass (*P. annua*), pl. 6, c. This is an exceedingly common species everywhere, as well in waste as cultivated ground, flowering from April to November. The root is fibrous. Stems pale, very smooth, oblique, compressed, 3 to 12 inches long. Leaves of a fine light-green, spreading, linear, bluntish, flaccid, roughish at the edge only. Panicle small, widely spreading. Spikelets ovate, five-flowered; florets a little remote, five-ribbed, without a web.

This is a good grass for fodder, abundant in proportion to the richness of the soil, easily raised, but not durable. The diminutive size of the plant, however, renders its cultivation unprofitable, compared with that of any other of the pasture grasses. It is the most trouble-

some weed that infests gravel walks, stone pitchings, and the like. The most effectual way to extirpate it in such situations is to sprinkle salt on it; some recommend boiling water and a layer of litter, &c.

This grass, which Dr. Darlington calls meadow-poa, in the Middle States goes by the name of green grass, spear-grass, and meadow-grass. Although it is styled an annual, it has a perennial root. This species varies considerably, in size and appearance, when growing in different soils and situations. In our best soils, the radical leaves are very long and luxuriant,—when it is known by the name of *green grass*. This has by some botanists been made a distinct species, under the name of *P. viridis*: but it is probably nothing more than a variety. It is, indeed, as Muhlenberg terms it, "*optimum pabulum*;" being decidedly the most valuable of all the grasses known in our pastures. It has not been found necessary to cultivate it, by sowing the seed; for when the land is duly prepared by lime and manure, it soon takes possession of the soil,—or *comes in*, as the farmers term it; and supersedes the artificial grasses. In very poor land, it deteriorates so much that it would scarcely be recognised as the same plant. It is generally believed by the botanists to be a naturalized foreigner in the United States.

8. Glaucous meadow-grass (*P. glauca*). This species is found on the mountains of Wales, Scotland, and the north of England.

9. Wood meadow-grass (*P. nemoralis*). This is a very common species in some districts in groves and woods, especially on chalk soils. The whole plant is very slender and delicate, $1\frac{1}{2}$ or 2 feet high. Stems several, slightly compressed, smooth, striated, leafy, with 4 or 5 joints. Leaves almost all on the stem, grass-green, narrow, flat, more or less rough, tapering to a fine slender point. Mr. George Sinclair speaks favourably of a variety of this species, which he names *P. nemoralis*, var. *angustifolia*. Although the produce is inconsiderable compared to that of many others equally nutrient, yet the early growth of this grass in the spring, and its remarkably fine, succulent, and nutritive herbage, recommend it strongly for admission into the company of the superior permanent pasture grasses. It flowers in the third week of June, and ripens the seed in the end of July.

The *P. aquatica*, Pl. 5, m, or water meadow-grass, of some botanists, is the reedy sweet-grass (*Glyceria aquatica*) of Smith. The decumbent meadow-grass (*P. decumbens*) is the decumbent heath-grass (*Triodia decumbens*) of Smith's *English Flora*. The reflexed meadow-grass (*P. distans*) of Sinclair is the reflexed sweet-grass (*Glyceria distans*) of modern botanists. The *Glyceria fluitans* is also sometimes called the *Poa fluitans*.

One or two exotic species are mentioned in Sinclair's work on the grasses, viz.,

The soft meadow-grass (*P. cenisia*). This alpine species is a native of Germany, and attains to a greater size than most others of the same class. The root is fibrous. Panicle diffuse, nodding. Its nutrient properties, as indicated by the quantity of nutritive matter it

contains, are not superior to those of several other grasses, which afford a greater abundance of herbage throughout the season.

The fertile meadow-grass (*P. fertilis*). It produces flowers about the first and second weeks of July, and seeds in the second week of August. This grass, which is also a native of Germany, seems to be allied to the *Poa nemoralis*. It differs in having the panicle more loose and spreading, and less attenuated. The spikelets are more oval, and nerved. The culm rises from a foot and a half to 2 feet in height, and sometimes more, ascending at the base, afterwards erect, somewhat compressed. The root is slightly creeping. In regard to early growth, this grass stands next to the meadow fox-tail, cock's-foot, and tall oat. The herbage is more nutritive than that of either of those grasses; and from its agricultural merits it deserves a place in the composition of rich pastures, and ranks with the superior grasses of irrigated meadows. It flowers in the beginning of July, and the seed is ripe towards the end of the month.

The nerved meadow-grass (*P. nervata*). This species is a native of North America. Panicle upright, often half a foot or more in length, with slender branches, pressed close and subdivided. Spikelets small, of a green colour. Valves of the blossom smooth, having five raised nerves on each valve. Leaves in two rows, resembling a fan, somewhat rough. Culm a little compressed. This grass is remarkably hardy, and possesses many very excellent properties: it will be found a valuable ingredient in permanent pastures, where the soil is not too dry, but of a medium quality as to moisture and dryness. The root leaves are produced on a shoot, and stand in two rows after the manner of a fan. This shoot, which is formed by the union of the base of the leaves, is very succulent, and contains a greater proportion of nutritive matter than the leaves, which accounts for the superior nutrient qualities of the latter. It flowers in the third week of June, and the seed is ripe in the last week of July.

POCKET. A large kind of bag in which hops are packed up.

POD. A term used to express the siliqua and silicula of botanists. A seed-vessel of some plants, consisting of two valves, separated by a linear receptacle, along each of the edges of which the seeds are alternately ranged. The wall-flower affords an example of the *siliqua*, which differs from the silicula merely in being oblong instead of being short and round. The satin-flower, or honesty, bears a pouch or silicula.

POISON (Fr.). Any substance which in small quantity disturbs, suspends, or destroys one or more of the vital functions. Poisons are classified by Orfila under the four heads of irritants, narcotics, narcotico-acrids, and putreficients, or septic, and, we may add, sedatives. The same poisons which affect men usually affect horses, cows, and dogs; but goats and wine eat many things that are virulent poisons to other animals. Sweet almonds and aloes are poisonous to dogs; sugar is poison to pigeons, parsley to parrots, and pepper to hogs.

On the other hand, hogs devour *Nux vomica* and henbane with impunity; goats browse on *Aconite*, *Cicula virosa*, and *Arnica montana*, harmless; and sheep eat common hemlock without suffering. See ANIMAL AND VEGETABLE POISONS, FUNGI, SHEEP, DISEASES OF, YEW, &c.

POITTEVIN'S MANURE. A compound organic and earthy manure powder, well adapted for the use of the drill. See MANURES APPLICABLE BY THE DRILL.

In three experiments with this manure, tried in 1840, on turnips against bones, the following are the results.

	Produce.	
	Tons.	Cwt.
First, on the stony soil.		
24 bushels of Poittevin's	-	9 2
16 bushels of bones	-	10 1
Second, on a sandy soil.		
24 bushels of Poittevin's	-	15 10
16 bushels of bones	-	13 14
Third, on a sandy soil with Swedes.		
13 bushels of Poittevin's	-	11 0
12 bushels of bones	-	10 5

This manure answers best on light soils; it is generally used too sparingly.

POLE. A measure of length equal to 16½ feet.

POLLARD. A name given to a tree that has been frequently polled or lopped, and its top taken off, or headed down to the stem, for the purpose of fire-wood or small poles for hurdle-wood and other similar uses, as well as for hop-poles, &c. The term is most commonly in use in the southern and eastern districts of Great Britain. *Pollard* is also applied to the fine bran or inner husk of wheat. It is a substance much used in feeding hogs and different domestic animals.

POLLEN. In botany, the pulverulent substance which fills the cells of the anthers of a plant, consisting of a multitude of little hollow cases, filled with a fluid holding very minute molecular matter in suspension. The latter is eventually discharged by the grains of pollen through their hollow tubes, and is supposed to be the spermatic fluid of a plant. When the pollen alights on the stigma of the plant, the membrane lining the shell is protruded to a tube, which enters the stigma, and lengthens until it reaches the ovule, into which it empties the impregnating fluid. The pollen grains vary in form and magnitude, being globular, angular, compressed, simple, and compound. *Pollen* is also a provincial name given to the hen-roost. It is sometimes written hen-pollen.

POLL-EVIL. An accident which sometimes occurs to horses, from the animal's rubbing or striking his head against the lower edge of the manger, or hanging back in the stall and bruising the part with the halter. Such injuries are serious in their nature and difficult of treatment, and will usually require the skill and anatomical knowledge of the veterinary surgeon.

POLYPODY. (*Polypodium*, from *poly*, many and *pous*, a foot; having numerous root-like feet. This is an extensive genus of very ornamental ferns. The hardy kinds are well adapted for ornamenting rock-work, or they may be grown in pots, in light loamy soil. All the species may be readily increased by dividing the roots, or by seeds.

There are in England four indigenous species.

POMEGRANATE (*Punica*, from *punicus* of "Carthage," near which city it is said to have been first found; or from *punicus*, scarlet; alluding to the colour of the flowers). A beautiful, hardy, deciduous shrub, growing from 12 to 15 feet high. There is no tree more showy than the pomegranate. *P. granatum*, and its varieties, produce their splendid flowers and fruit very plentifully from July to September, when planted against a south wall. They all grow well in a light, rich loam, and strike root freely from cuttings or layers; the rarer varieties are sometimes increased by grafting on the common kinds. The pomegranate requires shelter from frost. The pulp of the fruit is of an agreeable acid, and the rind is highly astringent.

POPLAR (*Populus*; some derive the word from *paipallo*, to vibrate or shake; others suppose it obtained its name from being used in ancient times to decorate the public places in Rome, where it was called *Arbor populi*, or the tree of the people). Most of the species of poplar are very ornamental, more especially in early spring, when the catkins of the males are produced. Their favourite place of growth is in moist soil, near a running stream; but they do not thrive in very marshy situations. All the species are readily increased by cuttings or layers, and some by suckers. There are in England four indigenous species of poplar: the white poplar, already noticed under the head ABLE TREE; the gray or common white poplar (*P. canescens*); the trembling poplar (See ASPEN); and the black poplar (*P. nigra*).

The black Italian, or necklace-bearing poplar (*P. monilifera*), appears to have been first introduced into Britain from North America, in 1772. Of all the poplars hitherto introduced, it is by far the most valuable, looking to it in the light of a useful and profitable timber tree, as it grows with astonishing rapidity, and produces a timber of large scantling and excellent quality, equal, if not superior, to that of any other of its genus. The wood is of a grayish-white colour, tough when seasoned, and, if kept dry, very durable; its great size renders it fit for the largest buildings, and as flooring for manufactories and other erections, nothing can surpass it; for, in addition to the property of not splitting by percussion, it possesses the peculiar advantage of not easily taking fire, and, even when ignited, burning without flame or violence. As an ornamental tree, it well deserves a place in extensive grounds, its spiry height and pyramidal form, before it becomes aged, being well calculated to break long horizontal lines, or the monotonous effect of round-headed trees: it also in a great measure, from its semi-fastigate growth in the young state, supplies the place of the Lombardy poplar in such scenery, either of wooded landscape or in combination with buildings, as is improved by the presence of that tree.

The Lombardy poplar (*P. fastigiata*). In its close fastigate growth and cypress-like form, which seems to be retained during the whole of its existence, the Lombardy poplar is too conspicuous not to be immediately recognised and readily distinguished from all other species of the genus. As a useful and profitable

timber tree it is greatly inferior to some of the species already described, the twisted and deeply-furrowed trunk, even of the tallest and largest trees, cutting to much waste, and affording boards of only a moderate size when sawn up. The wood is also softer and more spongy than that of the black and the black Italian poplars, and rapidly decays unless kept perfectly dry. In Britain, therefore, it is cultivated almost exclusively as an ornamental tree, for which its towering height and spire-like form eminently qualify it.

The Athenian poplar (*P. Græca*) as an ornamental tree is superior, in many respects, to the aspen (to which it is closely allied). It grows rapidly, young trees often making shoots in one season of 5 or 6 feet in length, and, though a slender-stemmed tree, it has the valuable property of resisting the wind, and is never seen, even in the most exposed situations, but an erect and perpendicular trunk.

The bark of all the poplars is more or less antiperiodic and tonic, containing an alkali, which can be procured separate, and is known by the name of *Salicina*. It may be used for curing agues in the same manner as *Quinine*, an alkaloid got from Peruvian bark.

There are many North American species of poplar, among which is the tulip tree (*Liriodendron tulipifera*), one of the most majestic trees of the American forests, but which has been improperly classed among the poplars. See TULIP TREE.

The other and more genuine species is the Carolina poplar (*P. angulata*). The lower part of Virginia, says Michaux, is the most northern point at which this species is found.

In the shape of its leaves and other characteristics, it bears a very strong resemblance to the cotton tree. The two species may, however, be readily distinguished by their buds, those of the Carolina poplar being short, of a deep green, and destitute of the resinous, aromatic substance which covers those of the cotton-wood, and of which the vestiges remain till late in the season. The wood of the Carolina poplar is white, but so very soft as to be of little value.

The Cotton-wood (*P. Canadensis*).—I have found this tree, says Michaux, in the upper part of the State of New York, on the banks of the Genesee, in some parts of Virginia, and on several islands in the Ohio, always on a fat, alluvial soil.

The leaves of this tree are trowel-shaped, approaching to heart-shaped. The seeds are surrounded with a beautiful plume which has the whiteness of cotton, and the young buds are covered with a resinous, aromatic substance of an agreeable odour. In the Atlantic States this poplar is rare, and has received no specific name.

American poplar (*P. Hæsonica*).—This species, Michaux says, he found only on the banks of the Hudson, above Albany, where it attained a height of 30 or 40 feet, with 12 to 15 inches in diameter. Several large poplars of this kind grow in and near the city of New York, where it is usually called American black poplar.

Virginia poplar (*P. monilifera*).—This species

was not found by the Michaux, but has been long cultivated in Europe as a North American tree. It is also called the Swiss poplar, and is confounded with the cotton-wood.

Cotton tree (P. argentia). This species is scattered over a great extent of country comprising the Middle, Western, and Southern States; but it is so rare as to escape the notice of the greater part of their inhabitants. It is called cotton-wood on the Savannah in Georgia, where it is confounded with the Carolinian poplar.

Tacamahaca or Balsam poplar (P. balsamica). This species belongs to the northern regions of America, being very abundant in Canada, in the districts watered by the river Sagney, between the 47th and 49th degrees of latitude, where, notwithstanding the severity of the winter, it rises to the height of 80 feet, with a diameter of 3 feet. In the spring, when the buds begin to be developed, they are abundantly coated with a yellowish, glutinous substance, of a very agreeable smell.

Heart-leaved balsam poplar (P. candicans). In the Northern and Eastern States, this tree, which Michaux says is a genuine balsam, is commonly seen growing before the houses in town and country. In spring, a fragrant resinous balsam exudes from its buds; but it differs from the Tacamahaca, its leaves being three times larger and more heart-shaped.

American aspen (P. tremuloides). See ASPEN, AMERICAN.

American large aspen (P. grandidenta). This species belongs rather to the Northern and Middle than to the Southern States. It is larger than the preceding species, with which it is usually confounded.

POPPY (*Papaver*, from *papa*, pap, or thick milk; the juice of the poppy was formerly used in children's food to make them sleep). These plants succeed best in a light, rich soil. The perennial kinds are increased by dividing at the roots. All the species are narcotic. In England there are six indigenous species of poppy, which are nearly all annuals. They are arranged under two sections:—1. Those with *bristly capsules*; 2. Those with *smooth capsules*.

The 1st section contains the round, rough-headed poppy (*P. hybridum*), which grows in sandy or chalky fields. This is not a hybrid, as its name implies, but a true permanent species.

Long, rough-headed poppy (*P. argemone*). This grows in grain fields and thin borders, also on gravelly or sandy soils. It is annual, and flowers in June and July. The herbage resembles the preceding, but the bristles are less closely pressed to the stem, and the segments of the leaves are somewhat broader. Petals pale-scarlet, black at the base, soon falling, often jagged.

The 2d section contains the long, smooth-headed poppy (*P. dubium*). This species is found in cultivated fields, especially on a light soil. Annual, and flowering in June and July. It is of a stouter, more luxuriant habit than the foregoing, with broader leaves. The stem is clothed with spreading hairs; the flower-stalks with close-pressed bristles. Petals broader

than they are long, of a light-scarlet, the margin mostly crenate.

Common red poppy, or corn rose (*P. rhæus*). See CORN POPPY. This is the only officinal species of the British poppies; but it is used in medicine merely as a colouring agent.

White poppy (*P. somniferum*). This species appears to grow wild on sandy ground in the neighbourhood of some of the fen lands. But it is probable that in places where it is found apparently wild, the seed from the cultivated poppy has been deposited by birds. The somniferous poppy is a native of Asia and Egypt. It is cultivated in Hindostan, Persia, and Egypt, on account of its opium; in Germany for the oil expressed from its seeds; and in England for the capsules, which are used in medicine. It is universally known in our gardens as an ornamental flower, and is much cultivated in the vicinity of London. The whole herb is glaucous, and generally smooth, though the flower-stalks now and then bear several rigid, spreading, bristly hairs. The stem is 3 or 4 feet high, erect, branched, leafy. Leaves broad, wavy, lobed, and bluntly notched, clasping the stem with their heart-shaped base. Flowers 3 inches broad, white or bluish-white, with a broad violet spot at the base of each petal. In gardens, double varieties of every shade of purple, scarlet, crimson, and even green mixed with white, are common, though nothing can be more liable to change. The capsule is nearly globular. Seed small, whitish-brown, oily, sweet, and eatable. There are two varieties, namely, *P. album* and *P. nigrum*, chiefly distinguished by the foramina under the stigma being absent in the former, and present and open in the latter. The milky juice of the capsules, when abstracted by transverse incisions and inspissated, forms opium, which, as Haller well observes, is far more potent and dangerous in hot countries than in our cooler climates. The capsules boiled afford a mild, narcotic decoction, more generally used for fomentations in inward pains, and for making a syrup, which is misused by lazy nurses, who administer it to restless infants, and sacrifice them to their own love of ease. Nothing is more to be condemned than the indiscriminate use of syrup of poppies. No opium, except as experiment, is made from poppies in England; and, could it be made, both it and the foreign opium should never be employed except by the advice of those who alone ought to direct its use.

Yellow poppy (*P. cambricum*). This is a perennial species (and the only indigenous one) which flourishes in moist, rocky situations in Wales and Westmoreland. It flowers in June. The herbage is tender, brittle, of a light, slightly glaucous green; its juice lemon-coloured. Stem a foot high, many-flowered, thinly covered with upright hairs, leafy, branched. Flowers of a most elegant, full lemon colour, deliciously fragrant.

Field poppy (*Papaver dubium*), bastard poppy. This foreign annual, says Dr. Darlington, has made its appearance in some of the cultivated grounds of Pennsylvania and other parts of the United States, and, if neglected, may become a troublesome weed.

POPPY, THE HORNED. See HORNED POPPY

POPULATION. As very erroneous notions with regard to over-population are often entertained, and as many of the most philanthropic men in England have, at considerable personal trouble and cost, promoted emigration, to avert the evils of war, pestilence, and famine, from what Mr. Malthus supposes to be the tendency of mankind to excessive population, it may be well for the public to peruse a paper (*Quart. Journ. Agr.* vol. iii. p. 89), which, in detail, ably examines and refutes many of Mr. Malthus's data, calculations, and conclusions. Mr. Malthus states, from data derived through a variety of sources, that the average births from each marriage are—

In Europe - - - - -	4·000
England - - - - -	4·136
France, during the six years ending in 1822 -	4·370
Russia - - - - -	4·110
America (in towns) according to Mr. Barton	4·500
America (in town and country average) -	5·000

But, from returns made to government, it appears that the average births in England and Wales, during the 30 years ending 1820, fell considerably under 4 from each marriage; and of these, from personal deformity, and a hundred other causes, a considerable portion of women must remain unmarried.

But supposing *every woman, married or single, who lived to 18 years of age*, should have 7 children, and the rate of mortality as favourable as at Carlisle, the population would require more than 26 years to double itself; and 25 years is the lowest rate of increase Mr. Malthus has contemplated. But, supposing one-tenth part of all the women who attain 20 to remain in a state of celibacy, and the rest were to bear each 3·66 children, which is stated by Mr. Sadler to be the average prolificness in England, and the mortality continued as at Carlisle, the population would remain entirely stationary. In the rich and fertile country of France, the population is nearly stationary, and in Ireland, population increases faster than in England; which can only be accounted for by the institutions which encourage increased forethought before entering on the married state. Amongst barbarous nations, the period of marriage is almost always early; but as countries become civilized, a portion of early life is devoted to labour of mind and body; and the desire of distinction in some, and, amongst all, the pursuit of gain, delays marriage; and, happily for mankind, nothing is less consistent with universal experience than the terrible succession of evils Mr. Malthus fears from over-population. Natural evils, and the more dreadful effects of misrule, have, indeed, spread death and desolation; but the consequences have not been increased plenty to the survivors: on the contrary, the page of history shows that, in the fairest portions of the habitable world, poverty and want have followed decreasing numbers.

Whereas the wiser the laws, and, consequently, the more *secure person and property*, the slower men are to marry till they have secured for themselves and families, in a habitation of their own, the conveniences they were used to under their paternal roofs; and, consequently, the

tendency to the excessive multiplication

of mankind; and we refer to Scotland, France, &c., as existing proofs.

No society, well governed, we repeat, has been known to outgrow, or tend to outgrow, its means of subsistence. When, in our own country, one of the most populous in the world, we see how far the earth is yet from producing all that labour, well-directed, can bring forth, when we look at the tracts lying waste or half-cultivated, we must see how little it is to be feared as a possible evil, that our population will ever increase beyond the means of supplying itself with food. We have only to look to what minute care can effect in multiplying the produce of the earth, to feel in what a prodigious ratio it may be multiplied. A piece of heath land, the most worthless, converted into a cottager's garden, yields a return of food exceeding that of the richest land of the cultivated fields. And nothing prevents the increase of this species of culture but the want of hands to cultivate and of mouths to consume. Every vegetable that grows, and is consumed, affords new materials for fertilizing the earth, and increasing its productions; and thus every increase of the number of consumers is a means of calling new food into existence.

The introduction of a single plant from another hemisphere has more than doubled the power of this and of every country in Europe to support their inhabitants. An acre of potatoes will supply food sufficient for the support, in healthful existence, of a family of 6 human beings for one year; a square mile of land producing potatoes, therefore, will support 3840 persons for the same time. But the produce of the potato is as nothing to that of the banana and other plants of the tropical regions. No one does the produce of the potato in our fields show the full power of the earth to produce food. By the minute cares of the gardener successive crops of vegetables may be produced from the same surface, and in the same season. Our present knowledge of agriculture shows us, that throughout the whole kingdom the productions of the earth may be prodigiously multiplied; but what our present knowledge of this art is in comparison with what it may become, we know not. What other plants are yet to be applied to the support of animal life, what other means of fertilizing the earth are yet to be discovered, what other applications of mechanical power may yet take place in aid of human labour, we know not; nor need we, with relation to our present subject, be too curious in inquiring. It suffices that, with our present means and knowledge, limited as they are, we can multiply our means of subsistence in a degree to furnish food for increasing numbers for more generations of men than the cares of the living race need extend to.

And if such be the case with a long-peopled country, what must we think of the fear that the entire world will be over-peopled? The richest regions of the globe have yet been scarcely trodden by the foot of the hunter; a great part of Europe is still a desert; and a long desolation has overspread lands that once were the seats of nations, and which only demand security that they may be blessed with abundance again. Such as Asia Minor, Syria

nd Greece, and such the long-desolated shores of Northern Africa. It is not Nature that is barren of her gifts, but it is man that has abused them all; and, in the climates and the lands where we might look for the verdure of an eternal spring, we find only the moving mountains and interminable tracts of the desert.

It is unnecessary, perhaps, to enlarge upon this statement, but one or two facts will surely convince the most incredulous that we are not yet nearly arrived at the maximum available produce of the earth. Even as regards the sowing in the seed-corn, we have witnessed in our time that the drill has done much, and the sowing system still more; but, by transplanting, greater things may yet be done. I will illustrate this position by only one or two facts out of many of a similar kind that I am acquainted with. At the Battle Horticultural Show (in 1837), R. White received a prize for 1 fine ears of wheat growing from one grain, which are deposited at the apartments of the Labourer's Friend Society in Exeter Hall, and another prize at the Society for Encouragement of Arts, &c., in the Adelphi, and similar premiums are again offered there and elsewhere. P. Brown raised that year 345 roots, with 4250 ears, from one grain, since June, 1836, the plants having been divided three times; and it is recorded in the *Philosophical Transactions* for 1768, that in the same space of time, one grain of wheat produced 21,109 ears, containing 76,840 grains, or nearly a bushel of clean grain; thus, an acorn cup would hold seed-wheat enough to raise plants for an acre of land, and full 10,000,000 bushels of seed-wheat might be saved on the 4,000,000 acres under wheat in England and Scotland; which quantity, allowing 8 bushels to each person, would support 1,250,000 persons, who, if employed in reeding the crops, would double the produce, as is shown by the increased crops raised by the tenants under the allotment system.

And again, as regards manuring the soil, agriculture is yet only in its infancy; crushed bones, now so extensively employed, were unknown as fertilizers 25 years since; gypsum, which abounds in England, is only slowly coming into use; and millions of tons of the richest manure are now annually wasted in our cities and towns—suffered to putrefy in cess-pools, or poured into the sea through a thousand sewers; “and yet,” says the Thames Improvement Company, “strange as it may appear, England is almost the only nation in Europe, notwithstanding its advance in agricultural knowledge, which suffers the peculiar manure in question to be wasted and cast away; while all the other nations on the Continent, and even China, husband it, and treasure it up for their lands, make it an object of extensive and lucrative traffic, and some export it to their colonies. The principal London sewers have been carefully gauged, and are found to convey daily into the river Thames 115,608 tons of mixed drainage.”

By these and other certain improvements, we may safely conclude that, as regards the cultivation of the most barren tracts, the drifting sands of Norfolk, the heath lands of the

north of England, and even the shingle of its sea-coast, hardly a tithe has yet been effected in the way of cultivation. At the suggestion of the Archbishop of Dublin, an acre of shingle at East Bourn was covered with 3 or 4 inches of clay, at a cost of only 16*d.* This has formed a plate to retain what mould, &c., the tenant has added, who has hired this ground for fourteen years at 40*s.* per acre. So no land is hopelessly barren. Let such improvements proceed; let science go hand in hand with the farmer; let the naturalist find new cultivatable vegetables, or new varieties of those already known; let the chemist yield his magic aid to demonstrate the best mode of promoting their growth and increasing the fertility of the soil; and then, I fearlessly assert that many times the present inhabitants of Britain may be amply supported by the produce of the land of our birth.

POPULATION, AGRICULTURAL, OF THE UNITED STATES. By the census of 1840, it appears that the number of all the males, of 10 years old and upwards, in the United States and Territories, exclusive of the naval service, was 5,907,752. The whole population of the Union was 17,069,453, of which the number engaged in agricultural pursuits is more than a fifth part of the whole population. When this is compared with the proportions engaged in some other pursuits, we find the next most numerous class comprised of those engaged in the various manufactures and trades, which, in the non-slaveholding states and territories, amounts to 1 in 17, and in the slave states to 1 in 40—averaging, in the whole Union, 1 to 22 of all the inhabitants. The largest proportion of manufacturers is in Rhode Island, where it constitutes about four-fifths of all the males above 20 years of age; next in Massachusetts; next in Connecticut; next in New Jersey; next in New York. The proportion employed in commerce comprises, in the free states, 1 in 122, and in the slave states 1 in 197—the average in all the states being 1 in 146 of the whole population. The largest proportion is in Louisiana, which contains the great depôt for the commerce of the Mississippi Valley. The next largest is in Wisconsin Territory, and the next in Rhode Island. The proportion employed in ocean navigation is greatest in Massachusetts, where it amounts to 27,153, being 1 in 31 of the whole population of the state, and nearly one-half of all those engaged in the same pursuits in the whole Union, viz., 56,021, or 1 in 305. The next greatest is in Maine, where it amounts to 10,091, being 1 in 49.72 of the state population. New York has 5511, Connecticut 2700, and Pennsylvania 1815, employed in ocean navigation. The proportion engaged in the learned professions, including engineers, amounts to 45,162, or 1 in 217 of the whole population of the free states, and 20,093, or 1 in 361, of the whole inhabitants of the slave states.

PORES. In botany, apertures, more or less visible, in the cuticle of plants, through which transpiration takes place. They may exist on the cellular tissue; and when there they are the organs of insensible perspiration of the

plant: they may exist as cortical pores; or on the leaf as stomata or breathing pores. Pores also exist in some kinds of anthers, through which the pollen is ejected; as in the potato (*Solanum tuberosum*).

PORK. The flesh of swine killed for culinary purposes. See **BACON, HAM, MEAT, SWINE, &c.**

PORTER. A well-known malt liquor. See **ALE, BEER, and BREWING.**

POTASH, or POTASSA. The name of one of the alkalies, composed of 39·15 parts of peculiar metal called potassium, 8 parts of oxygen, and 9 of water. It derives its common name from being first obtained from the ashes of vegetable substances which had been burned in iron pots, hence named pot-ashes. Potash is found in almost all land plants, in combination with the tartaric, citric, or other vegetable acid. The potash in these is no doubt an essential food or constituent of vegetation, and there is no fertile soil which does not, in some form or other, contain this alkali. It exists, however, in plants in varying proportions. See **ALKALI.** The potash of commerce is an impure carbonate mingled with salts of lime and other substances. In its separate or pure state, free from carbonic acid, it is a white salt, powerfully attracting moisture from the air, very soluble in water and in alcohol, corroding animal substances, consequently destroying the skin when applied to it. But potash usually means the carbonate. The quantity procured from different plants varies. Fumitory yields 79·0 in 1000 parts, wormwood 73·0, young wheat-stalks 47·0, thistles 35·0, vetch 27·5, common nettle 25·3, the sunflower 20·0, bean-stalks 20·0, barley straw 5·8, vine-shoots 5·5, wheat-straw 3·9, and flax 5·0. The younger a plant is, if full-grown, the more potash it yields.

“The perfect developement of a plant,” says Liebig (*Organic Chem.* p. 104), “according to this view, is dependent on the presence of alkalies, or alkaline earths, for when these substances are totally wanting, its growth will be arrested, and when they are only deficient it must be impeded. In order to apply these remarks, let us compare two kinds of trees, the wood of which contain unequal quantities of alkaline bases, and we shall find that one of these grows luxuriantly in several soils, upon which others are scarcely able to vegetate. For example, 10·000 parts of oak wood yield 250 parts of ashes, the same quantity of firewood only 83, of linden wood 500, of rye 440, and of the herb of the potato plant 1500 parts. Firs and pines find a sufficient quantity of alkalies in granitic and barren, sandy soils, in which oaks will not grow, and wheat thrives in soils favourable for the linden tree, because the bases which are necessary to bring it to complete maturity exist there in sufficient quantity. The accuracy of these conclusions, so highly important to agriculture, and to the cultivation of forests, can be proved by the most evident facts. All kinds of grasses, the equisetaceæ, for example, contain, in the outer parts of their leaves and stalks, a large quantity of silicic acid (silica), and potash in the form of acid silicate of potash. The proportion of this

salt does not vary perceptibly in the soil of corn-fields, because it is again conveyed to them as manure, in the form of putrefying straw. But this is not the case in a meadow; and hence we never find a luxuriant crop of grass on sandy and calcareous soils, which contain little potash, evidently because one of the constituents essential to the growth of plants is wanting. Soils formed from basalt, grauwacke, and porphyry, are, cæteris paribus, the best for meadow land, on account of the quantity of potash which enters into their composition.”

In the experiments of the Rev. E. Cartwright with various manures applied to potatoes, wood-ashes, which contain potash, were found to produce very superior effects to several others: thus, where the soil, without any dressing, produced 157 bushels per acre, the land dressed with 60 bushels of wood-ashes yielded 187; with 60 bushels of malt-dust, 184 bushels; with 363 bushels of decayed leaves, 175 bushels; with 363 bushels of saw-dust, 155 bushels; with 121 bushels of lime, 150 bushels per acre. (*Com. Board of Agr.* vol. iv. p. 370.) See **GREEN SAND, ALKALIS, and SALTS.**

POTATO (*Solanum tuberosum*). A valuable, well-known root, first imported from America into England by Sir Walter Raleigh, and first grown at Youghall, in Ireland. In many parts of England this tuberoso plant is very extensively cultivated, both in the field and in the garden; but, in districts removed from large towns, or convenient markets, its cultivation is of necessity restricted to the garden, or for the consumption of the live-stock of the farm. As regards the field management of the crop, a writer in a popular journal remarks, when speaking of the preparation of the ground—

“It is, I know, customary, upon a large scale, to plough the land and make it tolerably fine before potatoes are planted; but if it is ploughed 5, 6, or 7 inches deep, and made fine and mellow, still at the bottom of such ploughing the land is hard and smooth; and as the potato is a root that sends out fibres not only near the surface, but deeply, if possible, it can never produce such a crop as where the land is broken 18 inches to 2 feet. The potato, like the cucumber, only enjoys itself in deeply pulverized soils, which causes them to flourish so much in well-managed sandy land.

“I should therefore recommend that, in all land where potatoes are to be grown, if the land be springy, or otherwise damp, that it be drained deep enough to take off all springs or surface water. When this is done, the land should either be fully trenched, or bastard-trenched, by the spade or plough, but I prefer the spade. The width of the drills from each other must depend entirely upon the goodness of your soil: the richer the land, the wider apart must be your rows and sets in your rows; say, in ordinary land rows, at 2 feet from each other, and 12 inches from set to set may do; but if your land be very rich, 3 feet from row to row, and 18 inches from plant to plant, will not be too much.”

In preserving your sets, always select the largest and finest potatoes you can procure; do not use the small refuse or middling-sized,

the plant and produce from the latter being much inferior.

The potatoes most valued in field culture are the ox-noble, yam, champion, purple-red, rough-red, hundred-eyes, kidney, and Moulton white. The nutritive qualities of these were examined by Mr. George Sinclair, with his usual accuracy. "The yam," he observes, "is a very productive variety, attains to a large size, but is often hollow, and less nutritive than most others; 64 drachms afford of nutritive matter 190 grains, which consist of starch 164 grains, and saccharine and albuminous matters 31."

The ox-noble is a productive potato, adapted for stock; and 64 drachms of it contain 194 grains of nutritive matter, consisting of starch 164, and saccharine, mucilaginous, and albuminous matters 31.

The purple-red is smaller than the ox-noble, but well-flavoured, and very prolific in light, moist soils: 64 drachms afforded 200 grains of nutritive matter, consisting of starch 169, and albuminous and saccharine matters 31 grains.

The hundred-eye is very prolific on dry loams; 64 drachms afford 218 grains of nutritive matter, composed of 170 grains of starch, and the rest albuminous and other matters.

The rough-red produces plentiful crops on soils or climates of a moister nature than that adapted for the hundred-eyed variety: it is well-flavoured; 64 drachms afford 250 grains of nutritive matter, which is composed of 199 starch, and 46 mucilage, sugar, and albumen.

The champion grows to a moderate size; is very productive, and little subject to the disease called *curl*.

It is, hence, of great importance, in choosing seed potatoes, to consider the nature of the soil and climate; thus some of our finest varieties, which yield abundantly when planted in suitable soils and moist situations, will yield but inferior returns when planted in drier situations.

	Soluble matter.	Starch.	Fibre.	Water.
In 7000 grains, or 1 pound of the bread-fruit potato, 1 found by careful and repeated trials -	975	548	477	5000
— the Barbadoes potato	980	667	616	4737
— black kidney potato	970	695	622	4713

The soluble matters consisted of gum, or mucilage, extractive, and saline matters.

The potato, although a tender plant, is grown in nearly all parts of the world, from the equator to Norway; and although it is usual to plant it early in the spring, yet it is possible, by choosing a quick-ripening variety, to plant it successfully even as late as July.

The best manures for the potato crop are common farm-yard compost, only partially decomposed, decayed leaves, sea-weed, the potato haulm, and any organic manures, that, while they afford nutriment, have a tendency, by rendering the soil lighter, to facilitate the extension of the roots. Lime is injurious to it. Pond mud or ditch scrapings, to each cubic yard of which, a month previously, a bushel of bacon salt, or other refuse common salt, has been mixed, is excellent. The soils best adapted for the cultivation of the potato are of the light,

sandy, drained, peaty, or loamy description. It delights in fresh soils; those of a newly broken-up meadow, old woodlands, or the site of old yards or buildings, are excellent. It does not do well on wet clays.

Potatoes are readily consumed by live-stock in their unboiled state; but, generally speaking, they are best when steamed and mixed with chaff.

The cultivation of the potato is thus described by Mr. George Johnson; and although his remarks were intended for the gardener, yet they apply in a great measure to the field culture of this valuable root.

The varieties of the potato are numerous, and continually increasing, as well as becoming extinct; the number, however, is very largely increased by local names for the same variety being classed distinct.

For forcing, or first crop in the open ground:—there are Broughton Dwarf, Early Warwick, Ash-leaved Kidney; Fox's Seedling, Early Manly, Early Mule, earliest for general cultivation, Earley Kidney, Nonsuch, Early Shaw, Goldfinger.

For main crops, the varieties are ranged in this class, according to their forwardness in ripening:—Early Champion, Ox Noble, Red-nose Kidney, Large Kidney, Bread-fruit, Red-streak or Lancashire Pink-eye, Black Skin, Purple, Red Apple, Rough Red.

No inhabitant of the garden varies more in quality in different gardens than the potato; for a variety will have a strong, unpleasant flavour in one soil, that has a sweet, agreeable one in another. In a heavy, wet soil, or a rank black loam, though the crop is often fine and abundant, it is scarcely ever palatable. Silicious soils, even approaching to gravel, though in these last the tubers are usually corroded or *scabby*, are always to be planted in preference to the above. A dry, mouldy, fresh, and moderately rich soil is unquestionably the best for every variety of the potato; and, for the earliest crop, it may be with advantage more silicious than for the main ones. The black-skinned and rough red thrive better than any in moist or strong, cold soils. If manure is necessary, whatever may be the one employed, it is better spread regularly over the surface previous to digging, rather than put into the holes with the sets, or spread in the trench when they are so planted. Stable dung is, perhaps, the best of all factitious manures: sea-weed is a very beneficial addition to the soil, as is salt. Coal-ashes and sea-sand are applied with great benefit to retentive soils; but calcareous matter should never be used. The situation must always be open.

It is propagated in general from cuttings of the tubers, though the shoots arising from thence and layers of the stalks may be employed. New varieties are raised from seed. Planting in the open ground of the early kinds may commence towards the close of February, in a warm situation, and may thence be continued until the same period of March; and it is only during this latter month that any considerable plantation should be made, as the late frost are apt to injure, or even to destroy the advancing plants. In the course of April.

the main crops for winter's use should be inserted; for although in favourable seasons they will succeed if planted in May or even June, yet it ought always to be kept in mind that the earliest planted, especially in dry soils, produce the finest and most abundant crops.

Of the preparation of the sets, there is a great diversity of opinion. Some gardeners recommend the largest potatoes to be planted whole; others, these to be sliced into pieces, containing two or three eyes; a third set, to cut the large tubers directly in half; a fourth, the employment of the shoots only which are thrown out, if potatoes are kept in a warm, damp situation; and a fifth, that merely the parings be employed. Cuttings of the stalks, 5 or 6 inches in length, or rooted suckers, will be productive, if planted during showery weather in May or June; and during this last month, or early in July, it may be propagated by layers, which are formed by pegging down the young stalks when about 12 inches long, they being covered 3 inches thick with mould at a joint. These three last modes are practised more from curiosity than utility, whilst at the same time none of the first five mentioned plans can be individually followed to advantage, without modification. For the main crops, it is evident, from experiment, that moderate-sized sets, having two healthy buds or eyes, are most advantageously employed; middling-sized whole potatoes are the best, from which all but the above number of eyes have been removed, but especially having *the crown*, which is a congeries of small eyes always present, first removed; for from these proceed an equal number of little spindled stalks, which are comparatively worthless, and injure the main stem.

For the early crops, almost the very contrary to the above is the most advantageous to be practised. The set should have *the crown eye*, which is one growing in the centre of the congeries of small ones above mentioned, preserved. Some potatoes have two such eyes, but the generality only one. This is always the most prompt to vegetate; and if not known by this description, may be evinced by placing two or three potatoes in a pan of moist earth, near the fire; if the earth is kept moist, the crown eye will be in a state of vegetation in five or six days. Again, as Mr. J. Knight remarks, although abundant crops of late varieties may be obtained from very small sets, by reason that tubers are not produced until the stem and roots become capable of supplying them with nourishment; yet, to obtain early crops, where tubers are rapidly formed under a diametrically opposite state of the plant, large sets must be employed; in these, one or two eyes, at most, should be allowed to remain. Mr. Knight plants the largest undivided tubers, which, from experiments, evidently support the plants, and finally produce the earliest and largest produce he ever obtained. Another remark, which he makes, restrictively for the early crops, but may well be attended to for all, is, that if the sets are placed with their leading buds upwards, few and very strong early stems will be produced; but if the position is reversed, many weak and later shoots will arise,

and not only the earliness, but the quality of the produce be depreciated. For the earliest crops, there are likewise several modes of assisting the forward vegetation of the sets. These should be prepared in November, by removing every eye but one or two; and being placed in a layer, in a warm room, where air and light can be freely admitted, with a covering of straw, they soon emit shoots, which must be strengthened by exposure to the air and light as much as possible, by taking off the covering without injuring them. During cold weather, and at night, it must always be renewed. The leaves soon become green, and tolerably hardy. In early spring they are planted out, the leaves being left just above the surface, and a covering of litter afforded every night, until the danger of frost is passed. The only modification of this plan that is adopted in Cheshire, where they are celebrated for the early production of potatoes, is, that they employ chaff or sand for a covering instead of straw. The most preferable mode of inserting them, is with the dibble, in rows, for the early crops, 12 inches apart each way; and for the main ones 18. The set should never be placed more than 4 inches beneath the surface in the lightest soil, but in the more tenacious ones, 3 is the extreme. The potato dibble is the best instrument that can be employed; one person striking the holes, and a second dropping the sets, the earth being afterwards raked or struck in with the spade. There are several other modes of insertion, as opening a small hole with a narrow spade, and the set being dropped in, it is covered by the earth taken out in forming the next hole: or, at the time of digging over the ground, a second person follows the one so employed, and places the sets in the trench he opens in the pursuance of his work; but both these modes are open to numerous obvious objections.

The compartment may be laid out level and undivided, if the soil is mouldy and favourable; but if a heavy one is necessarily employed, it is best disposed in beds, 6 or 8 feet wide. If the staple of the soil is good throughout, the alleys may be 2 feet wide, and dug deep, otherwise they must be made broader, and only one spit taken out, the earth removed being employed to raise the beds. If the land is low and wet, it is still further of advantage, after the beds, which should not be more than 4 feet wide, have been thus raised, if they are dug in parallel ridges, and the sets inserted along their summits. Some gardeners, on such soils, without digging the surface, lay some long litter on the intended beds; upon this the sets being placed, some more litter is thrown regularly over them; the earth is then dug from the alleys, and turned to the requisite depth over the whole. As soon as the plants are well to be distinguished, they should be perfectly freed from weeds; and, of the early crops, the earth drawn round each plant, so as to form a cup, as a shelter from the cold winds, which are their chief enemy at that season; but the main crops need not be earthed up until the plants are 6 inches in height. It is contended by some that this practice is immaterial in its effect. If the earth is brought so as to be of

considerable depth about the stems, it must be even injurious; but if properly performed, it is certainly beneficial. Throughout their growth they should be kept perfectly clear of weeds. It is very injurious to mow off their tops, as is sometimes recommended. The foliage ought to be kept as uninjured as possible, unless, as sometimes occurs on fresh ground, the plants are of gigantic luxuriance, and, even then, the stems should be only moderately shortened. It is, however, of considerable advantage to remove the fruit-stalks and immature flowers as soon as they appear. This has been demonstrated by the experiments of President Knight, and others; indeed, that such would be the case is a reasonable expectation, since it is known that the early formation of tubers prevents the production of blossom. It is also worthy of notice, that a potato plant continues to form tubers until the flowers appear, after which it is employed in ripening those already formed.

The very earliest crops will be in production in June, or perhaps towards the end of May, and may thence be taken up as wanted, until October, at the close of which month, or during November, they may be entirely dug up and stored; or, at all events, before the arrival of any severe frost. Their fitness to be taken up for keeping is intimated by the decay of their foliage, which generally loses its verdure with the first frosts. The best instrument with which they can be dug up is a three-flat-pronged fork, each row being cleared regularly away. The tubers should be sorted at the time of taking them up; for as the largest keep the best, they alone should be stored, whilst the smaller ones are first made use of. The most common mode of preserving them throughout the winter is in heaps or clamps, sometimes called *pyeing* them. These are laid in pyramidal form, on a bed of straw, and enveloped with a covering 6 or 8 inches thick, of the same material, laid even, as in thatching, and the whole enclosed with earth, in a conical form, a foot thick, taken from a trench dug round the heap, well smoothened with the back of the spade. Potatoes should not be stored until perfectly dry, nor unless free from mould, refuse, and wounded tubers. It is a good practice to keep a hole open on four different sides of the heap, entirely through the mould and straw, for a week or two after the heap is formed; for in proportion to its size it always ferments, and these orifices allow the escape of the vapours, and perfect the drying. An equally good mode, and much more convenient, is to have them heaped in a dry shed, and covered thick with straw, as opportunity is given to look over them occasionally for the removal of decayed tubers, shoots, &c. If carefully preserved, they continue in perfection until late in the following summer. A variety of the potato is generally considered to continue about 14 years in perfection, after which period it gradually loses its good qualities, becoming of inferior flavour and unproductive. Fresh varieties must therefore be occasionally raised from seed. For doing this there are two modes; the first of these, about to be detailed, is, however, the one usually pursued.

The berries or apples of the old stock having hung in a warm room throughout the winter, the seed must be obtained from them by washing away the pulp during February. This is thoroughly dried, and kept until April, and then sown in drills about half an inch deep, and 6 inches apart, in a rich mouldy soil. The plants are weeded, and earth drawn up to their stems when an inch in height; as soon as this has increased to three inches, they are moved into a similar soil, in rows 16 inches apart each way, and during their future growth earthed up 2 or 3 times. Being finally taken up in the course of October, they must be preserved until the following spring, to be then repanted, and treated as for store crops. (*Dr. Hunter's Georg. Essays.*)

Some gardeners sow in a moderate hot-bed, very thin, in drills, the same depth as above, and 9 inches apart. Water is frequently and plentifully poured between the rows, and earth drawn about the stems of the seedlings, until they are a few inches in height. They are then transplanted into rows, water given, and earthing performed as usual. The only additional advantage of this plan is, that as the seed can be sown earlier, the tubers attain a rather larger size the first year.

It is to be remarked, that the tubers of every seedling should be kept separate, as scarce 2 will be of a similar habit and quality, whilst many will be comparatively worthless, and but few of particular excellence. If the seed is obtained from a red potato, that flowered in the neighbourhood of a white-tubered variety, the seedlings in all probability will in part resemble both their parents, as a cross fecundation may take place; but seldom or never does a seedling resemble exactly the original stock. At all events, only such should be preserved as are recommended by their superior size, flavour, or fertility. It may be stated as an indication before these qualities can be positively ascertained, that President Knight remarks, that the rough, uneven surface of the foliage, which in excess constitutes the curl, appears to exist as, and form a characteristic of every good variety; for he never found one with perfectly smooth and polished leaves which possessed any degree of excellence, though such are in general more luxuriant and productive.

The early varieties, on account of their never flowering, were, until 1807, obtained by chance from plants that might now and then be produced from seed of the late kinds. In that year, Mr. Knight discovered that the cause of their deficiency of bloom was the preternatural early formation of the tubers. His mode of causing them to produce seed is to plant the sets on little heaps of earth, with a stake in the middle, and when the plants are about 4 inches high, being secured to the stakes with shreds and nails, to wash the earth away from the bases of the stems, by means of a strong current of water, so that the fibrous roots only enter the soil, and these being perfectly distinct from the runners that furnish the tubers, and which spring from the base of the stem, none of these are produced, and the effect is, that blossoms appear and perfect seed.

There are numerous valuable communica-

tions with regard to the potato dispersed through the agricultural journals, among which is one "On the Manures best adapted for Potatoes," by the Rev. E. Cartwright. He remarks, "The soil on which my experiments were tried is a ferruginous sand, brought to a due texture and consistence by a liberal covering of pond-mud. Of this soil, in its improved state, I mean by the accession of pond mud (for, having been used merely as a nursery for raising forest trees, previous to these experiments, the nurseryman had not thought it necessary to make use of any other manure), the following is the analysis 400 grains gave:

Of silicious sand, of different degrees of fineness	Grains.	280
Finely divided matter - - - - -		104
Loss in water - - - - -		16
		<hr/> 400

"The finely divided matter contained—

Carbonate of lime - - - - -	Grains.	18
Oxide of iron - - - - -		7
Loss by incineration (probably vegetable decomposing matter) - - - - -		17

"The remainder, principally silex and alumina. There were no indications of either gypsum or phosphate of lime.

"On the 14th of April, 1804, a portion of this soil was laid out, in beds 1 yard wide and 40 in length, and were manured as in the following table. On the same day the whole was planted with potatoes, a single row in each bed, and that the general experiment might be conducted with all possible accuracy, each bed received the same number of sets. On the 21st of September the potatoes were taken up, when the produce of each row was, in succession, as follows:

Manures in bushels, per acre.	Produce.
1. No manure - - - - -	157
2. Salt 8 bush., soot 30 bush. - - - - -	240
3. Chandler's graves 9½ cwt. - - - - -	220

25. Lime 121 bush. - - - - -	150

The following experiments upon potatoes are extracted from Mr. George Sinclair's Communication to the Board of Agriculture, February 25th, 1820. These experiments were made upon a soil composed of three-fourths silicious sand, in plots of 36 square feet.

	Bushels of Salt per Acre.	No.
1. Planted without any kind of manure - - - - -	0	124
2. Twelve cubic inches of salt with the seed - - - - -	13½	106 the smallest.
3. Six cubic inches of salt with the seed - - - - -	6½	90
4. Twelve cubic inches of salt mixed with the soil - - - - -	13½	93 the largest.

"The weight of the crop of potatoes was not taken. The superior size of the roots produced by No. 4, left no room to doubt of the advantage of 13 bushels of salt per acre, applied to the soil previous to planting, over the other modes of application; still the superiority was not very great." "I may notice here," observes Dr. Holland, "a practice pursued at Weston, near Frodsham, in the culture of potatoes, which seems deserving of attention. At this place, situated close to the junction of the Mersey and Weaver, sea mud is used as a manure for crops of potatoes; 20 loads being the quantity usually laid on an acre. The ground thus manured not only gives a larger produce of potatoes, but is in a state of excellent preparation for a succeeding crop of either wheat or barley. The adoption of this practice has increased very greatly the value of land about Weston."

There is also a paper by Mr. Knight "On the advantages of employing large Tubers for Seed." "The good effects," he observes, "which I have proved to arise from planting large tubers of the potato plant, obviously spring from the large accumulation of fecula in them. Fed by means of this, not only a large breadth of foliage is produced, and exposed to sight more early in the year, but that foliage contains much disposable organizable matter, which once formed a part of the parent tuber." Knight thought that the ordinary produce of potatoes might be very materially increased. He remarks, "My opinion is, that more than a thousand bushels of potatoes may and will be obtained from an acre of ground."

Potatoes are fermentable, and are consequently employed along with barley by the Scotch distillers; and, also, by the London bakers in the manufacture of bread. The fecula is also separated and sold as arrow-root: it is a good and sufficiently pure starch; but it is less nutritive than the potato itself, owing to the separation of the saccharine matter and the albumen.

POTATO-FLY or BEETLE. The green cantharides, or Spanish-flies, as they are commonly called, are found in the south of Europe, and particularly in Spain and Italy, where they are collected in great quantities for exportation. In these countries they often appear in immense swarms on the privet, lilac, and ash, which are quickly stripped of their foliage by these leaf-eating beetles. In like manner the American species of cantharides devour the leaves of plants, and sometimes prove very destructive to them, especially to those of the potato. Four native species of the cantharides found in the United States, have been tried and ascertained to be as effectual in raising blisters as the imported species. The kind found on the potato is the striped cantharis (*Cantharis vittata*). It is of a dull, tawny yellow or light yellowish-red colour above, with two black spots on the head, and two black stripes on the thorax and on each of the wing-covers. The under-side of the body, the legs, and the antennæ are black, and covered with a grayish down. Its length is from five to six-tenths of an inch. In this and the three following species the thorax is very much narrowed before

and the wing-covers are long and narrow, and cover the whole of the back. The striped cantharis is comparatively rare in New England; but in the Middle States it often appears in great numbers, and does much mischief in potato-fields and gardens, eating up not only the leaves of the potato, but those of many other vegetables.

The most destructive kind of *Cantharis*, found in Massachusetts, is of a more slender form than the preceding, and measures only from five and a half to six-tenths of an inch in length. Its antennæ and feet are black, and all the rest of its body is ashen gray, being thickly covered with a very short down of that colour. Hence it is called *Cantharis cinerea*, or the ash-coloured cantharis. When the insect is rubbed, the ash-coloured substance comes off, leaving the surface black. It begins to appear in gardens about the 20th of June, and is very fond of the leaves of the English bean, which it sometimes entirely destroys. It is also occasionally found in considerable numbers on potato-vines; and in Cambridge, Massachusetts, it has repeatedly appeared in great profusion upon hedges of the honey-locust, which have been entirely stripped of foliage by these voracious insects. They are also found on the wild indigo-weed. In the night, and in rainy weather, they descend from the plants, and burrow in the ground, or under leaves and tufts of grass. Thither also they retire for shelter during the heat of the day, being most actively engaged in eating in the morning and evening. About the 1st of August they go into the ground and lay their eggs, and these are hatched in the course of one month. The larvæ are slender, somewhat flattened grubs, of a yellowish colour, banded with black, with a small reddish head, and six legs. These grubs are very active in their motions, and appear to live upon fine roots in the ground; but I have not been able to keep them till they arrived at maturity, and therefore know nothing further of their history.

About the middle of August, and during the rest of this and the following month, a jet-black cantharis may be seen on potato-vines, and also on the blossoms and leaves of various kinds of golden-rod, particularly the tall golden-rod (*Solidago altissima*), which seems to be its favourite food. In some places it is as plentiful in potato-fields as the striped and the margined cantharis, and by its serious ravages has often excited attention. These three kinds, in fact, are often confounded under the common name of potato-flies; and it is still more remarkable, that they are collected for medical use, and are sold in our shops by the name of *Cantharis vittata*, without a suspicion of their being distinct from each other. The black cantharis, or *Cantharis atrata*, is totally black, without bands or spots, and measures from four-tenths to half of an inch in length. I have repeatedly taken these insects, in considerable quantities, by brushing or shaking them from the potato-vines into a broad tin pan, from which they were emptied into a covered pail containing a little water, which, by wetting their wings, prevented their flying out when

the pail was uncovered. The same method may be employed for taking the other kinds of cantharides, when they become troublesome and destructive from their numbers; or they may be caught by gently sweeping the plants they frequent with a deep muslin bag-net. They should be killed by throwing them into scalding water, for one or two minutes, after which they may be spread out on sheets of paper to dry, and may be made profitable by selling them to the apothecaries for medical use.

A species of the genus *Meloe* (*angusticollis*), or narrow-necked oil-beetle of Say, about an inch long, and of a dark indigo-blue colour, is very common on butter-cups in autumn, and is also found on potato-vines.

POTATO MURRAIN. Since the year 1815, when the great destruction of potatoes in Great Britain and Ireland took place, with the consequent famine, this disease has been the subject of most active and earnest investigation. It would be vain to attempt giving even an epitome of the various views put forth on the subject. At present we will only refer to a single fact, which seems to afford the best clue towards determining the origin of the disease, as well as suggesting the best means of preservation and cure; namely, that the proportion of water, always large in the healthy potato, is greatly increased, say 6 to 8 per cent., in those about to become diseased. One of the best remedies is said to be planting in the fall; even partially diseased tubers planted in autumn have yielded good sound potatoes the succeeding season.

POULTICE. An external application employed for soothing pain and abating inflammation, and where this is advanced, promoting suppuration in gatherings, &c. The best for animals are prepared of ground flax-seed, or rye-meal. The main object is to have the poultice large enough to continue long moist and soft: a hard and dry poultice is much worse than none at all. In renewing poultices, the parts should always be previously well fomented with warm water. To remove unpleasant smells, mashed carrots and powdered charcoal will be found to make a good poultice.

POULTRY. A general term including every kind of domestic fowl, which is reared about the house or farm-yard, as cocks and hens, ducks, geese, turkeys, &c. Poultry constitutes a part of every farmer's stock, but the rearing of it in England is not often productive of any pecuniary advantage; for though fowls are considered chiefly as an article of luxury, and sold at high prices in the market, they seldom or ever repay the value of the corn which they have consumed, especially if such grain must be purchased. Indeed, where profit is the object of the husbandman's labours, no poultry should be admitted into the vicinity of barns, unless for the purpose of picking up scattered grain; though, in general, it cannot be denied, that they acquire their fat substance from the corn left in the straw by negligent thrashing. The poor villager may, however reap, in some cases, benefit from poultry, as the fowls are able to shift for themselves the greatest part of the year, by feeding on insects, corn, or any thing of that nature.

There are many different breeds of this sort

of live-stock; but those best known are the *game* breed, the *white* or *English* breed, the *black* or *Poland* breed, the *Dorking* breed, the large or *Shakebag* breed, and the *Malay* breed. The two first are much smaller breeds than the others. This kind of stock affords profit in the eggs, as well as the chickens; therefore such as are the best layers and sitters should be chosen, which are in general the game and Poland breeds, but the other breeds have probably the advantage in respect to the size of the eggs: as food, the game and the white breeds are said to be the most delicate.

The care and management of the poultry-yard usually devolves upon the farmer's wife, and the industrious housewife will do well to see to their food and rearing, &c., herself, and not trust too much to servants. For the most economical methods of keeping and managing poultry, &c., I refer the reader to the different heads of DOVECOTE, DUCKS, FOWLS, GOOSE, TURKEY, &c. See also EGGS, FEATHERS.

The comparative value of the keep for domestic fowls is as follows: geese 5 per cent., ducks $7\frac{1}{2}$ ditto, pigeons 10 ditto, dunghill fowls 40 ditto, turkeys and Guinea fowls 50 ditto. From a series of observations made on the diseases of domestic poultry, Mr. Flourens makes the following conclusions:—1. In these animals cold exercises a constant and determinate action on their lungs. 2. The effect of this action is the more rapid and more severe, the younger the animal is. 3. When cold does not cause acute and speedily fatal inflammation of the lungs, it produces a chronic inflammation, which is pulmonary consumption itself. [This, however, is a mistake, as pulmonary consumption is the deposition of tubercles in, not inflammation of, the lungs.] 4. Heat always prevents the attack of pulmonary disease: when the latter has taken place, heat suspends its progress, and even sometimes arrests it entirely, and effects a complete cure. 5. Pulmonary consumption in any stage is never contagious: fowls affected with that disease were not only all day along with the healthy fowls, but at night roosted in the same places, without communicating their disease to them. 6. Lastly, the action of too long confined air exposes these animals to abscesses of the cornea, and inflammation of the ball of the eye. These abscesses and inflammations are also caused in a still more cruel manner by cold, especially when accompanied with moisture. (*Annales des Sci. Nat.*) The reader will find an interesting essay by Mr. England on the rearing and management of domestic poultry, in the fourth volume of the *Trans. of the Highl. Soc.*, to which a premium was awarded. There is also a paper on the same subject in the eighth volume of the *Quart. Journ. of Agr.* p. 509.

POUND. In law, a place where cattle and goods which have been distrained are to be lodged and kept until redeemed. The common meaning in the United States is, a place where cattle are enclosed and kept. See DISTRESS.

POVERTY GRASS, or Forked *Aristida*; frequent in the Middle States, on dry, sterile soils.

PREGNANCY. In cattle, the state of being with young. Under the heads ABORTION,

CALVING, GESTATION, &c., I have gone very fully into this subject. The following excellent observations by Mr. Youatt, on the detection of pregnancy in the mare and the cow, are highly practical and useful.

Among healthy animals, the impregnation of the female rarely fails to be the result of an intercourse between the sexes. The assurance, however, of this having taken place, is, occasionally, an affair of considerable interest, and of no little difficulty; and the value and the destiny of the female may very much depend on the decision of the question. A certain time having elapsed, the thing will speak for itself; but are there any symptoms or circumstances that will warrant the veterinary surgeon, or the agriculturist, in giving a decided opinion on the case in an early period of supposed pregnancy?

It occasionally happens that the fifth or the sixth month arrives, and, even to the practised eye, there are few or no indications of conception having taken place. There are, also, but somewhat unfrequently, diseases which very closely simulate this natural process. Can the veterinary surgeon or the breeder decide? The answer is in the affirmative, and plainly and unequivocally. This is one of the boons which the veterinary art can now confer on the agriculturist. The altered character of the female is regarded, and very properly, as a circumstance of no little weight. She is comparatively calm and quiet; her appetite returns, and she regains her former condition and her former habits. Five or six weeks pass, and there is no outbreak of any kind. The owner concludes, and he is not often wrong, that she is impregnated. He, however, has had little to do with mares or with cows who has not witnessed the return of the most furious œstrum, after a much longer period of time has elapsed. I have known more than 3 months pass in this delusive quietude, and then a salaciousness worse than at first has indicated that no actual impregnation had taken place. On the other hand, the œstrum, but not with all its former fury, has returned, 2, and 3, and 4 months after the connection; and yet, as the result finally shows, impregnation had taken place at their first intercourse.

Many circumstances may cause the owner to be anxious to know the truth of the matter. He may wish to sell her, or he may be unusually desirous to breed from her. Let the animal be examined per vaginam. Let the hand be slowly and cautiously passed up the vagina until it reaches the os uteri. Let there be no attempt to penetrate farther. No information can be gained from introducing the fingers into the uterus. It is simply wished to ascertain the character of the os uteri. In its natural and unimpregnated state it will be closed; but it will not be tightly or spasmodically so, and the contraction of the mouth of the womb will form a kind of cup, with the base towards that viscus. If she is impregnated, the entrance to the uterus will be more firmly closed, and the protrusion will be towards the vagina. This is the only exploration per vaginam which I would allow; it is easily made, and it will be satisfactory. If an exploration of this kind is

attempted when half or more than half of the period of pregnancy has passed, it is not at all unlikely that so much irritation of the parts will ensue as to cause the expulsion of the fetus.

I will suppose that 2 months have passed since the supposed impregnation. The fetus is still remaining in the pelvic cavity. The heart has begun to beat, and the blood to circulate through its little veins. It will be situated immediately below the rectum. I introduce my hand into that intestine. I have not occasion to pass it very far up. I feel the little substance; for it then is small in proportion to its after growth. I feel it under my hand. I am certain that I am pressing upon the uterus and its contents. I cannot perhaps detect the pulsation of the embryo; but if I had delayed my examination until the fetus was 3 months old, I should have assurance that it was there by its now increased bulk, while the pulsation of its heart would tell me that it was living.

For 2 months from this period in the cow, and for 3 in the mare, I should have no other indication of the presence of the fetus, nor of its life and growth, except from the gradual enlargement of the abdomen of the mother; and, by that time, the little one would have increased in size and strength, and would have begun to take occasional exercise in its first domicile, and then would become the more evident, but not more satisfactory proof of the life of the fetus; its motion strong enough to be seen through the integument.

I might, perhaps, wish to give this assurance of the life of the fetus to some curious spectator, or to some intended purchaser. I would not gallop the mare in order to effect this: I would not so far disturb her or the young animal that she bore within her. Much less would I give her cold water to drink, and which she usually would drink until she annoyed the fetus, and the unborn animal told us how much we annoyed him by endeavouring to shift his quarters and get away from the action of the cold. I would not run the hazard of giving her the colic, and perhaps destroying him or her by this unscientific and somewhat cruel method of exploration; but I probably should give a tap or two on the outer wall of his dwelling, just sufficient to rouse him from his slumbers, and induce him to express his anger at the annoyance by a tolerably distinct plunge or kick.

Most certainly, if it was a cow that I was exhibiting, I would not give, nor would I suffer any one else to give those terrible punches in the right flank which I have no doubt are the cause of much unsuspected injury, and, occasionally at least, connected with, or the origin of a difficult or a fatal parturition.

I may here observe that the fetus of the mare, from the beginning, occupies nearly the centre of the belly. In the early stage, Mr. Mogford generally found it "lying across the pelvic cavity, the spine being immediately under; the head on the left side, and the tail on the right side." In the latter portion of its fetal state its motions are pretty equally distributed on either side, and the beating of the fetal heart is most plainly heard at the very base of the abdomen.

The fetus of the cow is huddled up on the right side of the belly. There its motions are most seen, and the beatings of its heart best heard. The enormous paunch, lying principally on the left side, presses every other viscus, and the uterus among the rest, into the right flank. This also explains a circumstance familiar to every breeder. If the cow should happen to carry twins, they are crowded together in the left flank, and one seems absolutely to lie upon the other. Whenever the farmer notices the kicking of the fetus high up in the flank, he at once calculates on twins.

To return from this digression. If half the period, or more, of utero-gestation had passed, and I could not get the little stranger to move by my gentle tapping, and it was a cow with which we had to do, and a quiet one, I would have her carefully held by the cowherd, while I stooped and applied my ear flat upon the flank, and then slowly and with gentle pressure upwards and downwards, and forwards and backwards, over the flank and the lower part of it, until I heard—and which I should do in a great majority of cases—the pulsations of the fetal heart. I should recognise it by their quickness, the pulsations of the fetus being double or more than double those of the other.

If it was a mare, I would have a halter put on her, and an assistant should hold up one of her legs, while some person interested reached under, or perhaps knelt under the belly of the mare, and passing one ear along an imaginary line from between the teats to the chest, and deviating a little from one side to the other, he would then also recognise the quick pulsation of the fetal heart.

These observations are addressed to practical men, and will be speedily put to the test by them. The object of the author is to get rid of the vulgar and inefficient methods of detecting pregnancy which are now in general use, and to introduce others that are founded on a surer and more scientific basis.

This subject has been treated of by others, and Dr. J. C. Ferguson, of King's College, London, has published an *Essay on Auscultation, as the only unequivocal Evidence of Pregnancy*. Auscultation is the method employed by physicians to determine the healthy or diseased condition of the lungs and other internal parts, by means of the ear and stethoscope.

PRICKING. In hunting, the tracing of a hare, where her footing can be perceived. In farriery, the term is used to signify the driving a nail into the soft or quick part of a horse's foot, so as to cause temporary lameness.

PRIMROSE (*Primula*, from *primus*, the first; in allusion to the early flowering of the plants). This is an extensive genus of small, but very pretty and desirable plants. All the species of primrose succeed best in a mixture of loam and peat, and increase readily by seeds, or by dividing the plants, which should be done as soon as they have flowered. There are in England five indigenous species.

1. The common primrose (*P. vulgaris*), grows common everywhere in England, adorning the groves, hedges, and waste grassy places in spring; flowering from March to June. Flowers numerous, large and showy.

coloured, with a darker radiating spot in the middle; their scent agreeable; though slight. There are cultivated varieties, white, purplish, or brown, single or double, of which the double sulphur-coloured is peculiarly elegant.

2. Oxlip primrose (*P. elatior*). This is a less common species, found in woods and pastures, but rare. It is perennial, and flowers in April.

3. Common cowslip, or paigle (*P. veris*). See COWSLIP.

4. Bird's-eye primrose (*P. farinosa*). This species is found growing in wet pastures and by rivulets, on mountains in the north of England as well as in Scotland. It flowers later than the preceding species, in June and July, and is only about half the size of the cowslip. It is distinguished by the white mealiness of the flower-stalks and backs of the leaves, whose upper sides are green, smooth, and even, as well as by the beautiful rose-coloured flowers, whose mouth is surrounded with a notched, yellow, glandular border.

5. Scottish primrose (*P. Scotica*). This species is met with occasionally in the north of Scotland, and is near akin to that last described.

PRIMROSE PEERLESS, or NARCISUS.

PRIVET (*Ligustrum*, from *ligare*, to tie; in allusion to the very flexible branches). The common privet, print, or prim-print (*L. vulgare*), is a hardy shrub, growing from 6 to 8 feet in height, in its wild state tenanted rather moist thickets and hedges, on a gravelly or chalky soil: but it grows well in any situation, and in all soils. It may be propagated by seeds, layers, or cuttings. These plants are well suited for making cut-hedges in gardens, especially the evergreen varieties of the common privet. The branches are straight, filled with pitch, and the wood is hard.

PROPAGATION OF PLANTS. The greater number of plants are propagated naturally by means of seeds; but, in addition to these, many plants are extended over the surface on which they take root by the production of runners, or lateral shoots, which spread along the surface, and root at the joints or buds, from which they send up new plants, by suckers, or side shoots from the roots, by bulbs, by tubers, rhizomes, and by various other natural means. Artificially, plants are propagated by seed, by runners, suckers, offsets, dividing the tubers, layers, cuttings, grafting, budding, inarching, &c. Seeds are gathered when mature, and sown on recently-stirred soil, and covered to different depths according to the size of the seed, the nature of the soil and situation, and other circumstances. The plants formed by runners are separated from the parent plant by cutting through the runner, and removing the young plant, in order to plant it elsewhere. Suckers, slips, or side-shoots from the roots are separated from the parent plant by being slipped down, or cut off, so as to carry with them a portion of fibrous roots; and they are afterwards planted in suitable soil, &c. Offsets are small bulbs which are produced round the base of larger ones, or on stems, in the axillæ of the leaves, and, being taken off and planted, become plants. Tubers are underground stems containing leaf-buds; and these may be

separated and planted entire; or cut into as many pieces as there are buds, in either of which cases new plants will be formed. Layers are branches or shoots of either woody or herbaceous plants, which are bent down, and a portion of their length buried a few inches in the soil; that portion having been previously wounded by cutting, bruising, or twisting, which, by checking the descent of the sap, gives rise, after a certain period, to the production of roots.

After these roots are formed, the portion of the layer which has produced them is separated from the main stock or parent plant, and planted by itself.

Cuttings are portions of shoots, either of ligneous or herbaceous plants, and they are made of the young shoots with the leaves on, or of the ripened wood, either with or without its leaves; and after they have, either in an herbaceous state with the leaves on, or with the wood mature, and with or without the leaves, been properly prepared and planted, they form roots at the lower extremity, each cutting becoming a perfect plant. In general, cuttings should be taken from those shoots of a plant which are nearest the soil; because, from the moisture and shade there, such shoots are more predisposed to emit roots than those on the upper part of the plant.

The young, or last-formed shoots, are to be taken in preference to such as are older, as containing more perfect buds in an undeveloped state, and a bark more easily permeable by roots; and the cutting is to be prepared by severing its lower extremity across at a joint, the lenticells, or root-buds, being there most abundant. When the cutting is planted, the principal part of the art consists in making it quite firm at the lower extremity, so as completely to exclude the air from the wounded section. Cuttings emit roots at this section, either in consequence of the action of the accumulated sap in the cutting, as in the case of the ripened wood in deciduous trees and shrubs; or in consequence of the joint action of the accumulated sap and of the leaves, as in the case of cuttings of soft wood with the leaves on, and in a living state. A few plants are propagated by cuttings of the leaves, the petiole of the leaf being slipped off from the parent plant, and probably containing the latent embryos of buds. Grafting, inarching, and budding, are processes which have been already explained. See BUDDING, GRAFTING, LAYERING, &c.

PUCCOON (*Batschia Canadensis*). A plant in the United States with an extremely red root, called American Alkanet.

PULSE. A term applied to all leguminous plants, as peas, beans, tares, vetches, lupins, &c. All the species of pulse afford excellent manure when turned into the soil in a green state. The custom of ploughing in green succulent plants of this kind is very ancient. All the Roman agricultural writers commend it highly. Columella, particularly, advises lupins as a manure, which, if cut down and turned in while green, will have as good effect as the best and strongest dunging whatever. They may be sown upon poor land about the middle of

September, and be ploughed in before they attain their full growth. In gravelly soils they should be cut down after they have put forth their second flower; and in strong lands, where a little more advanced. In the former of these grounds they are turned in while young and tender, that they may quickly rot; and in the latter, are let stand till they grow stronger, that they may produce a better effect on the stiff clods of earth, and render them more mellow and friable. This practice is still extensively followed in northern Italy.

Peas, beans, lupins, vetches, and other succulent plants, have also been strongly recommended by the older writers on husbandry, as excellent manures, especially for sandy ground; these plants enriching the earth greatly if ploughed in, either green, or when in bloom. In strong land they are advised not to be turned down till the pods begin to harden. See GREEN CROPS, LEGUMINOUS PLANTS, PEAS, ROTATION OF CROPS, &c.

PUMPKIN (*Cucurbita pepo*). The pumpkin is extensively cultivated in the United States, where there are many varieties, some of them attaining the enormous size of 2 feet or more in diameter. But such large ones are not so highly esteemed. The better sorts are often used at table, affording the celebrated pumpkin pie of New England; and the coarser varieties are esteemed for feeding stock. When growing in the vicinity of squashes, the fruit of this is liable to be converted into a hybrid, of little or no value. Crops of pumpkins have been totally spoiled by that cause, the fruit becoming very hard and warty, unfit for the table, and unsafe to give to cattle. *Flora Cestrica*.

PURGATIVES. In farriery, such medicines as tend to evacuate the crudities of the bowels by stool, and which are sometimes called cathartics. See PURGING.

The purgatives most frequently employed for horses and cows are sulphur, jalap, aloes, gamboge, *Rhamnus catharticus*, and calomel. Saline purgatives are not often required; but when they are, Epsom salts (the sulphate of magnesia), is adequate for every purpose.

PURGING is necessary in a variety of cases, for different sorts of animals, particularly in diseases of the inflammatory kind, swellings in the extreme parts. Aloes is the best form of physic; but Epsom salts, linseed, and olive oil, are sometimes used on certain occasions as laxatives with great propriety and benefit, and in gross, full horses, in some disorders of the stomach, liver, &c., but it should always be directed with caution.

Violent purging or scouring, attended with inflammation, will sometimes arise when a horse is worked hard upon green meat. The remedy is change of diet or less labour. Astringents should be used with much caution. It is probably an effort of nature to get rid of something that offends. A few doses of gruel will assist in effecting this purpose, and the purging will cease without astringent medicine. See ALOES, BALLS, DRENCHES, LINSEED OIL, &c.

PURSLANE (*Portulaca*; from *porto*, to carry, and *lac*, milk; juicy nature of the plants). purslane is now but little noticed as a garden

flower, but in Britain is still cultivated as a salad and pot-herb. The species usually grown in the kitchen garden are the green or garden purslane (*P. oleracea*), and the golden purslane (*P. sativa*).

PUTREFACTION (Lat. *Putrefactio*). The spontaneous decomposition of animal and vegetable substances, attended by the evolution of fetid gases. The putrefactive fermentation of animal substances is usually attended by more fetid and noxious exhalations than those arising from vegetable products. This appears principally referable to the more abundant presence of nitrogen in the former; and, hence, those vegetables which abound in nitrogeniferous principles, such as most (if not all) of the cruciform plants, exhale peculiarly nauseous effluvia; hence, also, such animal products as are destitute of nitrogen, are either unsusceptible of what is commonly called putrefaction, or suffer it slowly and imperfectly. The formation of ammonia or of ammoniacal compounds is a characteristic of most cases of animal putrefaction; while other combinations of hydrogen are also formed, especially carburetted hydrogen, and sulphuretted hydrogen, together with complicated and often highly infectious vapours or gases, in which sulphur and phosphorus are frequently discerned. These putrefactive effluvia are, for the most part, easily decomposed, and resolved into new and comparatively innocuous compounds by the agency of chlorine; hence the importance of that body as a powerful and rapidly acting disinfectant. The rapidity of putrefaction and the nature of its products are, to a great extent, influenced by temperature, moisture, and access of air; they do not ensue below the freezing point, nor in dry substances, nor under the entire exclusion of oxygen; and hence various means suggest themselves of retarding or preventing putrefaction, as well as of modifying its results. A temperature between 60° and 80°, a due degree of humidity, and free access of air are the circumstances under which it proceeds most rapidly. The most effective antiputrefactives, or antiseptics, are substances which either absorb or remove a portion of the water or moisture, and enter into new combinations with the organic matter. The astringent or tannic principle of vegetables is also a powerful preserver of most organic tissues; it enters into chemical combination with the albuminous and gelatinous membranes and fibres; and the resulting compound, of which leather furnishes a characteristic example, is comparatively little prone to change, although the tanning material itself, as well as the animal principles with which it unites, are separately liable to decay. Among saline substances, the antiputrefactive powers of salt are commonly known: when a piece of flesh is salted, brine runs from it, in consequence of the energy with which the salt abstracts the component water of the muscular fibre; the flesh becomes indurated, and its susceptibility to putrefactive changes is greatly diminished; but it becomes at the same time less easy of digestion as an article of food. Corrosive sublimate is a far more powerful preservative than common salt and it appears to act not by the mere abstrac-

tion of water, but by entering into chemical union with the fibre. Sulphate of copper and several other metallic salts are similarly efficacious; but their poisonous nature prevents their employment in the preservation of articles of food.

The inhabitants of northern climates avail themselves of freezing to prevent the putrefaction of their food, and the supplies of game and other articles in the Russian markets are retained in a frozen state. Our fishmongers resort to the same expedient for the preservation of their unsold fish, which is daily removed to the ice-house, after having been exhibited in their shops; salmon is packed in ice for the purpose of transport and preservation. See DECOMPOSITION, DRY ROT, FERMENTATION, MANURES, ORGANIC CHEMISTRY, &c.

PYROLIGNEOUS ACID. This term is generally applied to the acid liquor which passes over along with tar and gaseous products, when wood is subjected to destructive distillation. This acid liquor is an impure vinegar, from which acetic acid is obtained. It has in its impure state a powerful smoky odour, not unlike that of Westphalia ham. The acid is purified by converting it into acetate of soda, and decomposing that salt by means of sulphuric acid. This acetic acid, after distillation, is in a high state of concentration; but it differs from concentrated acetic acid, by being neither combustible nor crystallizable. It is usually lowered by the addition of water. If intended for the table or for domestic use, as a substitute for other forms of vinegar, it is usually coloured with a little burned sugar. This manufacture of vinegar is now carried on upon a very large scale, and the greater part of the vinegar used for domestic purposes and in the arts, in many of which it is largely consumed, is derived from this source. Ordinary vinegar, besides containing acetic acid and water, contains also sulphate of lime, some ethereal matter, a portion of sulphuric acid, and a colouring principle. See VINEGAR.

Q.

QUAKING GRASS (*Briza*; named from *briza*, to nod, on account of the quaking character of the spikelets). A genus of grasses of which some species are pretty and interesting, as *B. minor*, *B. rubra*, and *B. clusii*; but the greater portion are mere weeds. The whole are of easy cultivation. Two species are indigenous to Britain, the smaller quaking grass (*B. minor*), and the common quaking grass (*B. media*), pl. 6, n. See BRIZA.

QUARRY. A pit or drift from which stones, gravel, slates, or some other similar material is raised.

QUARTER. The fourth part of any thing, as of a carcass. As a term of weight it denotes the fourth of a hundred weight, or 28 lbs.; as a dry measure it signifies the fourth of a chaldron. Quarter is also a measure of grain containing 8 bushels: it is the common measure by which grain is sold in the southern districts of England, especially when in large quantities.

QUARTZ. A German term, now universally adopted in scientific languages, and commonly applied in mineralogy to the purer varieties of silica, especially to rock crystal. Quartz occurs also in beds: it is usually granular, white, sometimes mixed with mica.

QUICKS. The young sets of the white thorn used in planting hedges. The term is also applied to couch-grass in some places. See QUICKSET.

QUICKSANDS—Are sandy spots of soil which contain water in such a proportion as to form a sort of shaking *quag* at certain times.

QUICKSET. A term applied to the white or hawthorn, the sets or young plants of which are raised by the nursery gardeners for sale for this purpose. See FENCE, HAWTHORN, and HEDGE.

QUINCE (*Cydonia*). A well-known genus of fruit trees. *C. vulgaris* is the species generally cultivated for its fruit. It is a native of Candia; but cultivated over most parts of Europe and North America. It belongs to the natural order *Pomaceæ*. The fruit, or quince, is of a roundish, somewhat pyriform shape, and contains ovate-pointed, plano-convex seeds, yielding to boiling a large quantity of mucilage, which is employed in medical practice as a demulcent. The quince will thrive in any soil, and may be multiplied by suckers. *C. japonica* is one of the handsomest hardy shrubs, producing its beautiful scarlet or white flowers in great abundance. The Portuguese quince is reckoned the best. Quince-marmalade is greatly admired by those who are fond of the fruit, and all good housewives know its value in adding richness of flavour to apple-pie.

QUINOA, or PERUVIAN RICE (*Chenopodium quinoa*). Humboldt speaks of this plant as one of the few cultivated in the highest and coldest regions of the Andes and the Mexican Cordilleras, where it ranks in utility with the potato, Indian corn, and wheat. Whilst young, the leaves are used as spinach, oxalis (sorrel), or common greens, whilst the seeds are boiled in soups and used as a substitute for rice. The plant is an annual, and resembles French spinach, or its kindred Lamb's-quarter (*Chenopodium album*), which is so widely diffused throughout the United States. The seeds are small, about the twelfth of an inch in diameter, yellowish-white, flat, resemble those of millet, and are easily pulverized. The plant attains about 3 feet in height, and produces greenish flowers about the 1st of August. Mr. Gideon B. Smith has raised the quinoa at Baltimore, and found it very productive. (*Am. Farmer*, vol. 13.) There are a great many species of chenopodium, many of which are enumerated under the head of *goose-foot*. In Peru, it would seem the quinoa is subjected to a process of scalding or part-boiling, before it is disposed of by the cultivator, whether for the purpose of assisting in its preservation, or to prevent its cultivation in other countries, is not ascertained. To this fact may probably be ascribed the failure of all previous attempts to cultivate it. Having, says Mr. Smith, eaten the quinoa, prepared in several ways, we are of course enabled to speak of its qualities from experience. Gentlemen who have eaten it in Peru, speak

of it in the highest terms of praise. It has a very pleasant flavour, although this is peculiar and may not at first be relished. The taste more resembles that of oat-meal than rice. The grain is chiefly composed of a grain or sprout of the young plant, closely coiled, and imbedded in farina. In boiling, this spiral germ is detached, and the dish presents the appearance of being full of skippers, something similar to a dish of boiled beans. The description of the mode of sowing and cultivating the quinoa in Peru, together with the seed, was furnished Mr. Smith by Lieut. Fitzhugh, U. S. N. From this it appears that it is sown broadcast, and gathered in the same seasons as wheat. When ripe, the grain shells off very easily, and to prevent loss, it is cut carefully and gathered in on cloths of cotton or linen.

QUITTER. In farriery, an ulcer formed between the hair and hoof, usually on the inside quarter of a horse's foot; it often arises from treads and bruises, sometimes from gravel, which, by working its way upwards, lodges about the coronet; if it is only superficial, it may be cured by cleansing dressings, bathing the coronet every day with spirits of wine, and dressing the sore with lime-water, or a detergent application, such as red precipitate.

R.

RABBIT. (*Lepus cuniculus*). A well-known animal, resembling the hare, smaller in size, belonging to the order *Rodentia*. The rabbit has shorter hind-legs than the hare, and the ears are more thinly covered with hair. Rabbits abound in England, and are in many cases preserved in warrens. They are very prolific, and begin to breed at six months old, and have several broods in a year, and from five to seven young ones in a brood. The young are blind at birth, and nearly naked. Their fur, in a wild state, is of a brown colour; but varies when domesticated. It constitutes a principal article in the manufacture of hats. Owing to its slight conducting power, it is, next to hare's fur, an excellent thing to wear over the shirt for those predisposed to consumption.

RACEME (Lat. *racemus*, a bunch of grapes). In botany, a form of inflorescence, in which the flowers are stalked along a common unbranched axis, as in the hyacinth.

RACHIS (Gr.). A branch which proceeds in nearly a straight line from the base to the apex of the inflorescence of a plant. It is also applied to the petioles of the leaves of ferns.

RACK. A railed convenience formed above the manger in a stable for the reception of the hay. It should be constructed with openings at the bottom for the seed or dust to pass through.

RADICLE. In botany, that portion of an embryo which eventually becomes the descending axis or root. It is the lowest of the two opposite cones of which an embryo plant consists.

RADISH, CULTIVATED (*Raphanus sativus*). There are two kinds of cultivated radish, the fusiform, or spindle-rooted, and the globular, or turnip-rooted; and these again are di-

vided into the spring and autumn varieties. As for the designation of short and long top, by which the old gardeners divided the varieties, I perfectly agree with Mr. Strachan, the gardener of the London Horticultural Society, in considering it as giving importance to a difference that is by no means permanent. The first may be sown at all times of the year; but the last, requiring a greater length of time to perfect their roots, can only, as the name implies, be obtained during the latter part of the year.

Spring Varieties.—*Fusiform-rooted*: 1. Long white, called also the white transparent, white Italian, and Naples radish. 2. White Russian, probably the *Raphanus sativus* of Gerard. 3. Twisted radish of Mons. 4. Scarlet or salmon, or scarlet-transparent radish. 5. Purple, formerly called exclusively the short-topped. 6. Red-necked white.

Turnip-rooted: 7. White turnip is the only one noticed by Gerard, as the *Raphanus orbiculatus*. 8. Early white turnip. 9. Pink, rose-coloured, scarlet, and crimson turnip. 10. Purple turnip. 11. Yellow turnip.

Autumn and Winter Varieties.—These are all of the turnip-rooted kind; and in the following list they are described in the order they follow in coming into use. 1. Yellow turnip. 2. Round brown. 3. White Spanish, is Miller's *Raphanus albus orbicularis*. 4. Oblong brown. 5. Black Spanish. 6. Large purple winter, or purple Spanish.

The soil best suited for this vegetable is a mouldy loam, rather silicious than otherwise, and moderately fertile. It should be dug a full spade deep, and well pulverized. The subsoil is best to be rather hard. Manure should not be applied at the time of sowing, if avoidable, as it is apt to cause the roots to be fibrous. If employed, it should be in a finely-divided, putrescent state. The situation should always be open; but for early and late crops, warm and sheltered. Radishes are propagated by seed, which may be sown at all times throughout the year. For the earliest productions, during December, January, and February, in a hot-bed; and in the open ground once a month during winter, and every fortnight during the other seasons of the year.

The time of drawing radishes is by no means indifferent. They eat in the greatest perfection if pulled in the morning before the sun has attained any power, and laid in a cool, damp place until wanted. The bed should have a plenteous watering the morning before that on which they are taken, but none afterwards until subsequent to the drawing. In November, those wanted for winter must be taken up during dry weather, and preserved in sand.

Forcing.—A moderate hot-bed is required for this crop, of a length according with that of the frame to be employed; the mould, about eight inches deep, on the surface of which the seed is to be sown as soon as the violent heat is abated, and an additional half inch of mould sifted over it. The seedlings are in general up in less than a week, and in six they will be ready to draw. Throughout their growth air must be admitted as freely as is allowable. The glasses, however, must be closed on the

approach of evening, and mats or other covering put on in proportion to the severity of the season. When the mould appears at all dry, a light watering must be given during noon. The plants must not stand nearer than two inches to each other. The temperature required is from 50° to 70°; and it must be kept to this heat by moderate coatings as required.

If there is a deficiency of frames, hoops and mats may be employed, a frame of boards being formed round the bed, light and air being admitted as freely and as often as possible. If seed is sown within a frame without any bottom heat, the plants will be two or three weeks forwarder than if sown in the open ground.

RADISH, THE HORSE. See **HORSE-RADISH.**

RADISH, THE GREAT WATER. See **CRESS.**

RADISH-MAGGOT. Radishes, while growing, are very apt to be attacked by maggots, and rendered unfit to be eaten. These maggots are finally transformed to small, ash-coloured flies, with a silvery-gray face, copper-coloured eyes, and a brown spot on the forehead of the females; they have some faint brownish lines on the thorax, and a longitudinal black line on the hind-body, crossed by narrower black lines on the edges of the rings. They vary in size, but usually measure rather more than one-fifth of an inch in length. They finish their transformations, and appear above ground, towards the end of June. The radish-fly is called *Anthomyia Raphani*, in my "Catalogue," from the botanical name of the radish, on the root of which its larvæ feed. It closely resembles the root-fly (*Anthomyia radicum*) of Europe. (*Dr. Harris.*)

RADISH, WILD (*Raphanus Raphanisticum*). A troublesome weed found in arable lands. See **CHARLOCK.**

RAG. A torn piece of cloth of any sort: when of the woollen kind, they are used as manure. Woollen rags are almost entirely composed of animal matter: they are found to contain a very large proportion of albumen, (a substance similar in appearance to boiled white of egg), minute portions of lime and silica, and traces of various salts. They form, therefore, an excellent manure, by slowly decomposing in the soil; and are found to remain dissolving in it, and forming soluble and elastic matters for the service of plants, when applied at the rate of 1200 weight per acre, for periods varying from two years on the heavy clays, such as those of the hop-grounds of the Weald of Kent, to three or four on the light, chalky soils of the valley of the Kennet, in Berkshire. The lightness of carriage, and its readiness, as well as cleanliness of application, render it peculiarly eligible as a fertilizer; it keeps, too, for any length of time, until the farmer is ready to apply it to his ground, and is much more slowly decomposed and consumed than either blubber, rape-cake, train-oil, or bone dust.

The consumption of these rags by the Berkshire and Oxfordshire farmers, and especially in Kent for the hop grounds, is very considerable. I am informed by an extensive dealer in these rags, that at least 20,000 tons are annually consumed by the farmers of the south of

England. My informant himself has a sale of more than 500 tons per annum, which he delivers free on board a vessel, at any of the London wharves, for 5 guineas per ton. The custom of the farmer is, to cut the woollen rags, by means of a chopper and block, into shreds about the size of a crown-piece, and then spread them on their fields by hand, out of a common seed-basket, as evenly as they can; they find that this manure is admirably adapted for hops, wheat, turnips, &c., and that the beneficial effect is as great the second year as the first. It appears that one farmer in Kent, Mr. Ellis, of Barming, purchases annually 4 or 500 tons of these rags, almost exclusively for his hop grounds. The farmers of Kent think the application of the rags "warms" the ground, as they slowly putrefy in the soil; they certainly afford nourishment to the crop, for wool is composed almost entirely of a peculiar animal substance, with a slight portion of phosphate of lime, or earthy matter of bones.

RAGWEED (*Ambrosia elatior*). See **HOGWEED.**

RAGWORT (*Senecio*). A portion of the species of this extensive genus has already been noticed under the head **GROUNDSEL**; but there are in England four or five species of ragwort, properly so called. These belong to that section of the genus which have flowers with spreading rays and pinnatifid leaves; the others to that with undivided leaves and radiant flowers.

RAIN (*Ger. regen*). In meteorology, water falling from the clouds.

As the effects of rain upon vegetation are so highly important, it will be useful to ascertain the quantity or depth of rain that falls annually in various places, and the difference in the effects which are produced by it, more especially for the formation of reservoirs for agricultural purposes. To use the words of Mr. G. Tatem:—"Although 'fully aware, that little reliance can be placed upon any theory founded on data so uncertain as the quantities of rain that fall in different years, I am convinced that something might be done towards establishing rules for the guidance of agriculturists and botanists, if observations were made at the same place for a series of years, and the results recorded." The average quantity of rain which falls in a year at any given place, materially affects the productiveness of the soil, and is necessarily influenced equally with the climate by a variety of general circumstances and local causes; such as latitude, proximity to the sea, elevation of the region, configuration of the country and of the mountain ranges, exposure to the prevailing winds, &c.

Near the foot of high hills a greater quantity commonly falls than over a level country; the currents of the atmosphere in their course meeting with a hill, are forced to ascend, and gaining a higher, and of course colder situation, the vapour is condensed into clouds, and even into rain, so that a deposition in showers very frequently follows. Hence the reason why clouds are so often observed on the sides and tops of mountains, which have been incorrectly supposed to attract them. The quan-

tity that falls, and the manner in which it falls, are the circumstances to be attended to. A great number of rainy days are more injurious to the soil, even where the quantity is not great, than heavy falls at distant intervals of time; the ground, in the first case, being constantly over-saturated, its fertility is much lessened; in the other, the superfluous moisture being soon drained off, only the portion necessary for the nourishment of plants is left, which is gradually given out in dry weather, during which the ground for a time is in its most productive state.

In general, more rain falls in the north of England than in the south. The east and southeastern counties have usually the driest seasons and years. The fall of rain is various, however, at any period of the year, as may be seen from the annexed tables. The mean quantity falling annually in England is reckoned to be 32 inches, or, according to Dalton, 31.3; but this is unequally distributed.

The annual amount in Westmoreland and

Lancashire, according to Mr. Whittlecraft, usually ranges from above 40 to nearly 70 inches, while that noted by the gauge in Essex and Suffolk is as low as from 14 to 32 inches; seldom, however, does it exceed 25 inches. It may, indeed, be fairly inferred, that these two parts of England produce extremes.

Mr. Howard gives the annual average at London equal to 24.9 inches; Professor Phillips at York 25.7; and Mr. Adie at Edinburgh 25 inches.

At Keswick, in Cumberland, the depth on an average of 7 years was found to be 67 inches; at Baverstock, near Salisbury, during the same period, 32½ inches; and at Plymouth, in Devonshire, 45 inches. In the western parts of Scotland the depth is from 30 to 35 inches, which is from 6 to 10 inches more than that on the east coast.

The mean monthly and annual quantities of rain at various places, deduced from the average for many years, by Dalton, is given in the following table:—

Months.	Manchester, 33 years.	Liverpool, 18 years.	Chatsworth, 16 years.	Lancaster, 20 years.	Kendal, 25 years.	Dumfries, 16 years.	Glasgow, 17 years.	London, 40 years.	Paris, 15 years.	Viviers, 40 years.	General average.

The greatest depth of rain which has been registered at any place in a year, is at Maranham, lat. 2½° S., and which is stated by Humboldt to be 277 English inches. But this is greatly above the average, and, indeed, more than double the annual quantity which has been observed at any other locality. At St. Domingo, the annual fall is estimated at 120 inches; at Cayenne, 116 inches; at the Havana, 91; at Calcutta, from 76 to 118; at Bombay, from 83 to 96; the island of Martinique, 87 inches; and at Sierra Leone, 86. Of European countries, Portugal appears to be the most humid, 123 inches having been observed at Coimbra in a year.

Although winter usually produces more rainy days than summer, the quantity of rain which falls is greater in the latter season. Dr. Dalton has ascertained that the first six months of the year may be regarded as dry, and the last six as wet months. Another ingenious author has inferred, from long observation, that in spring it rains oftener in the evening than in

the morning, but that towards the end of summer, oftener in the morning than in the evening. At St. Petersburg, rain and snow fall on an average 84 days of the winter, and the quantity amounts to about 5 inches; on the contrary, the summer produces 11 inches in the same number of days. In Canada, the average fall of rain usually is about 3 feet, which furnishes about 20 gallons of water for each square foot of surface during the year.

In the United States, the quantity of rain falling per annum increases in going south. At Philadelphia, a medium point, the results of 33 years' observation of the rain-gauge have been estimated by Mr. Owen Evans as follows:—Whole quantity, from 1810 to 1842 inclusive, 1276.435 inches; annual mean or average, 38.68 inches; greatest amount in any one year, 55.278 inches (in 1841); smallest quantity, 23.354 inches (in 1819).

Mr. Evans has also constructed the following table, showing the monthly averages of rain, estimated for 5 years (1838 to 1842 in-

	Jan'y.	Feb'y.	March.	April.	May.	June.	July.	August.	Sept'r.	October.	Nov'r.	Dec'r.	Annual mean.
Rain in inches -	3.687	2.574	3.224	4.600	4.290	4.669	4.785	5.581	3.555	3.698	3.399	4.083	48.145
Wind North -	2½	2	3	1½	1½	1½	2	4	2	2½	2	2½	26½

“ Northwest -	7½	8	9	7	6½	4½	5	3½	4½	7	8	9	79½

clusive), together with the number of days in each month during which certain winds prevailed, the last being the results of three observations each day.

RAIN-GAUGE. An instrument for measuring or gauging the quantity of rain which falls at a given place. It is also known under the several names of ombrometer, udometer, pluviometer, and hytometer. Its principles and construction are of the simplest nature; but it is made in a variety of shapes.

A convenient form of the instrument is that where the rain which enters a funnel of certain size, is collected in a bottle or other vessel, and afterwards measured in a graduated cylindrical glass tube, the marks on which not only represent the tenths and hundredths, but even the thousandth part of an inch of water. The height is read immediately on the scale.

It is requisite to be particular in the situation of the instrument. The gauge is best placed about 3 or 4 feet from the ground. In all cases an open space, free from trees, shrubs, or buildings, must be chosen.

RAKE. A tool of the toothed kind, of various sizes and forms, made use of in gardening, and for different agricultural purposes. There are several others used for field operations, some of which are worked by horses.

The drag-rake, in its simplest form, is merely a long cross-head, with a row of teeth placed in it: in some these are straight; they are, however, generally bent, with their points projecting forward. A very excellent and light instrument, having the teeth of steel, and made with screws, so as to admit of their being easily replaced in case of accident, is well known in England as Badgley's improved drag-rake. These rakes had, from time to time, increased in length and weight, till they became too large to be balanced by the hand. Two small wooden wheels were then added, which rendered them manageable by women or boys. Further additions having been made to them, they are now sufficiently strong to be worked by a horse. Used on fallows when foul, to remove the couch-grass, they act as a harrow, to get together the rubbish; or in harvest-time they act as a rake to collect the loose corn which may have escaped from the scythe or sickle. In order to clear them readily, there are different contrivances. One of the most simple and efficient is an arrangement which, by lifting the handle, causes the teeth to be raised and brought between two iron bars, which constitute part of the framing; by this means all the rubbish is stripped off from the teeth of the rake.

In "*Wedlake's Horse Hay-Rake*," the weight of the rake is balanced upon the carriage by two heavy balls projecting in front of it; so that a slight lifting power applied to the handle will raise it from the ground, and disencumber it of the hay or stubble it may have gathered. This rake obtained the commendations of the Committee on Implements, at the meeting of the Royal English Agricultural Society at Cambridge.

The East-Lothian Stubble-Rake is a machine not so well known in England as its merits deserve. Its advantages over those previously

described are as follows:—It has each tooth placed in a separate head, which, working upon a centre like the levers of a drill, adapt themselves to any inequality in the ground. To the handles, a bar the length of the harrow is firmly fastened, and from this bar each lever is suspended by a few links of chain. When it is necessary to clear the rake, these handles, on being elevated, lift all the levers between a framing of light iron rods.

An ingenious practical farmer, John Sayer, of Bodham, in Norfolk, made considerable improvement upon this rake, by altering the form of the teeth to avoid tearing the land; and in order to effect more work without increasing the width of the rake, the naves of his wheels were made to project inwards, so that two additional levers could be introduced, working quite close to the spokes.

But within the last few months a very improved implement of this character has been introduced and patented by J. C. Grant, of Stamford, which obtained the prize of the Royal Agricultural Society of England, at its meeting at Liverpool. Its advantages consist in the adaptation of a compound lever, by which the whole row of tines may be instantly raised, and as quickly allowed to resume their position, while the form of the teeth being such as to describe part of a circle, the centre of which is the axis of the separate levers to which they are attached, each portion of the curve is successively brought into a vertical position, thus rapidly disengaging the teeth from the material collected, so that, without stopping the horse, the process of collecting is resumed, leaving no interval beyond what is requisite for the deposit of the hay, corn, or stubble previously collected.

Several minor improvements are included in the patent, but as these mainly refer to modes of construction, it will not be necessary here to particularize them.

A hay-making machine invented by Robert Salmon, of Woburn, and patented in 1816, consists of a series of rakes revolving upon two skeleton frames, to which motion is communicated by cog-wheels attached to the naves of the wheels in which it travels. It has undergone considerable improvement by R. Wedlake, an ingenious manufacturer, residing at Hornchurch. These improvements consist in forming the cylinder in two parts, each of which has motion independent of the other, and in placing the tines or rake-teeth upon a bar, which, being supported by a spring, will yield to any obstruction caused by sudden unevenness of the surface of the ground, and return again to its original position. Its object is to spread the hay, and by thoroughly separating its parts, continually to expose them to the sun and wind, which it so thoroughly effects as to render the hay fit to cart much earlier than by the common process of shaking it by the hand. To the practical agriculturist, it will not be necessary to remark on the advantages accruing from the ability to hasten, if only by a few hours, the process of hay-making; but it will be valuable to know, that the universal testimony of all with whom we have conversed is,

that this implement is a time-saving machine, and therefore one of the greatest value.

American Revolving Hay-rake.—This rake is drawn by one horse; and it can be made to go either along or across the ridges, as may be required. It can carry between 100 and 200 lbs. of hay; and when that quantity is upon it, the hay can be deposited, by a simple revolution of the instrument, in rows, or at any particular place required, without stopping the horse.

The common horse-rake, much used in the United States, especially in the North, is described and figured in the *Cultivator*, vol. vii. p. 89. It is made of a piece of strong scantling, 3 inches square, and 10 feet long, into which about 15 teeth are inserted horizontally, and made of strong white ash or other tough wood. The teeth should be about 22 inches long, and 1 inch by 1½ at the place of insertion, and tapering on the under side, so as to give them a slight turn upward at the point, to prevent their running into the ground while using. The draught-ropes are attached to the end of 2 projecting pieces of wood parallel to the teeth at each end of the rake. These projecting pieces should be about one-third of the length of the teeth. Those unskilled in the use of the rake sometimes attach the ropes at once to the ends of the head; in this way, it becomes almost entirely unmanageable. The forward ends of the draught-ropes are to be fastened to the horse's collar, leaving space enough between the horse and rake for the collecting hay. Handles are to be inserted in the head near the middle, for guiding the teeth and lifting the rake from the ground when necessary.

In using this rake, instead of the teeth moving onward upon their points, as in the common hand-rake, they run along flat upon the ground, passing under and collecting the hay; when full, the handles are thrown forward, the rake emptied, and lifted over the winrow for another load. The rake thus passes backwards and forwards across the field, always emptying opposite the last heap, and thus forming regular winrows at right angles with the path of the rake. A few hours' practice will enable any one to use this rake without difficulty, the only skill required consisting in keeping the points of the teeth just so low as to pass under all the hay, and yet not run into the ground. When small obstructions occur, the handles are depressed, thus causing the teeth to rise, and the rake passes freely over. Large obstructions, as stumps and stone-heaps, require the rake to be lifted from the ground.

The chief recommendation of this kind of rake, is its cheapness and simplicity. A good one need not cost more than \$2. It may also be used on rougher ground than the revolving rake, as it is more easily lifted over obstructions. Where the ground is very uneven, the teeth should be much shorter. When one becomes well accustomed to the use of it, work may be done nearly as fast with this, as with a revolving rake, though much more laborious. Twelve acres of hay, part of it yielding nearly 3 tons to the acre, on a meadow of the writer, were raked into winrows, by means of one of these rakes, in about 6 hours' working time.

It possesses another advantage over the revolving rake—it may be used for scraping the winrows into heaps for drawing, and if the hay is stacked in the field, for drawing the hay to the stack. A man with a rake and horse not only raked the hay, but drew it at the same time to the stack, a distance of from 10 to 20 rods, as fast as an active man could pitch with a fork. A hand-rake need scarcely ever be used on the meadow, as all the scattered hay may be raked up in a short time after the rest of the hay has been drawn off.

The horse-rake is very useful in raking stubble of wheat, and eminently so in pulling and gathering peas.

Shafts, instead of ropes, have been attached to the head of the rake, and have been strongly recommended; but they diminish the simplicity of the rake, and appear to possess no advantage on the whole, and for gathering and drawing hay, are positively detrimental.

RAMPIONS, or RAMPION BELL-FLOWER (*Campanula rapunculus*). The esculent roots of this vegetable are far more delicate than turnips or radishes. They are long, white, and in the shape of a spindle. Like the radish, it is eaten raw, having a nut-like, pleasant flavour. The plant rises to the height of 2 feet, with blue flowers.

It is propagated by seed, which may be sown during March, April, and May; the plants from sowings in the two first months, soon, however, run up to seed. The insertions may be performed either in drills 6 inches apart, or broadcast; in either mode the seed to be buried ½ an inch deep, effecting it in the latter by sifting mould over it; for, if the seed is raked in, from its minuteness, it is apt to be buried too deep. The plants are to remain where sown; though, in case of any deficiency, those which are taken away in thinning the crops may be transplanted successfully. The best time for performing the removal is of an evening. They are fit for thinning when about 2 inches in height, they must be set at a distance of 6 inches apart, being hoed at the time, and the same operation repeated two or three times, which, if performed in dry weather, will keep them free from weeds until used.

The plants of the sowings during the two first mentioned months will be fit for use at the close of August, or early in September, and continue throughout the autumn. Those of the last one will continue good throughout the winter, and until the following April. The soil, throughout their growth, must be kept moist, effecting it in dry weather by giving frequent but moderate waterings through the fine rose of a watering-pot.

The root, for which it is cultivated, either to be sliced, together with its leaves, in salads, or eaten as the radish, as well as to be boiled like asparagus, is most palatable when drawn young, and eaten fresh from the ground.

For the production of seed, a few of the winter standing plants are left unmoved. These shoot up in the spring, flowering in July and August, and ripening abundance of seed in early autumn. (*G. W. Johnson's Kitch. Gard.*)

RANUNCULUS (From *rana*, a frog, several of the species being found in moist places fr-

quented by that reptile). Many of the plants belonging to this extensive genus are well worth the cultivator's care, and they have long been favourites with the florist. The aquatic kinds require to be grown in water. The grumose-rooted species will thrive in any common soil and situation; they are increased by offsets from the roots, or by seeds. These plants are acrid, and most of them poisonous. See CROWFOOT and SPEARWORT.

RAPE. A plant of the cole kind, greatly cultivated in Flanders for the sake of the seed, but extremely valuable also as green food for cattle and sheep in winter and spring. "The plants," says Mr. Low, "usually cultivated under the name of rape, are the fusiform varieties of the following species of brassica. Cole or rape (*B. napus*), colza (*B. campestris*), fusiform common turnip (*B. rapa*), and early cole (*B. præcox*)." There are different modes of treating this plant, according to the uses for which it is designed. The whole plant is of great service in feeding cattle; and after the seed is thrashed, the straw and chaff, on being burnt, afford ashes equally valuable as the best potashes. Wheat yields an excellent crop after rape, and the plant is grown with great advantage on bog plant, where paring and burning has been practised. Rape is very hardy, and with fair treatment it never fails on any soil. Cattle are so successfully fattened with it, that many farmers prefer it to turnips. See COLE.

For garden culture, rape is propagated by seed, and, like mustard, and other small salad-ing, may be sown at any period of the year, when in request; being allowed a separate bed. For the production of seed, some plants of a sowing which has been made about the middle of July, must be thinned to about 18 inches apart: they will survive the winter in England, and flower in May and June of the next year. The seed, which is produced in great abundance, ripens in July and August, and must then be cut and laid upon cloths to dry, as it is very apt to shed.

In England, rape (*Brassica napus sylvestris*) is frequently called *colseed*, and in France *navette*. In both countries it is highly prized, not only for the value of the oil expressed from the seed, but for the cake left after pressure, which is extensively used for feeding cattle, its qualities for this purpose resembling those of the oil-cake left after pressure of flaxseed in making linseed oil. Rape belongs to the cabbage or turnip family, but it never heads, like the former, and its roots are of little value compared with the latter. Of the two kinds most commonly cultivated, one is biennial, sown one summer and harvested the next, whilst the other is a spring or summer crop.

Rape, though but little known in the United States, has been tried in various parts, and found to stand the winters even in New York and New England. Whenever, therefore, a demand shall be made for this valuable production of the soil, or its near kindred of the cabbage family, *colza*, the United States can yield them abundantly, in almost every part.

According to Loudon, the place which rape occupies in a rotation, is between two culmi-

ferous or grain crops. On rich soils it may be succeeded to the greatest advantage by wheat, as it is found to be an excellent preparation for that sort of grain; and by its being taken off early, there is sufficient time allowed for getting the land in order for sowing wheat.

In *Notes on the Agriculture of Germany*, by Mr. Carr, an English gentleman, he says the after course is as follows:—

- 1 year fallow, well dunged,
- 2 " rape,
- 3 " wheat,
- 4 " barley,
- 5 " peas, light dunging,
- 6 " rye,
- 7 " oats, with rye, or timothy grass-seeds, and red clover.

The clover and peas plastered in May. The clover is mown twice for hay, and left two years for pasture, when it is heavily manured, fallowed, and again sown with rape. "The rape-seed is sown broadcast in the last of July or first of August. This crop is greatly benefited the following spring by dusting gypsum over it, about 100 lbs. to the acre. In July the seed is ripe, and as the weather is generally fine, is trodden out by horses very expeditiously on large canvass sheets in the field. The oil of this seed pressed out, when purified, is without smell, gives a brilliant, clear-burning flame, and is universally used all over Germany, in the saloon of the rich, and the cottage of the poor. The value of the crop is somewhat precarious, because it is subject to so many contingencies; the turnip-fly and caterpillar prey upon it when young, and when in flower, a small beetle (*Haltica nemorum*) often eats away the blossom-bud, or lays its minute larvæ in the petals, ultimately furnishing every seed-pod with a maggot which either eats the seeds away, or, forcing the pod open when nearly ripe, causes it to fall out. When spared these calamities, it is, however, a very remunerating crop, worth from 10*l.* to 20*l.* an acre, especially if there is a foreign demand. The straw is generally burned, and the ashes scattered over the field; it is sometimes sold to the soap-makers, who prize it highly. Two furrows are now given for wheat sown broadcast in September."

Mr. Blackie, in his *Essay on the Improvement of small Farms*, says, that the produce of rape, when *well manured*, is beyond any thing almost that can be imagined, if let stand until it gets into blossom. Manure, he adds, makes the stalk tender and juicy, which would otherwise be hard and dry, so that if cut into small pieces for the purpose of feeding green to cattle, not a bit will be lost, and it grows to a height of 6 feet. I am, he says, almost afraid to say, that I believe, with the addition of some straw, an acre will keep 30 head of cattle in full milk for a month.

RAPE, *edible-rooted*. This name may be applied to a variety of the rape mentioned by Mr. Dickson, one of the vice-presidents of the Horticultural Society. Its root is white, and carrot-shaped, about the size of the middle finger. It is much more delicate in flavour than the turnip, like which root it is cooked, only that it is not peeled, but scraped, its skin being re-

markedly thin. It has been cultivated for a great length of years on the continent, and for about 30 years in England, but only by one person, as far as Mr. Dickson is aware. It is propagated by seed, which, for the main crop, may be sown from the middle of July to the end of August, or even later: these will supply the table until April; and, if wanted throughout the year, a little may be sown in the latter end of October, the plants from which will be fit for use, if they succeed, during April and May: the last crop to be inserted from the middle of January to the middle of February, which will come in at the end of May and during June. On a north border, and if the soil is sandy and moist, it is possible to have them sweet and tender during the whole summer, to effect which the seed must be sown at the close of March and May. They require the same modes of cultivation and treatment as turnips. In dry weather the beds must be watered regularly, until the plants have got three or four leaves. One great advantage attending the cultivation of this vegetable is, that it requires no manure. Any soil that is poor and light, especially if sandy, is suitable to it. In rich manured earth it grows much larger, but not so sweet and good. For the growth of seeds, Mr. Dickson recommends, in February or March, some of the finest roots to be transplanted to 2 feet asunder; but it would, perhaps, be a better practice to leave them where grown.

RAPE-CAKE. The refuse or marc remaining after the oil has been expressed from the rape or cole-seed. (See **LINSEED CAKE.**) The use of rape-cake as a manure is pretty extensive in some parts of England, and its effects are so immediate and powerful, that its expense alone retards its more general employment. It contains a large quantity of mucilage, some portion of albuminous matter, and a small proportion of oil. It should be kept dry, and used when recently made. It answers admirably for turnips. When first recommended as a fertilizer, it was used in the proportion of half a ton per acre; but by pulverizing it, and drilling it in with the seed, about half that quantity has been found sufficient. Rape-cake produces, when ploughed in with wheat, excellent crops. It has been found exceedingly noxious to the wireworm, and other field vermin, and when applied in compost, with 30 times its weight of farm-yard dung, it forms a very excellent manure.

Rape-cake, in common with all fertilizers of an oily nature, is much more decided in its effects in wet than in dry seasons. In Yorkshire and Lincolnshire the quantity applied is about 16 bushels per acre. It is more serviceable on clays and other moist lands than on dry soils; its benefit extends to only one crop, although there have been occasional instances of its extending to two. It may be either drilled with the seed or spread on the land before it is ploughed. See **LINSEED, OIL-CAKE, PALMA CHRISTI, &c.**

The practical benefits which are capable of being derived from a correct knowledge of the mode in which green manures operate, are considerable. It should teach the cultivator to

carefully bury in the soil every portion of either animal or vegetable matter he can command; for every weed, every fragment of straw he thus employs, will again, under judicious management, be returned to him in new forms of beauty and usefulness.

RASPBERRY (*Rubus idrus*). This shrub, in its wild state, is found growing in our mountainous woods and thickets: flowering in May and June. The root is creeping. The stems are biennial, erect, 3 or 4 feet high, branched, round, pale or purplish, more or less besprinkled with small, straight, slender prickles, frequently rather resembling bristles than prickles, and sometimes altogether absent. Leaves primate, of five or three ovate, rather angular, lateral leaflets, serrated or cut, and angular, green, and nearly smooth above, very downy beneath, and a larger terminal leaflet. The footstalks are furrowed, downy, and prickly, with narrow lateral stipules. The flowers are small, white, or pinkish-white, pendulous, in drooping terminal clusters. Fruit crimson, of numerous juicy grains, beset with the permanent styles, and highly fragrant, with a very deliciously perfumed sweet and acid flavour, more exquisite in the wild state, in general, than when cultivated.

The wood of the raspberry bush produces fruit but one year, therefore that should be carefully cut down below the surface of the earth, and the young shoots should be shortened to about 2 feet high; and not more than three or four shoots should be left to each root, as these will produce a greater number of berries, and larger fruit, than would be obtained if twice that number of suckers were left. The middle or end of October is the proper time for this pruning. The fruit is produced from young branches out of the last year's shoots or suckers. The plants raised by layers are much preferred to those taken from suckers; they should also have plenty of room, for when there is not space for the air and light to pass between the rows, the fruit will be small, and not ripen well. They require a fresh, strong loam, deeply trenched and well manured in the first instance, for in warm, light ground they produce but little fruit.

The following selection is recommended for a small garden:—Barnet, Cornish, Double-bearing red Antwerp, Williams's preserving yellow Antwerp.

This fruit is employed for the dessert; it is also in very general use for jams and tarts, and is converted into wine and vinegar, which is a refreshing beverage, when diluted with water, in fevers. The young and fresh leaves of the common raspberry are eagerly eaten by kids. (See **BRAMBLE.**)

RAT. The name of a large, destructive, and very prolific species of the genus *Mus*, the brown, or water-rat (*Mus decumanus*, Linn.), introduced into the British islands from Asia, not, as is commonly believed, from Norway. It has spread over all the country, and multiplied at the expense of the old British species, called the "black rat" (*M. rattus*, Linn.).

Of all the four-footed animals (says the author of *Brit. Husb.*) included in the rank of vermin, rats and mice are the most pernicious.

for they build their nests under the floors and in the roofs of barns, nor are even the stacks exempt; and are so prolific that, if not destroyed, they occasion incalculable mischief. It therefore behooves every farmer to use all possible means to check the evil, and one might suppose that every exertion was invariably made for that purpose; yet we constantly find homesteads overrun with these pests, without any other pains being taken than an occasional rat-hunt by farm servants, aided by a terrier, which, though not to be neglected, is a very ineffectual remedy. The best is, unquestionably, the construction of the barn-floor and roof in such a manner as to prevent them obtaining a permanent harbour in the building. The next is, before the entire clearance of the barn, while yet a little corn remains to prevent them from quitting it, to close every part of the barn, by carefully covering any holes there may be with sacks and tarpaulings, so as to prevent all access of the outward air, leaving only the door for a few minutes open while the process is going on. This done, some common iron chafing-dishes, which may be purchased for a trifle, should be placed upon the floor, and in the bags; or, if they cannot be had, build up a few bricks, clay, or any rubbish that will secure a fire from spreading, leaving a cavity in the centre, and filling it up with charcoal. Then light the charcoal from the bottom, and when the heaps are all burning, quickly strew a good quantity of broken brimstone upon the top; retire immediately, shut the door fast, and leave the building entirely closed during a couple of days following. On opening it, the greater portion of the rats and mice will be found dead around the charcoal; and, although some may have been suffocated while in their holes, and if not discovered will occasion an unpleasant smell until their remains are dried up, yet it will not last long. The operation should be again repeated just previous to harvest, and if any opening be found into the barns while they are full, by the burrowing of the rats, brimstone matches should be inserted into them before they are stopped up. Traps and poisons are only partially efficient; but an effectual mode of trapping is detailed in a small pamphlet, published some years ago by Mr. B. Broad, of Thurton, under the sanction of the Hereford Agricultural Society, which ought to be in the hands of every farmer in the kingdom.

The ferret is a decided enemy to the rat, and if kept in a hutch or cage, and only occasionally used, will be found very serviceable: but he should be well fed to induce him to return, or otherwise he will escape and become destructive to poultry. A cat or two should also always be reared about a barn. In new barns and outhouses, the entrance of rats is effectually prevented by steeping the joints, rafters, and flooring in a solution of corrosive sublimate. If a rat or a mouse attempt to gnaw wood so prepared, their saliva moistens the sublimate, they take it into the stomach, and are so destroyed by it. See MICE and VERMIN.

REAPING. Cutting down wheat or other corn, grain, or pulse with a sickle, hook, or scythe, or by a reaping-machine. These operations are more advantageously performed

when the corn or pulse is not quite ripe, than when it is thoroughly ripe; because, in the latter case, the seeds are apt to drop out in the process of handling, turning, and drying.

Mr. Hannum enters into some elaborate calculations on the advantages of reaping wheat a fortnight before it is ripe, from which he deduces the following results; that, independently of a gain of 4 per cent. on the value of the grain, we have, 1st, straw of a better quality; 2dly, a better chance of securing the crop; and, 3dly, a saving in securing it. (See WHEAT.) The smaller the sheaves are, the better, especially in a wet harvest: in general, the diameter of the sheaf should not exceed 30 inches. It is of some importance, also, not to tie the sheaves too near the ears. In making the shocks, they should be placed across the furrows, in order to procure a free circulation of air around them.

In some districts in England, the scythe has of late years been partially employed for the purpose of reaping, but with no satisfactory result; and in Berwickshire the scythe-hook is now generally used in preference to the toothed sickle of our fathers. Cutting corn with a sickle of some sort is, however, considered preferable to mowing it with a scythe, unless the crop stands up well, and time presses. Barley and oats may be frequently mown with advantage; but wheat, which requires immediate and clean binding, and is too valuable to admit of any irregularities or wastefulness in harvesting, should be reaped. The mode of reaping called *bagging*, and practised a good deal about London, and part of the west of England, is thus executed:—The left leg being pushed into the standing corn, and the straw inclined with the left hand over the left foot, is then cut close to the bottom with a stroke from the right hand. The increase of straw, where this is valuable, renders this a good method of reaping.

In England the mode of reaping varies with the nature of the crop. Barley and oats are generally cut with the scythe, beans with the sickle; peas with what are called fagging-hooks, which rather tear up than cut; and tares in the same way.

Reaping is a great part of the expense of a crop. The average price in England is from 12s to 15s. an acre. See BANDS, BARLEY, HARVESTING, WHEAT, &c.

REAPING-HOOK. An implement used to cut down corn. It is one of the oldest instruments employed in husbandry. There are two kinds of hooks; that which is principally used by the British labourer has a smooth blade of wrought iron and steel, about 25 inches long, and curved nearly to a semicircle; the other, which is universally preferred by the Irish reaper, has a finely serrated edge, and towards the lower point recedes from the curved direction to nearly a straight line. The real action of the reaping-hook is that of a saw, consequently the serrated edge is an advantage. See SICKLE.

REAPING MACHINE. A contrivance for the purpose of reaping grain by means of animal labour. With this view, and to facilitate an operation of such importance to the farmer,

different attempts have been made to construct machines, so as to despatch the work in a rapid manner by the assistance of horse labour, but the success with which they have been attended in England has hitherto been far from complete.

Many contrivances have also, of late years, been resorted to for supplying the place of the reaping-hook, but hitherto none have proved effectual, nor are the difficulties arising from roughness and irregularity of surface likely soon to be surmounted. No one will dispute the great utility and advantages of an efficient reaping machine, if it could be carried into operation, as these advantages are universally acknowledged. In England, such an implement is the more required now that the agricultural labourers are greatly reduced in number by emigration, and harvest work has become more expensive. There is now a much greater quantity of corn to cut down, and most of the grain ripens about the same period. In 1815, Mr. Smith, of Deanston, invented a reaping machine, which, in some experimental trials, appeared to perform its work exceedingly well; but, upon longer trial, it has not answered the favourable expectation formed of it. Since that period, another invention of a similar nature, by Mr. Patrick Bell, has attracted considerable attention, but does not appear to be of sufficient merit to have come into general use. The original cost of these machines, 40*l.* or 50*l.*, must, in many instances, preclude their employment.

An excellent article on the advantages of a reaping machine will be found in the first volume of the *Quart. Journ. of Agr.* p. 137; and Mr. Bell's machine is figured and described at p. 217 of the same volume.

American ingenuity has been active in the invention of machines for harvesting wheat and other grains. Among those which have been brought into the field, "*Wilson's Mowing Machine, or Grass and Grain Cutter,*" is highly commended by some who have tried it. It has been most in use along the Hudson river, and is considered an improvement of Smith's English reaping machine.

But the machine that is perhaps best entitled to the notice of farmers, is the one invented by Obed Hussey, which is recommended for its simplicity, durability, and the great regularity and cleanness with which it performs its work. Even when the grain is too much lodged to be cradled, it will cut at the rate of two acres per hour, nearly as clean as if it had been standing. It can be adapted to the inequalities of the surface of a field, and has been so improved by its original inventor as to operate with great facility on stony land. This machine has received the most unqualified approbation of nearly all farmers who have tried it, or witnessed its operation. The Board of Trustees of the Agricultural Society for the Eastern Shore of Maryland, in their *Report*, made in 1836, say, "We deem it a simple, strong, and effective machine, and take much pleasure in awarding unanimously the meritorious inventor of it (Mr. O. Hussey) a handsome pair of silver cups."

The committee appointed by the Philadel-

phia Society for Promoting Agriculture, to superintend the operation of Mr. Hussey's machine, make a very favourable report, recommending it to the attention of the society and the agricultural community generally. They state that it was put in operation in a piece of several acres of heavy wheat, considerably lodged, and, contrary to their expectations, it performed remarkably well.

"The committee estimate the ordinary performance of the machine at from ten to twelve acres per day; although they fully believe, that on an emergency, it would accomplish twice this amount of work. In confirmation of this they would state, that it cut, on this occasion, 630 square yards in 2 minutes, doing its work in the most perfect manner." The cost of the machine is \$150. (See *Farmer's Cabinet*, vols. ii. and iii., *Cultivator*, and other American agricultural periodicals.)

McCormick's Reaping Machine is used in Virginia, and spoken of very favourably by the editor of the *Southern Planter*, who has furnished a cut and explanation of it in the number of that excellent periodical for January, 1843. It is said to cut 15 acres per day without leaving a single stalk in the field, and some think the wheat saved in harvesting a large crop will more than repay the first cost of the machine. It weighs about 600 lbs., rests upon two wheels, and is drawn forward by two horses. The cost of the machine is \$100.

A machine for harvesting grain has been invented by G. G. Carpenter, of Caledonia, New York, which not only reaps the crop, but thrashes it out. In speaking of his machine and its merits, Mr. Carpenter observes,—"*The great saving in grain and labour is in finishing the work without laying the grain on the ground. It may be gauged to cut as high as the grain will admit, and the 9-foot swath streams from the cradles to the thrasher so evenly, that no more power is required to finish 15 to 20 acres a day than is necessary to drive a common thrasher, which only thrashes say 200 bushels in a day, with many hands in attendance.*" This machine costs \$600. The hands required to attend it are, one to drive the team, and one to take care of the machine. (See *Cultivator*, vol. vii.)

Other labour-saving contrivances for harvesting grain have been invented in the United States of late years, descriptions of which may be found in various agricultural periodicals.

RED BAY (*Laurus Caroliniensis*). An American species of the laurus genus found in the Southern States. (See Michaux's *North American Sylva*, vol. ii. p. 150.)

RED BUD. See **JUDAS TREE.**

RED GUM. A disease of grain, a kind of blight. See **BLIGHT.**

RED-ROOT (*Lithospermum arvense*). Stone-weed. A worthless plant which has been introduced into the United States, where it has spread itself extensively, especially in some parts of New York, where it is considered even a worse pest of the fields than the Canada thistle. Dr. Darlington describes the plant as being hispid, or beset with bristle-like and rather short hairs; the root annual; stem 12 to 18 inches high, generally much branched from

the root, and often branched near the summit. Leaves 1 to 2 inches long, and $\frac{1}{4}$ to $\frac{1}{3}$ wide, without stems, narrowed at the base, and spear-shaped flowers, which show themselves in May in the Middle States, have yellowish or milk-white and rather small corollas. The seed-nuts are ovoid, with tapering points, rough, wrinkled, and brown, when mature. When this formidable weed, which is the pest of the northern wheat-crops, first appears in a field, it may be removed by carefully pulling it up while in flower, and thus preventing it maturing seed and propagating itself. Where it once gets possession, it is exceedingly difficult to destroy, as the seeds will lie many years in the soil without coming up, in this respect resembling those of charlock or the wild radish and mustard. One of the best methods of treating it, says the editor of the *New Genesee Farmer* (vol. i. p. 92), is to harrow, or lightly plough the wheat-stubble immediately after harvest, to cause the fallen seeds to vegetate, and destroy the young plants the next season by summer crops, which should be repeated for a year or two, when the land may be summer fallowed for wheat. Successive crops of buckwheat are said to be advantageous.

RED-ROOT (*Ceanothus Americanus*). New Jersey tea. A plant with a large, red, perennial root, found in the United States. The stem grows 2 to 4 feet high, and is branched. It possesses considerable astringency, and during the revolutionary war the leaves were substituted for tea.

RED-ROOT (*Sanguinaria Canadensis*). The generic name is derived from the colour of the sap, which resembles blood. This American plant, which abounds in the forests, is variously called puccoon root, turmeric, and Indian paint. The root is perennial, with fibres attached to a reddish, horizontal stem, about 2 or 3 inches long and $\frac{1}{2}$ an inch thick, growing under ground. It possesses emetic and other medicinal properties. It is the only species of its genus.

RED SPIDER (*Acarus*). A well-known pest of gardens. It may be destroyed by application to plants of whale-oil soap, in the manner directed in the destruction of plant-lice. See **APHIS**.

RED TOP. See **HERN'S GRASS**.

RED TOP, TALL (*Tricuspis Seslerioides*). A perennial grass, found in the Middle States, on dry banks and sterile fields, flowering in August and seeding in September. It has an erect, jointed culm or stem, 3 or 4 feet high and very smooth. Pursh calls it "a most excellent grass," and says he has seen "most excellent crops" of it, in the mountain meadows of Pennsylvania, where they mow it twice a year. Such crops may possibly pass for "excellent" in mountain meadows; but, observes Dr. Darlington, they would be not so considered in Chester county. If Mr. Pursh has not misapprehended the fact, he is certainly mistaken in the character of the plant; for it is a dry, rigid grass, with unusually hard culms, and altogether unfit for making good hay. It is the only species of the genus in the United States. (*Flor. Cest.*)

RED-WATER. In Britain, a well-known disease in cattle. "The disease commonly called

red-water, brown-water, black-water, moor-ill, &c.," says Mr. R. Thompson, of Auchterarder, "is most prevalent in old, foggy pastures. It is seldom seen in hill pastures, or in new-sown pastures, in which there is abundance of clover; but it sometimes happens at the stall, where the animal has no other allowance than straw, turnips, and potatoes. It usually makes its appearance after a few days of rain, followed by cold, dry weather. As the disease appears at times in all situations, it is difficult to trace its existing cause, which may be the nature of the pasture, or the state of the weather, or both combined. It attacks every breed and kind of cattle.

"The first symptom is the appearance of something like blood mixed with the urine. So trifling is the complaint in some instances, that no inconvenience seems to be felt by the animal, who eats and drinks as usual, chews the cud, and is free of the disease in a few days. In such cases a natural diarrhœa comes on, to which the cure may be attributed. In general, however, the disease is not observed until the animal refuses food, separates from the rest of the herd, appears dull and heavy, and manifests great langour and apathy. The ears droop, the urine is of a reddish or brownish colour, and if it be a milch cow, the milk is often similarly tinged. The pulse ranges from 60 to 70; there is obstinate constipation of the bowels; the urine is discharged in moderate quantity, and apparently without pain. If relief is not afforded by some brisk purgative, at the period when the urine changes colour from red to brown, the pulse begins to sink, and if a little blood be drawn at this time, its surface assumes a brownish colour; the eye appears of a yellowish-brown tint; the urine acquires a darker hue; the animal refuses to rise; the pulse sinks; the legs, tail, and horns turn cold; and the animal dies, to all appearance perfectly exhausted, although it has manifestly no symptoms of acute pain during the course of the disease.

"Purgatives of any kind, if given in large quantities of water, are found to be the best medicines that can be employed. Medicines given to cattle that have lost the power of chewing the cud, generally pass into the first and second stomachs, and if a good draught of water is not given to wash them from thence, if the animal dies, the greater part of the medicines will be found in these stomachs; and upon this principle, common salt, if properly managed, will be found among the best. Dissolve the quantity to be given in as much water as will enable it to pass freely from the bottle or drenching horn, and let the animal have plenty of water to drink afterwards. Should it refuse to drink, no time should be lost in drenching it profusely with water. Without a plentiful dilution, there is no certainty of purging cattle that have lost their cud. If purging does not commence in from 12 to 24 hours, a second dose should be given. Injections of soap and water should also be tried, if the case is obstinate, and when they operate, a pint of linseed oil should be given as a laxative. So obstinate is the constipation in some cases, that the salt acts only as a diuretic,

causing a plentiful discharge of urine. Diuretics and astringents combined seem only of service when the bowels are open, and their improper administration often causes inflammation of the bowels and kidneys. If, after purgation, the bowels are kept open by laxatives, such as linseed infusion, the disease will gradually disappear without their use. In the last stage of the disease, when the urine assumes a dark-brown or black colour, no remedy seems to have any efficacy; the animal is sunk beyond recovery, the bowels lose their action, suppression of urine follows, the animal stretches itself out and dies, as if perfectly exhausted.

“There are two diseases which in their symptoms bear some resemblance to red-water in cattle, viz., inflammation of the kidneys, and inflammation of the mucous membrane of the bladder or the urethra, which often happens at calving. In these cases the urine, which is discharged with pain, is mixed with blood, but not so intimately so as the coloured urine in red-water, and it has generally more or less mucus mixed with it. Inflammation of the kidneys in cattle is comparatively rare. I have seen only one well-marked case, which terminated fatally. The animal experienced considerable pain upon pressure being applied to the region of the kidneys. The urine was small in quantity, and nearly as thick as blood; and pulse ninety and very hard. As the disease advanced, the urine became black and fetid. The animal all along exhibited symptoms of excruciating pain, until death terminated its sufferings. Post-mortem examination disclosed extensive inflammation of the peritonæum. The abdominal cavity contained a large quantity of dark-coloured, fetid fluid; the fat surrounding the kidneys, as well as the kidneys themselves, was in part gangrenous; and the fat generally exhibited a yellow colour, as is usual in cases where death terminates inflammatory diseases.” (*Trans. High. Soc.* vol. ix. p. 9.)

REED (*Arundo*). A genus of aquatic plants, in most instances mere weeds, infesting boggy low lands or meadows on the sides of rivers.

The best method of destroying reeds, is by draining the land; for if the drains be cut deeper than their roots, it will take away their nourishment, and consequently destroy them. Common salt, ashes, or soot, will likewise sometimes kill them; and so will ploughing up the land, and laying it in high ridges. Reeds always indicate a deep, good, moist soil, as a bad one will not nourish or support them. See **ARUNDO**, **AROMATIC REED**, and **BENT** or **STARR**.

The term *reed* is sometimes provincially applied to the straw of wheat, rye, &c., that has not been bruised.

REED-GRASS. See **CANARY-GRASS**.

RENNET, or **RUNNET**. The prepared inner membrane of the calf's stomach, which has the property of coagulating the albumen of milk, and converting it into *curd and whey*. The maw is cleaned, salted, and suspended in paper bags. Previously to its use, the salt is extracted by washing the rennet; which is then soaked in hot water during the night; and in

the morning the infusion is poured into the milk to coagulate it. This is the result of the gastric juice, which is acid; and acts upon the caseous part of the milk, in the same manner as other acids. It sometimes happens that no rennet sufficiently good for curdling milk can be procured; hence various plants have been advantageously substituted for this purpose. The principal of these are the flowers of the yellow ladies' bedstraw (*Galium verum*), used in England, and the cardoon (*Cynara cardunculus*), in Spain. A strong infusion is made of the down of the latter vegetable in the evening, and on the succeeding morning $\frac{1}{2}$ a pint is poured among 14 gallons of new milk, which is thus effectually coagulated, and in consequence produces a delicious cheese. See **CHEESE** and **CHEESE RENNET**.

RENT (*Redditus*; from *redeundo*). The sum of money or other consideration issuing yearly out of lands and tenements paid by the occupier to the owner. This, in Britain, has gradually taken the present form of payment in money, from a very different original tenure; for, in former days, the land was generally held of the superior lord, by certain services rendered, of either a military or servile nature, such as carrying out the lord's manure on to his land; certain days of ploughing, digging, or cutting the corn, &c. of the landlord; the general adoption of a fixed rent or money payment in lieu of these arbitrary and vexatious tenures, was an advance of modern days.

RESERVOIR. A conservatory of water. The husbanding of water is now becoming a subject of peculiar interest to the English agriculturist. This arises from its scarcity in many districts, in consequence of the improved drainage of the land, and from the many uses to which machinery may be applied in farming operations by the agency of water power. The construction of reservoirs must resolve itself into the following heads:—

First, where a sufficient quantity of water can be diverted directly from the channel of a stream or river.

Second, where the supply is to be obtained from drainage, which maintains a stream during part of the year, but which stream fails during the summer months.

Third, where there are grounds affording a favourable situation for the construction of a reservoir, but through which there is no natural stream passing. See **PONDS** and **TANKS**.

RESINS. Peculiar vegetable substances of allied properties, composed of carbon, hydrogen, and oxygen; the most common of which is the rosin of commerce, or residue after the distillation of turpentine, in order to obtain the volatile oil. When no water is used in this process, an empyreumatic, brownish-yellow, semi-transparent substance remains, namely, *colophony* or *fidler's rosin*; when water is used, the residue is the opaque yellow substance called *yellow rosin*. When every particle of water is evaporated from the last, and it is kept in a state of fusion at a moderate temperature, and then allowed to cool slowly, the best resin is procured. It is translucent, brittle, fusible at a moderate heat, inflammable, and soluble in spirits of wine, volatile oils, and

also fixed oils and fat, when aided by heat. The mineral acids convert it into artificial tannin; the alkalis into soap. Resin in combination with wax, a little oil of turpentine and wax, forms a good polish for furniture. Resin contains oxygen 13.337, carbon 75.944, hydrogen 10.719. The chief of the other resinous substances are *elemi*, *copal*, *mastic*, *sandarac*, *lac*, *labdanum*, *amber*, &c. They are almost all soluble in alcohol.

REST-HARROW (*Ononis*, from *onos*, an ass, and *onemi* to delight; some of the species are said to be grateful to asses). All the plants belonging to this genus are of easy cultivation, and several of them are rather handsome when in flower. The common rest-harrow or cammock (*O. arvensis*), is a native plant, with a woody, tough, and strong root, resisting the harrow's prongs, whence the English name. The stems are annual, though often considerably woody, or shrubby, various in length, hairy. Leaves generally simple, entire towards their base. Flowers mostly solitary, large, and handsome, of a brilliant rose colour. See *Pl. x. k.*

RHIZOMA (Lat. *Rhiza*, a root). A term applied to roots which spread under ground, like those of the iris.

RHODODENDRON (From *rhodo*, a rose, and *dendron*, a tree, because of the appearance of the terminal bunches of flowers). The rhododendron is decidedly one of the finest of all known genera, containing some of the most handsome, elegant, and showy shrubs; all of which are admirably adapted either for ornamenting the green-house or shrubbery, or for planting singly on lawns. Peat soil is most suitable to these plants, but they may also be grown in very sandy or vegetable mould. They are propagated by layers or seeds. The small-wooded kinds may be also increased very freely by young cuttings, planted in sand, under a glass.

The species found in the United States are, the *Rhododendron nudiflorum*, or naked-flowered rhododendron, commonly called the wild honey-suckle, a beautiful American shrub found in the Middle States, frequent in woodlands and thickets, where it blooms from April to May. The flowers are of various shades, from very pale to bright purple. There are apparently several varieties of this beautiful flowering shrub. The leaves are subject to large green excrescences, produced by the puncture of insects. See *AZALEA*.

Rhododendron viscosum, clammy rhododendron, or sweet white honeysuckle, a fragrant, pretty species, with very clammy white flowers, found in rocky woodlands in the Middle States, flowering in June. The stems grow to the height of 4 or 6 feet, with numerous short and crooked branches. See *AZALEA*.

The *Rhododendron maximum*, or dwarf rose bay, forms a magnificent ornament of the American mountain forests. It generally presents itself in the form of a shrub, of less than 10 feet in height, although it occasionally attains an elevation of 20 to 25 feet, with a diameter of 4 or 5 inches.

RHUBARB (*Rheum rhaponticum*, from *ῥῆον*, to spread, and *Rheum hybridum*). A hardy perennial plant, a native of Asia. The leaves are

very broad, and 2 feet long. Their petioles or stalks are large, and these only are used. They are agreeably acid and vinous, very wholesome, and much admired, whether stewed alone with sugar for tarts, and puddings, and pies, or combined with other fruits. Its use with us is fast increasing, and although its introduction to the London market did not take place, it is said, till 1815, yet now, we are told, a thousand cart-loads are there annually sold. The soil best suited to these plants is one that is light, rich, deep, and moderately moist. A poor heavy or shallow soil never produces them in perfection.

It may be propagated by cuttings, but the mode almost universally practised in England is by seed. This should be sown soon after it is ripe in September or October, for if kept out of the ground until the spring, it will often continue dormant for twelve months; if the danger of this, however, is risked, it must be inserted early in February or March. The seeds are best inserted in drills 3 feet apart and an inch deep, the plants to remain where raised; for although they will bear removing, yet it always checks and somewhat lessens their growth. When they make their appearance in the spring, and have been thoroughly cleared of weeds, they may be thinned to 6 or 8 inches asunder, and the surface of the ground about them loosened with the hoe. Towards the conclusion of summer, when it can be determined which are the strongest plants, they must be finally thinned to 3 or 4 feet, or the hybrid to 6. They must be continually kept clear of weeds. In autumn, when the leaves decay, they are removed, and the bed being gently turned over, a little well-putrefied stable-dung added, and some of the earth applied over the stools. In the spring, the bed may be again dug, previous to the plants making their appearance; and as the stalks, when blanched, are much less harsh in taste, require less sugar to be rendered palatable, and are greatly improved in appearance, at this period a trench may be dug between the rows, and the earth from it laid about a foot thick over the stool. This covering must be removed when the cutting ceases, and the plants allowed to grow at liberty. As the earth in wet seasons is apt to induce decay, the covering may be advantageously formed of coal-ashes or drift-sand, which are much less retentive of moisture. Those plants produce the seed in greatest perfection that are not gathered from, but on no account must they be subjected to the process of blanching. Two year old plants often produce seed, but in the third year always. It must be gathered as soon as ripe, and great care taken that none is scattered over the beds, for the plants then produced often spring up and greatly injure the old plants by growing unobserved amongst them.

Varieties.—1. *Buck's new early Scarlet Rhubarb*.—A new and beautiful variety, and very early. The stalks and the juice are of a beautiful red colour, and quite as high-coloured as the juice of red currants, and of excellent flavour. Fit for use, in our climate, in April.

2. *Tobolsk*.—A new and very superior variety; the earliest of all the early, not excepting, perhaps, *Buck's Early Scarlet*. The stalks

are of a beautiful pink colour, and of excellent flavour. Originated in England by Mr. Youle, and fit for use here in April.

3. *Dulley's Goliath*.—A new variety, which grows to a very large size.

4. *Dulley's Admiral*.—A variety of a still more recent date, and remarkably large.

5. *Elfrot Rhubarb* (Var. *Undulata*).

6. *Giant Rhubarb*.—A new and large species.

7. *Wilmot's Early Red*.—Early and fine, with red stalks.

8. *Myatt's Victoria*.—A magnificent production, with leaves and stalks of enormous size, exceeding, in this respect, all other varieties. New, and of excellent quality.

9. *Australian Rhubarb* (*Rheum Australe*).—A new variety and valuable acquisition; later in its vegetation than any other kind: it also continues to grow vigorously, and to furnish a supply of leaves long after all other varieties are gone, or till hard frosts. By protection and a frame, it lasts till January. The flavour of *Rheum Australe* resembles apples; and, though thought by some to be more medicinal in its effects than other sorts, yet those who have used it for years have never found it prove injurious.

Young seedling plants only need to be protected the first winter by soil. Rhubarb may be forced very early, by being covered with boxes or barrels, surrounded by horse-manure at the top and sides. The rhubarb is highly deserving of cultivation by every family.

Rhubarb Wine.—The leaf-stalks of green-coloured rhubarb, being cut in pieces as for tarts, and bruised with a mallet to extract the juice, will make a delicious wine, quite equal to green gooseberry wine, and very closely resembling Champagne. Of the red rhubarb a fine red wine is made.

Rhubarb Jam and Jelly.—A superior jam or jelly is thus made from the tender leaf-stalks of rhubarb, equal or superior to that from currants, and of excellent flavour. To one pound of the stalks, cut as for tarts, add one pound of loaf or brown sugar; boil till the ingredients acquire a proper consistence. Unground ginger and lemon peel added to the jelly have been found a decided improvement. Buck's early scarlet rhubarb has a preference in point of colour, which is beautiful red; it is also of fine flavour, though not, perhaps, superior in this respect to other varieties. Rhubarb will answer for jelly three months before the currant is ripe. An excellent preserve is also made of rhubarb. For this purpose the stalks are cut into inch pieces, and preserved in the usual way with sugar. (*Kenrick*.)

RHUS (Derived from *rous*, in Greek, which is from *rhudd*, a Celtic word, signifying red; alluding to the colour of the fruit and leaves of some species in autumn). The hardy kinds are rather ornamental, and well fitted for shrubberies; some are propagated by cuttings of the roots, and others by cuttings and layers. The juice of *R. radicans*, poison or swamp sumach, and *R. toxicodendron*, poison vine or poison oak, is milky, stains black, and is extremely poisonous. *R. coriaria* is powerfully astringent, and is used in tanning Turkey or Morocco leather.

RIB-GRASS. See **PLANTAIN**.

RIBBON-GRASS (*Phalaris*). The variety of the genus *Phalaris* called *picta*, from its striped leaves, is found in gardens and yards as an ornamental plant. From its tendency to strike deep roots and spread, it often becomes troublesome to eradicate. The species called reed-like or American *Phalaris*, is common in swampy places in the Middle and Northern States. When, says Dr. Darlington, the panicles of this plant first appear, they have some resemblance to those of orchard grass; but he thinks it far inferior to the orchard grass, and too much of an aquatic for regular culture. Another species, the *Phalaris canariensis*, or wild canary grass, is particularly naturalized in some of the Northern and Eastern States, where it produces crops of the greatest luxuriance. It is perennial, spreads rapidly, and may be easily propagated by transplantation.

RICE (*Oryza*, from the Arabic word *êruz*, the Greeks coined their word *εργυρα*, and the various modern nations of Europe their *rice*, *riz*, *reis*, &c.). *O. sativa*, the common rice, has the culm from 1 to 6 feet in length, annual, erect, simple, round, jointed. Leaves subulate-linear, reflex, embracing, not fleshy. Flowers in a terminating panicle. Calycine leaflets lanceolate. Valves of the carolla equal in length; the inner valve even, awnless; the outer twice as wide, four-grooved, hispid, awned. Style single, two-parted.

O. mutica, the dry or mountain rice, cultivated in Ceylon, Java, and of late in Hungary, has the culm 3 feet high, and more slender. Fruit longish, with awns the longest of all. It is sown on mountains and in dry soils; rots with a long inundation, and perishes with sea-water.

The varieties of rice, as of other cultivated grain, are as numerous as the different soils, climates, and other physical circumstances, in which it is cultivated: besides the dry rice, the chief sorts, by some considered species, are the *O. praecox*, or early rice, and the *O. glutinosa*, or clammy rice, both cultivated in irrigated lands.

The native place of rice, like that of the other sorts of grain in common use, is unknown; it is cultivated in great abundance all over India, where the country will admit of being flooded; in the southern provinces of China, in Cochin China, Cambodia, Siam, Japan, &c. In Japan it is very white, and of the best quality. It has also been introduced into cultivation in the southern kingdoms of Europe, Italy, Spain, the south of France, and within a few years into Hungary and Westphalia. In Carolina it has long been a staple commodity. Houghton's account of its introduction there is, that Ashby was encouraged to send a hundred pound bagful of rice to that province, from which, in 1698, 60 tons were imported into England. Dalrymple says, that rice in Carolina is the result of a small bag of *paddy*, given as a present from Dubois, treasurer of the East India Company, to a Carolina trader. A Dutch vessel also, from Madagascar, brought rice into the same province; and to this is attributed their having two kinds.

In the hilly parts of Java, and in many of the Eastern islands, the mountain rice is planted

upon the sides of hills, where no water but rain can come; it is, however, planted in the beginning of the rainy season, and reaped in the beginning of the dry season. The natives call it *Paddy Gunung*, which signifies mountain rice. It is entirely unknown in the western parts of India, but it is well known in Cochin China, where it thrives in dry, light soils, mostly on the sides of hills, not requiring more moisture than the usual rains and dews supply, neither of which are frequent at the season of its vegetation.

There is a kind of hill rice which is hardy enough to grow on the edge of the Himalayan snows. This, it may be expected, will, at some future time, prove an acquisition of value to the European and American cultivators.

Rice is extensively cultivated in the East Indies and China, chiefly on low grounds near large rivers, which are liable to be annually inundated, and enriched by the deposition of mud. According to Sir George Staunton's account, the Chinese obtain two crops of rice in a year from the same ground, and cultivate it in this way from generation to generation on the same soil, and without any other manure than the mud deposited by the water of the river used in overflowing it. After the waters of the inundation have withdrawn, a few days are allowed for the mud to get partially dry; then a small spot is enclosed by a bank of clay slightly ploughed and harrowed, and the grain, previously steeped in dung, diluted with animal water, is then sown very thickly on it. A thin sheet of water is immediately brought over it, either by a led stream, or the chain-pump. Thus a seed-bed or nursery is prepared, and, in the mean time, the remainder of the tract is preparing for being planted. When the plants are 6 or 7 inches high, they are transplanted in furrows made by the plough, so as to stand about a foot apart every way; water is then brought over them, and kept on till the crop begins to ripen, when it is withheld; so that when harvest arrives the field is quite dry. It is reaped with a sickle, threshed with a flail or the treading of cattle, and the husk taken off by beating it in a stone mortar, or passing it between two flat stones, as in a common meal mill. The first crop being cut in May, a second is immediately prepared for by burning the stubble, and this second crop ripens in October or November. After removal, the stubble is ploughed in, which is the only vegetable manure such lands can be said to receive from man. In Japan, Ceylon, and Java, according to Thunberg, Davis, and Raffles, aquatic rice is cultivated nearly in the same manner. Mountain-rice is grown much in the same way as barley.

In Lombardy and Savoy rice is sown on rich lands, the sower often wading to the knees in water: one crop a year only is obtained; but four crops are often taken in succession. In America a similar practice obtains.

In Westphalia, and some other parts of the south of Germany, rice has long been cultivated; there it is sown on lands that admit of irrigation; but the water is not admitted till the seed has germinated, and it is withdrawn, as in Italy, when the crop comes into flower. From

long culture, in a comparatively cold country, the German rice has acquired a remarkable degree of hardiness and adaptation to the climate; a circumstance which has frequently been alluded to as an encouragement to the acclimating of exotics. It is found, Dr. Walker remarks (*Essays on Nat. Hist.*), that rice seeds direct from India will not ripen in Germany at all, and even that Italian or Spanish seeds are much less early and hardy than those ripened on the spot.

In Hungary rice has not been long cultivated: the mountain sort has chiefly been tried, and that in the manner of our barley or summer-wheat.

In England a crop of rice has been obtained near Windsor, on the banks of the Thames.

By far the best imported rice is that from Carolina: it is larger and better tasted than that of India, which is small, meager, and the grains frequently broken. As an article of diet, rice has been extolled as superior almost to any other vegetable: but whatever it may be in warmer climates, where it is a common, and to many persons almost their only food, it does not appear so well calculated for European constitutions as the potato; for we find that the poor constantly reject the use of rice when potatoes are to be had; and whilst these can be obtained, we may venture to predict, that rice will always be considered, in Britain, rather as a dainty, to be eaten with sweet condiments, spices, fruit, &c., than as ordinary food. *Loudon's Ency. of Plants.*

The mountain rice has been raised in Maryland by Mr. Bordley, on dry sandy land. The following comprehensive directions respecting the *water culture* of rice, were furnished by one of the most successful cultivators in South Carolina:

Begin to plant about the 25th March, trench shallow and wide, and scatter the seed in the row; make 72 or 75 rows in a task, and sow 2 bushels to an acre.

1. Hoe about the end of April or beginning of May, when the rice is in the fourth leaf; then flood, and clear the field of trash. If the planting be late, and you are likely to be in grass, flood before hoeing; but hoeing first is preferable. The best depth to flood is 3 or 4 inches. It is a good mark to see the tops of the rice just out of the water: the deep places are not to be regarded; the rice will grow through in 3 or 4 days. Observe to make a notch on the frame of the trunk, when the water is at a proper depth: if the rains raise the water above the notch, or it leaks out, add, or let off accordingly. This is done by putting a small stick in the door of the trunk, about an inch in diameter: if scum or froth appear in 8 or 10 days, freshen the water, take off the trunk doors, run off the water with *one ebb*, and take in the next *flood*; then regulate as before. Keep the water on about 15 or 17 days, according to the state of the weather; that is, if a hot sun, 15 days; if cool and cloudy, 17 days, counting from the day the field is flooded; then leak off with a small stick for 2 days, then run off the whole, and keep the field dry. In 4 or 5 days after, hoe the second time, stir the ground, whether clean or not, and comb up the fallen

rice with the fingers. Keep dry and hoe through the field. Hoe the third time and pick clean. This will be about the beginning of July. Then flood as you hoe. Let the water be the same depth as before. If any grass has escaped, it must be picked in the water after it shoots out. This is called the fourth hoeing, but the hoe is never used except for some high places or to clean the dams. If the rice is flaggy and likely to lodge, flood deep to support it, and keep it on until fit to harvest. (*Domestic Encyclopedia.*)

If land is *well drained* and in *good order*, it is calculated that 5 acres of rice and 1 or 1½ of provisions may easily be cultivated to the hand.

Rice was formerly almost altogether exported in the form of clean rice, but at present the largest amount of that taken to England is in the husk or rough state, called *paddy* or cargo rice. The rice crop for 1842 has been estimated by Mr. Ellsworth at 94,007,484 pounds.

The following statement shows the annual quantities and value of rice exported from the United States at different periods:

Years.	Exports in Tierces.	Value.
1791 - - -	96,980	
1792 - - -	141,762	
1803 - - -	81,838	\$2,455,000
1816 - - -	137,843	3,555,000
1818 - - -	88,181	3,262,697
1836 - - -	212,983	2,548,750
1838 - - -	71,048	1,721,819
1841 - - -	101,617	2,010,107

(*Hunt's Merchants' Magazine, July, 1843.*)

RICE WEEVIL. See GRAIN WEEVIL.

RICE, WILD (*Zizania*). Nuttall mentions three species of aquatic grasses, called wild rice, found in the United States, viz.: the *Zizania aquatica* (Pl. 4, c); *Z. miliacea*; and the *Z. fluitans*. This last is very small and easily confounded with other aquatic grasses. He found it around Savannah in Georgia.

The *Z. aquatica* is found in almost every part of the Northern and Middle States, where it goes by the names of water oats, Indian rice, and reed. The seeds resemble those of Polish millet. It is exceedingly prolific. The root is perennial. It grows in swampy places, and in deep water at the edges of ponds and sluggish streams. Stock of all descriptions are fond of the plant when green, or cured as hay. It resembles, at a distance, slender shoots of Indian corn. The stems are jointed, and as large as the little finger. The panicle or head is a foot or more in length, and the seeds blackish, smooth, narrow, cylindrical, about three-quarters of an inch long, white and farinaceous within. Gilleland's *Ohio and Mississippi Pilot* contains the following interesting details relative to wild rice: "Among the vegetable productions of the Western Territory north of Illinois and west of Green Bay, on the Ouisconsin and Fox rivers, the wild rice, called *Folle avoine* by the French, and *Menomen* by the Indians, claims particular attention. It grows in inexhaustible abundance, through all parts of the territory, in almost every one of the innumerable lakes, ponds, bays, rivers, and creeks. It is said to be as palatable and as nourishing as common rice, and if so, it will be incomparably more valuable. It grows where the water is from 4 to 6 feet deep, and where the bottom is not hard or sandy. It rises above the surface of the water from 4 to 8 feet, and

is often so thick as almost to prevent canoes from passing through or among it. The stalk is soft like the bulrush, but grows in joints like reed-cane, which it much resembles. It is usual for the Indians to force their canoes through it, just before it ripens, and tie it in large bunches for the purpose of preventing the wild ducks and geese from breaking it down and destroying it. When fully ripe, they pass through it again, and, spreading their blankets in the inside of their canoes, they bend the branches of the wild rice over them, and thresh off the grain with sticks; an operation which requires little time, and is generally performed by the women. After drying it in the sun, they put it into skins, for future use. Every autumn and spring the wild ducks and geese resort to the wild rice lakes in flocks incredibly numerous. It is thought by many that the *Zizania aquatica* will some day be an object of culture, which may afford a means of bringing into use large tracts of inundated land."

RICK. A pile of corn, hay, straw, &c., regularly heaped up in the open air, and sheltered from wet by thatch. See STACK.

RIDDLE. A sort of sieve used to separate dust and the seeds of plants from corn. They are made of various sizes for different uses.

RIGGIL. An imperfect male sheep, having only one or no testicle in the scrotum.

RIME. A hoary or white frosty appearance, sometimes on the ground in the autumnal, winter, and early spring mornings. See DEW and FROST.

RING-BONE. In farriery, a callus growing in the hollow circle of the little pastern of a horse, just above the coronet. It has its name from the resemblance to a ring.

RINGS, FAIRY. See FAIRY RING.

RIPPLE GRASS. A popular name of the English plantain (*P. lanceolata*).

ROADS. See HIGHWAYS.

ROARING. In farriery, a disease well known to jockeys and horse-dealers, which usually accompanies or precedes broken wind. It is generally the result of long-continued or violent exercises. It is connected with dilatation of the air-cells of the lungs, and is incurable. See BROKEN WIND.

ROCHAMBOLE. See GARLIC.

ROCK CRESS. See CRESS, WALL.

ROLLERS. An implement of simple construction, like the roller, the main object of which is to render smooth the surface of arable lands. would not seem to admit apparently of much variety in its construction. Nevertheless, it is an implement in which greater diversity of form is found to exist than in most other agricultural machines. Rollers are of all sizes, weights, and lengths; and the material of which they are made is occasionally iron, sometimes stone, but most commonly wood. Of these, the first is undoubtedly the best, and particularly for the jointed roller, by which the operation of turning at the ends of the ridges is materially facilitated, and the slading of the earth which would otherwise take place on the head-lands, not only to their great detriment, but to the small increase of labour to the horses, is thereby prevented.

An ingenious gentleman, the late George

Booth, Esq., of Allerton, near Liverpool, who to a great love of farming added a very tolerable share of mechanical skill, and to both ample means to carry out his various devices, constructed a roller, or rather a nest of rollers, on the lever principle. He contended for a very small diameter as the most effective in crushing the clods, and throwing the greatest possible weight on the surface of the ground. We regret being only able to give an idea of his invention from memory; but do not think his roller was more than a foot in diameter at the outside. It consisted of five cylinders or rollers, arranged in such manner that three hind ones, separated from each other, have the two spaces overlapped by two cylinders placed in front.

Drill rollers.—These are made of rings adapted to a shaft. They are not by any means of modern invention, having been well known to the English farmers of Norfolk and Suffolk for the greater part of a century. The only improvement they have undergone has been to render each ring independent of its neighbour, so that the process of turning at the end of the field is facilitated, as in the case of the jointed roller. The modern drill rollers in other respects have not improved, if the doctrine of Mr. Booth, already noticed, be correct, that a small diameter is better than a large one. The drill roller is used for the double purpose of crushing clods on rough lands, and making grooves ready to receive the seed of wheat or other grain sown broadcast on light soils. It is a capital tool for either purpose. In the first case it is followed by a harrow, of sufficient weight to lighten up the surface; in the other, the fine, short-toothed harrow, or even a mere bush-harrow, will be found sufficient. The less such land is disturbed after sowing the better, and the more distinct will be the several rows or grooves of corn.

Heavy rollers.—The heavy roller is a very effective implement. It is formed of 3 separate cylinders, about 2 feet in diameter, and of the same length; the axis of each being independent of the other. On turning, they consequently revolve in different directions, and thus “slading” at the land’s end is avoided.

The *double-jointed barley roller* is a very useful implement. It is so constructed that the two sides, being separate rolls or distinct frames, may revolve at opposite angles; and, when required, one may be placed behind the other. A plan has for many years been in use in Norfolk, of constructing them with twisted joints, so that the under end of one roll shall work behind the end of the other, thus leaving no seam between the roller.

Crosskills’ clod-crusher is, under many circumstances, a valuable implement. It is composed of a series of iron rings, with notched edges, set apart from each other about 3 or 4 inches. Small cross-bars or knives are placed at frequent intervals on the faces of these, and near their outer notched rims, so as to intersect every portion of land over which it passes. Its construction, combined with its great weight, renders it very effective for the purpose which its name denotes. Indeed, as an old farming

bailiff once aptly remarked, it is a roll and a harrow combined. The roller is an implement which requires some judgment as to the time of its use, and this remark applies with increased force to the one under consideration.

Seam or land-presser.—If a drill is so effective an implement, far more so is the seam or land-presser, inasmuch as its whole force and weight is directed to each individual furrow, as it is turned over by the common plough. The seam-presser is in fact an abstract of a drill roller, consisting of but two cylinders of cast-iron, which, following in the furrow, press and roll down the newly turned-up earth, and it is more particularly useful when applied to clover stubbles intended for wheat. (*Ransome on Agr. Imp.*)

In the United States the roller is constructed of wood, stone, or cast-iron, according to convenience or the purposes for which it is used. In American husbandry we have yet no reason to expect, or perhaps desire, any but those made of wood, and such as any farmer, who has a moderate degree of mechanic skill, and the carpenter’s tools which every farmer ought to keep, may readily construct himself. A good, sound, oak log, with the frame and shafts appended, makes a good roller. They are made of different lengths and sizes, varying from 15 to 30 inches in diameter. The lighter kinds are made in one piece, but the larger and heavier kinds are advantageously made in two pieces, with an iron rod passing through the centre of both, and upon which they revolve. English farmers construct the frame so as to rise above the roller, upon which a box is fixed, either to contain stones to add to the pressure of the roller, or to receive small stones and rubbish, collected on the field while at work, which are to be carried off. Their shafts, when at work, are generally horizontal. We think the roller is more easily drawn when the draught is on a right line from the collar or yoke of the team to the point of resistance. This may be done, and the advantages of the box retained.

The uses and advantages of the roller are many and important, and no farmer should be without one. They are particularly important in the seeding process, to break down the clods, pulverize and smooth the surface, and to press the earth to the smaller seeds, which otherwise often fail to germinate for lack of moisture. This is particularly the case with oats, barley, and the grass seeds. In autumn the roller is sometimes passed over winter grain, with a view to counteract the effects of frost the following winter. In spring it is advantageously passed over winter grain, as soon as the ground is so solid and dry that the feet of the cattle will not poach the surface. It renders light ground more compact; presses the soil to the roots of the grain, and thus promotes their growth; and upon all soils closes the innumerable cracks and fissures which abound on the appearance of dry weather in spring, and, by partially burying the crown, causes grain to tiller better, that is, send up more seed-stalks. Finally, the roller is of great advantage to grass lands in the spring, by reducing the in-

equalities of surface, and pressing down the plants or earth which have been thrown up by the frost.

There are also rollers for other purposes, viz., the *spiked roller*, which is used for pulverizing stiff soils, preparatory for wheat. This is formed by inserting several rows of spikes, or cast or wrought-iron darts, in a common hard-wood roller. The *concave* or *scalloped roller* is adapted to the form of ridges, and is often attached to the turnip drill. (*Cultivator*).

ROLLING. In agriculture, the action or operation of drawing a roller over the surface of the ground, with the view of breaking down the clods, rendering it more compact, and bringing it even and level; or for only leveling the surface, as in grass lands. This is a practice that becomes necessary both upon the tillage and grass lands, and which is of much utility in both sorts of husbandry. In the former case it is made use of with different intentions, as for the purpose of breaking down and reducing the cloddy and lumpy parts of the soil in preparing it for the reception of crops. It is also of great use in many cases of light soils, in rendering the surface more firm, even, and solid, after the seed is put in.

ROOT. In botany, that part of the central axis of a plant which is formed by the descending fibres, and whose function is to attract liquid food from the soil in which it is mingled. It differs from the stem in not having leaves or buds upon its surface, and in its tendency to burrow under ground, retreating from light; nevertheless, some kinds of roots are exclusively formed in air and light, as in the ivy and other such plants; but these are to be regarded as prehensile organs, to support the plants, rather than as roots, or nutritious organs. The root-stock or rhizome is a prostrate, rooting, thickened stem, which yearly produces young branches or plants. Ginger and orris-root are common instances of it. It is often confounded with the root. There are many appendages to the roots, namely, tubers, bulbs, &c., which are mere reservoirs of food for the lateral progeny of the plant. See **BULB, RHIZOME, TUBER, &c.**

ROSE (Lat. *Rosa*, from the Celtic *rhod*, red, in reference to the prevailing colour of the flowers). In botany, the English name for the well-known and universally cultivated flower of the genus *Rosa*. It is an extensive family, but all of the species love a stiff soil. No roses will thrive in shallow, poor ground. Standard roses are obtained by budding them upon vigorous stocks raised from the seed of the hedge or dog-rose, managing the stocks in the same way as fruit-stocks. Their heads must be pruned occasionally to prevent their rambling. The dwarf roses in flower borders should be pruned in January, down to a foot high, cutting out the old and dead wood. They will produce finer flowers. Roses bear their flowers upon wood of the last year. Only the China roses flower upon the shoots of the same year. Roses continue blowing a long time, if the fading flowers are cut off instead of being allowed to seed.

Nearly a dozen species of the wild rose are found in the United States, among which are

those familiarly known as the swamp, rock, dwarf, wild, &c.

ROSE BAY, or MOUNTAIN LAUREL.
See **RHODODENDRON MAXIMUM.**

ROSE-CHAFER, or ROSE BUG, is a diurnal or day-flying beetle of the Melolonthian genus. Dr. Harris states that this insect, which is common in the vicinity of Boston, is, or was a few years ago, unknown in the northern and western parts of Massachusetts, New Hampshire, and Maine. The natural history of the rose-bug, one of the greatest scourges with which American gardens and nurseries are afflicted, was for a long time involved in mystery, but is at present fully cleared up.

For some time after they were noticed, says Dr. Harris, rose-bugs appeared to be confined to their favourites, the blossoms of the rose; but within 30 years they have prodigiously increased in number, have attacked at random various kinds of plants in swarms, and have become notorious for their extensive and deplorable ravages. The grape-vine, in particular, the cherry, plum, and apple trees, have annually suffered by their depredations; many other fruit trees and shrubs, garden vegetables and corn, and even the trees of the forest and the grass of the fields, have been laid under contribution by these indiscriminate feeders, by whom leaves, flowers, and fruits are alike consumed. The unexpected arrival of these insects in swarms at their first coming, and their sudden disappearance at the close of their career, are remarkable facts in their history. They come forth from the ground during the second week in June, or about the time of the blossoming of the damask rose, and remain from 30 to 40 days. At the end of this period the males become exhausted, fall to the ground, and perish, while the females enter the earth, lay their eggs, return to the surface, and, after lingering a few days, die also. The eggs laid by each female are about 30 in number, and are deposited from 1 to 4 inches beneath the surface of the soil; they are nearly globular, whitish, and about one-thirtieth of an inch in diameter, and are hatched 20 days after they are laid. The young larvæ begin to feed on such tender roots as are within their reach. Like other grubs of the Scarabæians, when not eating, they lie upon the side, with the body curved so that the head and tail are nearly in contact; they move with difficulty on a level surface, and are continually falling over on one side or the other. They attain their full size in the autumn, being then nearly three-quarters of an inch long, and about an eighth of an inch in diameter. They are of a yellowish-white colour, with a tinge of blue towards the hinder extremity, which is thick and obtuse or rounded; a few short hairs are scattered on the surface of the body; there are six short legs, namely, a pair to each of the first three rings behind the head; and the latter is covered with a horny shell of a pale rust colour. In October they descend below the reach of frost, and pass the winter in a torpid state. In the spring they approach towards the surface, and each one forms for itself a little cell of an oval shape, by turning round a great many times, so as to compress the earth, and render the inside of the cell

vity hard and smooth. Within this cell the grub is transformed to a pupa during the month of May, by casting off its skin, which is pushed downwards in folds from the head to the tail. The pupa has somewhat the form of the perfected beetle; but it is of a yellowish-white colour, and its short, stump-like wings, its antennæ, and its legs are folded upon the breast, and its whole body is enclosed in a thin film, that wraps each part separately. During the month of June this filmy skin is rent, the included beetle withdraws from it its body and its limbs, bursts open its earthen cell, and digs its way to the surface of the ground. Thus the various changes, from the egg to the full development of the perfected beetle, are completed within the space of one year.

Such being the metamorphoses and habits of these insects, it is evident that we cannot attack them in the egg, the grub, or the pupa state; the enemy, in these stages, is beyond our reach, and is subject to the control only of the natural but unknown means appointed by the Author of nature to keep the insect tribes in check. When they have issued from their subterranean retreats, and have congregated upon our vines, trees, and other vegetable productions, in the complete enjoyment of their propensities, we must unite our efforts to seize and crush the invaders. They must indeed be crushed, scalded, or burned, to deprive them of life, for they are not affected by any of the applications usually found destructive to other insects. Experience has proved the utility of gathering them by hand, or of shaking them or brushing them from the plants into tin vessels containing a little water. They should be collected daily during the period of their visitation, and should be committed to the flames, or killed by scalding water. The late John Lowell, Esq., states that, in 1823, he discovered on a solitary apple tree the rose-bugs "in vast numbers, such as could not be described, and would not be believed if they were described, or, at least, none but an ocular witness could conceive of their numbers. Destruction by hand was out of the question" in this case. He put sheets under the tree, and shook them down and burned them. Dr. Green, of Mansfield, whose investigations have thrown much light on the history of this insect, proposes protecting plants with millinet, and says that in this way only did he succeed in securing his grape-vines from depredation. His remarks also show the utility of gathering them. "Eighty-six of these spoilers," says he, "were known to infest a single rose-bud, and were crushed with one grasp of the hand." Suppose, as was probably the case, that one-half of them were females; by this destruction 800 eggs, at least, were prevented from becoming matured. During the time of their prevalence, rose-bugs are sometimes found in immense numbers on the flowers of the common white-weed, or ox-eye daisy (*Chrysanthemum leucanthemum*), a worthless plant, which has come to us from Europe, and has been suffered to overrun our pastures and encroach on our mowing lands. In certain cases it may become expedient rapidly to mow down the infested white-weed in dry pastures, and consume it, with the sluggish rose-bugs, on the spot.

Our insect-eating birds undoubtedly devour many of these insects, and deserve to be cherished and protected for their services. Rose-bugs are also eaten greedily by domesticated fowls; and when they become exhausted and fall to the ground, or when they are about to lay their eggs, they are destroyed by moles, insects, and other animals, which lie in wait to seize them. Dr. Green informs us that a species of dragon-fly, or devil's needle, devours them. He also says that an insect, which he calls the enemy of the cut-worm, probably the larva of a *Carabus*, or predaceous ground-beetle, preys on the grubs of the common dor-bug. In France the golden ground-beetle (*Carabus auratus*) devours the female dor or chafer at the moment when she is about to deposit her eggs. I have taken one specimen of this fine ground-beetle in Massachusetts, and we have several other kinds, equally predaceous, which probably contribute to check the increase of our native Melolonthians. (Harris.)

ROSE-LICE. See APHIS.

ROSEMARY (*Rosmarinus officinalis*; from *ros*, dew, and *marinus*, of the sea, on account of its maritime habitat. Poetically implying "the dew of the ocean"). There are 3 varieties—the green, golden-striped, and silver-striped. The first is the one in general cultivation.

ROSE-SLUG. See SLUG.

ROSIN. See RESIN.

ROT. In farriery, a disease in sheep and other animals, in which both the liver and lungs are affected, and there is commonly a dropsical tendency. Its ravages are chiefly, however, confined to sheep, and it is most commonly closely connected with excess of moist food, or placing these animals in low, wet situations, every way foreign to their natural habits; for sheep, in a state of freedom, seek the most elevated, dry, and healthy situations—an instinct which long imprisonment and domestication has not yet eradicated: every farmer is aware with what tenacity his sheep adhere to the very highest portions of a field. It is only when we force them to inhabit low grounds, and situations foreign to their habits, that they thus become diseased. In a state of nature, too, they browse upon the heath plants, and seek with avidity at certain periods salt springs and salt exudations, facts which have not entirely escaped the notice of modern flockmasters. Thus the argali or wild sheep of Siberia, which are the presumed origin of all our domestic sheep, are found about the size of the fallow deer, on the immense chain of mountains reaching through the middle of Asia to the Eastern Ocean. They are found in small flocks, ranging over the highest elevations. As the winter approaches, they move downwards into the plains, and exchange their food from the mountain plants to grass and other vegetables. They are so partial to salt, that they scrape away the earth in considerable quantities in the neighbourhood of saline places in order to procure it. All animals in fact seek salt with the greatest avidity. In Flanders, sheep owners deem it use an *effectual prevention of the rot*, and there is very considerable reason to believe that by the use of this valuable con-

diment, the ravages of this dreadful disease might either be very materially modified, or perhaps entirely prevented.

Many years since, Ellis, in his *Practical Husbandry*, recommended the use of salt, mixed with wort, in which had been boiled sage, pennyroyal, wormwood, shepherd's purse, comfrey, &c., as a prevention of the rot; 7 or 8 spoonfuls was the dose, once a week after April, whenever the weather was wet.

More than three centuries since, Fitzherbert, the earliest of the English agricultural writers, alluded to this dreadful disorder in his *Boke of Husbandry*, and in his section entitled *What thynges rotteth Shepe*, he says, "It is necessary that a shepherde shoulde knowe what thynges rotteth shepe, that he myghte kepe them the better. There is a grasse called sperewort, and hath a longe narrow leafe lyke a spere heed, and it wyll growe a fote hyghe, and beareth a yellowe floure in lowe places where the water is used to stande in wynter. An other grasse is called peny grasse, and groweth lowe by the erthe in a marshe grounde, and hath a leafe as brode as a peny or two pence, and neuer beareth floure. All manner of grasse, that the lande floudde runneth ouer, is very evylle for shepe, because of the sande and fylthe that stycheth uppon it. All moorish grounde and marsche grounde is yll for shepe. The grasse that groweth upon falowes is not good for shepe, for there moche of it wede, and ofte tymes it commeth uppe by the rote, and that bryngeth erthe with it, and they eate both, &c. Myldewe grasse is not good for shepe, and that ye shall knowe two wayes: one is by the leaves on the trees in the morninge, and specially of okes; take the leaves and putte thy tongue to them, and thou shalt fele like hony uppon them. And also there will be many kelles upon the grasse, and that causeth the myldewe, wherefore theye may not well be left out of the folde, tyll the sonne have domination to drye them awaye. Also hunger rotte is the worst rotte that can be, for there is neither goode fleshe nor goode skynne, and that cometh for lacke of meate, and so for hunger they eate suche as they can fynde, and so will not pasture shepe, for they seldom rot but wythe myldewes, and than wyll they have much talowe and fleshe, and a good skyn. Also white snailes be yll for shepe in pastures, and in falowes there is an other rotte whiche is called pelte rotte, and that commeth of greatte wete, speciallye in woode countreys where they cannot drye."

The symptoms of the rot, and of some of its most decided remedies, have been thus described by Dr. Brown, of Boston (*Mag. of Nat. Hist.* vol. v. p. 98), "It cannot, I conceive, be demonstrated that in this disease the bile is thrown back upon the system, and mingles with the circulating fluid; for in the early stages there is no obstruction to the bile; and in the latter, what little is secreted is intercepted by the flukes on the hepatic side of the gall-bladder. The eye, which some persons take to be an index to the bilious condition of the system, has really not that 'tinge of yellow and jaundiced-like appearance' at the commencement of the disease. On the contrary, the peculiar whiteness of the eyes is the first

symptom which guides the shepherd to the unwelcome truth. If the bile ducts be carefully examined in the earliest stage of the complaint, there will be found a few flukes in the duct which conveys the bile from the gall-bladder to the intestine, but none in the gall-bladder, and none beyond it, a sound liver, no 'tubercles,' no 'abscesses,' and withal a fine, fat, healthy-looking carcass. If it be in the latest stage when the examination is made, the gall-bladder will be found filled with flukes instead of bile: and the animals will be seen making their way up those channels which convey the bile from the liver to the gall-bladder, arresting it in its course, and pressing forward and enlarging the biliary tubes. Thus, when but few of these animals have possession of this viscus, its function is not materially impaired; the parenchyma, or substance of the liver, is unaltered in appearance; the mucous channels, which convey the bile to the gall-bladder, and from the gall-bladder to the intestines, have not yet felt their presence, and the bile itself is secreted apparently unaltered in quality or quantity: but here, as they live in a medium of perpetual nourishment, they multiply to an extent incredible, and impede the natural action of the liver and subordinate organs of the body. They at length completely block up the conduits of the bile, devouring the bile as fast as it is secreted; spreading irritation and disease from the vessels in which they live to the whole mass of the liver itself; and in some instances they carve their way through the membrane which encircles them, and escape by myriads into the cavity of the abdomen; thus completing the destruction of an important organ, and with it the life of the animal. These extreme states are generally associated with dropsy and a total degeneracy of the muscular tissue; the blood is deficient in quantity, very serous, and almost destitute of fibrin. A correspondent inquires the class and family of the fluke, in hopes of finding a remedy for a disease so fatal. He will find it in the class *Vermes*, and order *Intestina*, and it is the *Fasciola hepatica*. Contemplating it, as it is, as a variety of exotic worm, it occurred to me that vermifuges, destructive to other species, might be employed with advantage against this. But in instituting experiments on the living animals, I discarded those popular remedies which have only a mechanical action, and which could never reach the liver, for those which operate by a wider range of influence. What I have observed is, that there are in this class of remedies those which have little or no effect when brought in contact with the living fluke; and there are others which destroy the animal immediately. To the first of those which are inert, belong solutions of vegetable bitters, spirits of tar, and several others, which need not be enumerated. To the second, or to those which destroy the animal, belong solutions of mercury and the spirits of turpentine. For example: a little calomel suspended in water, and dropped upon the animal, quickly deprives it of life; and a drop of the spirits of turpentine kills it in a few seconds. The oil of turpentine is a deadly poison to the fluke. The next consideration is, how far it may be safe

to administer this medicine to the living sheep, and what probability there is of its disturbing an animal inhabiting the liver. With regard to the first exception, there can arise no difficulty. The spirit of turpentine is borne readily by children, and has been given to adults in doses of a quarter of a pint; it is likewise applied externally to blistered surfaces, and as a styptic to the bleeding mouths of ruptured blood-vessels. There can be as little doubt with regard to the second exception, when we consider the penetrating nature of this drug; when we know that the mere immersion of the hand in it is sufficient to impregnate the urinary secretion; nor can we doubt that its influence will be acknowledged by an organ approximating and communicating with the stomach, and by the worm inhabiting that organ."

The outward symptoms of this disease were many years since well described by Dr. Harrison of Boston, Lincolnshire, when he said, "If in warm, sultry, and rainy weather, sheep that are grazing on low and moist lands feed rapidly, and some of them die suddenly, there is reason to fear that they have contracted the rot: this suspicion will be further increased, if in a few weeks afterwards the sheep begin to shrink, and become flaccid in their loins. By pressure about the hips at this time, a crackling is sometimes perceptible. Now or soon afterwards the countenance looks pale, and upon parting the fleece, the skin is found to have parted its vermilion tint for a pale-red, and the wool is easily separated from the pelt; as the disorder advances, the skin becomes dappled with yellow or black spots. About this time the eye loses its lustre, and becomes white and pearly, from the red vessels of the *tunica adnata* and eyelids being contracted or entirely obliterated. To this succeeds debility and emaciation, which increase continually till the sheep die, or else ascites or perhaps general dropsy supervene before the fatal termination."

Such are the symptoms and the most powerful known remedies for this disease; an equally important research is its origin, its predisposing circumstances, or immediate cause. In this, however, in common with most other diseases of animal and vegetable life, difficulties occur at every turn, of a nature almost entirely inexplicable. We must be content to do little more than merely trace its symptoms and the course in which it commonly runs. No flock-masters are perhaps more anxiously alive to the disease, or more often its victims, than the owners of the noble water-meadows of the south of England, such as those of the valleys of the Kennett, the Itchen, and the Wiltshire Avon.

These excellent farmers have noticed, that the first crop of spring water-meadow grass never imparts the rot to sheep; but that the second crop, which they therefore make into hay, is almost certain to do so. They notice, also, that the worst rotting-time is from Midsummer to Michaelmas; that almost all meadow land, if chance flooded in summer, that is, if covered by the overflowing of rivers, so as to be covered with their muddy waters, is

almost certain to rot the sheep; that *gravelly bottomed water-meadows*, like those between Marlborough and Hungerford, never rot the sheep fed on them, in any season or period of the year. This would appear to confirm the very common suspicion that it is not the grass which rots the sheep, but the gaseous or aqueous vapours which emanate from such places, more copiously as the weather becomes warmer in the summer; but, then, against such a conclusion we have the fact, well known to owners of the water meads, that when sheep are soiled even upon fine dry elevated soils (such as never render sheep rotten), with the second crop of grass from water-meads—that then the sheep become as equally rotten as if they had been pastured on the very meadows from whence the grass was carried. It would seem, therefore, that there are more watery matters, or other sources of disease in the second crop than in the first.

That the grass of the second crop varies very materially in its chemical composition from that of the first, has been clearly shown by the analysis of the late Mr. George Sinclair. He found that rye-grass (*Lolium perenne*) at the time of flowering, taken from a water-meadow that had been fed off with sheep till the end of April, afforded of nutritive matter 72 grains. The same grass from the meadow that had not been depastured in the spring, afforded 100 grains. The same weight of this grass, taken from a rich old pasture that had been shut up for hay about the same time, afforded of nutritive matter 95 grains. That from the rich pasture that had not been depastured, afforded 120 grains. (*Hort. Gram. Wob.* p. 384.) And in the great majority of instances, the aftermath of the upland grasses is considerably less rich in nutritive matters than that of their first or spring crop.

Such, then, are the supposed causes, symptoms, and treatment recommended for the cure of this disease. For the cure, both turpentine and common salt seem to have sometimes been successfully used. But the effect of salt seems to be much more decided when employed as a prevention, rather than a cure. As a preventive, too, the use of aromatic vegetable substances seems to be excellent. It is the kind of prevention also which might be supposed to be efficacious from following the order of nature, and observing the habits of the sheep in their wild state, browsing as they invariably do upon the aromatic plants, and the shoots of mountain shrubs; and never descending to live upon the rank and watery grasses of the valleys, until compelled by the severity of the weather. Every farmer is aware with what avidity they consume such domestic herbs—the parsley, for instance—as abound in essential oils. An attempt has indeed been recently made to cultivate this herb in the fields as feed for sheep; and I have little doubt that if some attention were paid to the cultivation of such plants (if the parsley will not bear the browsing of the sheep, they might be occasionally soiled with it), by way of condiment or change; if the flock were allowed, at all times and seasons, access to common salt (and this might be mixed, if necessary, with aromatic substances

grateful to the sheep); and, lastly, if some care were taken in supplying them, when feeding on watery plants, with a little hay, corn, or oil-cake, that then the destruction caused by this melancholy scourge of the flock-master would be either entirely prevented or very materially reduced. See FLUKE.

ROT IN TIMBER. It has been noted, that wood saturated with common salt is never subject to this disease. Mr. Bethel has proposed a plan for its prevention, by saturating the wood with coal-tar. Mr. Ryan uses for the same purpose a solution of corrosive sublimate (muriate of mercury). Sir W. Burnet employs a solution of muriate of lime. See **DRY-ROT.**

ROTATION OF CROPS. The order in which different crops are made to succeed each other. It was only towards the middle of the last century, that the importance of a scientific rotation of crops began even to attract the farmer's attention. Previous to that period we search in vain in the works of agricultural authors for the slightest notice of such a theme. The writers before those days, as Arthur Young noticed, recited courses of husbandry, good, bad, and execrable, exactly in the same tone as matters not open to praise or censure, and unconnected with any principles that could throw any light on the arrangement of the farm, or its more successful cultivation. And yet it is on this difficult part of the farmer's business being scientifically pursued, that much of the profits and advantages which he is to derive from his land for a course of years must depend. Arthur Young, the most popular and the most rapid of observers, saw the importance of this difficult inquiry in its true light: he correctly enough told the farmers of his day, that whenever very good or very bad husbandry is found on arable land, it is more the result of a right or wrong arrangement of crops than of any other circumstance; that no district is well cultivated under bad rotations, while it is extremely rare to find any badly cultivated under such as are good. More accurate and more generally diffused observations have long since, however, led the present race of cultivators to assign to the inquiry its proper value. The importance in fact of the investigation no modern farmer will for a moment doubt. It may not be a useless mode of conducting the research, if we inquire, as we proceed in our proposed examination, into the few yet valuable lights which chemical and entomological investigations have shed upon this important, yet, from the endless variety of soils and situations, somewhat intricate and laborious theme.

In regard to the general principles, as it has been well observed, on which the proper cropping of land depends, it is now perfectly understood, that some kind of crops deteriorate or exhaust the land to a much greater degree than others; that some by their capability of being consumed on the farm (though they do exhaust the soil) return, in such consumption by livestock, as much or perhaps rather more to the soil than they draw from it, during the period of their growth. And again, that other crops, by admitting of profitable tillage and cleansing the land during their growth, aid very much in

the essential destruction of weeds, insects, &c., and in ameliorating the land for the succeeding crop; while, on the other hand, different crops, by not permitting such cultivation, and being great exhausters when following in immediate and rapid succession, not only deteriorate the soil, but fill it with weeds and grubs. Hence it follows in practice, that by suitable arrangements of these different crops in rotation, most kinds of land may, without lying idle, be constantly preserved in a clean and productive condition. In the management of rotations, however, much careful attention and discrimination is requisite in the cultivator, to profitably adapt them to the nature of the soil, and the other circumstances under which he is placed. Above all, the farmer must remember, that as different kinds of plants require different kinds and proportions of nutritious materials to be drawn from the earth for their increase and perfect growth, so also they need different situations and conditions of soil for their most profitable development.

The farmer, too, is well aware that certain crops never prosper well two or more seasons together in the same land; that they in fact commonly exhaust or "tear out" the soil to such an extent, that every lawyer's clerk is aware of and notices it in some restraining covenant of "the lease."

Even the gardener, aided as he is by the most copious supplies of enriching composts, always avoids as much as possible planting a tree where one of the same species has preceded it.

Now it is of primary importance that we should endeavour to understand, if possible, the cause of this phenomenon. This question, therefore, has long engaged not only the attention of the most sagacious farmers, but of many distinguished philosophical philosophers. By these it has been regarded in chiefly two points of view. First, it has been contended, that as each plant has peculiar excretory matters, which it constantly deposits in the soil in which it is placed—matters which are found to be particularly noxious to other plants of its own species—that in consequence, until these are decomposed and removed from the earth by other plants, or by the gradual effects of decomposition, the same crop cannot advantageously prosper in the soil. And in support of this doctrine is adduced the well-known fact, that the excretory matters deposited or diffused through the water in which bulbs or other roots have been cultivated, will not well support other bulbs; yet still that such impure water is found to be more grateful than clear water to vegetables of another species.

And, again, that certain plants and trees are well known to be excellent and mutually fertilizing neighbours,—a knowledge indeed as old as the days of Rome under her emperors; for at those periods the Italian farmers commonly planted the elm as the companion, or "husband," as they called it, of the vine: and every farmer is aware, amongst other facts of a similar nature, that the corn-flower can be found only amongst his corn crops—it is in vain to search for it elsewhere. The gardener also well knows, that it is almost useless to

replant old orchards with the same trees, or to replace old quick-hedges with young quick plants, yet an old orchard or the site of an old hedge-row are proverbial for their fertility, when planted with other crops. There is considerable importance I think to be attached to this mode of accounting for the facts of the case, but it is by no means so complete an explanation as is desirable. There are some soils, for instance, which would seem (if this were the sole cause of the phenomenon) to defy all the excretory powers of the plant. Some of the newly-enclosed lands of the United States of America, for instance, have produced excellent wheat crops for even 20 years without interruption. Some of the alluvial soils of the lower portion of the valley of the Thames have yielded alternate crops of wheat and beans from time immemorial; and by the addition of manure, the potato grounds near London yield abundant crops for a series of years. There are other observations too, of a similar kind, which will readily be remembered by the intelligent farmer, which do not seem to assimilate entirely with this mode of removing the difficulties of the case.

The other way of explaining the reluctance with which a crop follows another of the same description is, by supposing that each kind of plant has some peculiar and essential ingredient which it absorbs from, and in a great degree exhausts the soil, and that it is, therefore, only after a lapse of some time, when that ingredient or those ingredients are restored by the application of manure, or by other modes, that the same plants can be again profitably cultivated. To a great extent this theory is not only a very plausible but a very probable and reasonable explanation of the difficulty. Thus the farmer is well aware that certain soils on which red clover formerly grew very successfully once in 4 years, will now only yield any profitable degree of produce of the same plant once in 8 or once in 12 years. The excretory powers of the plant in this instance, therefore, are useless in explanation of the difficulty; for according to that theory, the excretory matters which long were successfully dissipated or absorbed by other plants in the course of 4 years, should do so in our age just as well as in a former period. But if we admit what has been not only sometimes, but very often clearly proved to be the case, that the soils which are thus reluctant to produce red clover, are now totally exhausted of sulphate of lime (gypsum)—that, moreover, every fair average crop of this valuable grass contains from 100 to 200 pounds weight per acre of this salt—and that by dressing the land with this manure, in almost *exactly the same proportion* and quantity as that which is contained in the clover, that then the land will again grow the very same crop once in 4 years; when these and other similar facts are proved, the very strong probable conclusion to which we must arrive is apparent, viz., that the clover had gradually exhausted the land of an essential ingredient which only needed to be restored to it, to enable the clover again to flourish with its wonted vigour. And this is not a solitary instance: thus, marine plants will only grow successfully

in inland situations, where common salt is added to the soil. The sun-flower and the nettle need in an equal degree the assistance of salt-petre. The presence in the soil of phosphate of lime (the earthy salt of bones) is equally essential to the vigorous growth of almost all the grain crops.

Then, again, there are other facts of a different nature well known to the farmer, which appear to lead us to the same conclusion; for instance, every cultivator is aware that by cutting his crops green, his land is not nearly so much exhausted as when the same crops are allowed to ripen their seeds. And if, in explanation of this observation, it can be shown that the plant, when ripe, contains a larger proportion of any peculiar saline or earthy ingredient than it does when in a growing, unripe state, this will further tend to establish the truth of the last-named theory—that it is the abstraction from the soil by the plant of some peculiar substance, which thus exhausts and disposes it to support the same crop. Now this, according to chemical investigations, seems, at least in many instances, to be the case. Thus, M. Saussure, in his chemical researches, has shown by the results of his analysis, that the ashes of the plants of peas (*Pisum sativum*), when green and in flower, contain only 17·25 per cent. of phosphate of lime, but that, when ripe, they yield 22 per cent. And, again, that the ashes of plants of vetches (*Vicia faba*), which yielded only 13·5 per cent. of the same salt when in flower, contain 17·75 per cent. when they are ripe. The same result was obtained from other plants: the *Solidago vulgaris*, for instance, which yielded 8·5 per cent. of phosphate of lime when first in flower, contained 11 per cent. when ripe. The turnsole (*Helianthus annuus*), which afforded only 6 per cent. when flowering, contained 22·5 per cent. when ripe. The wheat plant, which held 10·75 per cent. in flower, contained 11·75 when ripe. The ashes of the straw of wheat were found to yield only 6·2 per cent. of this essentially present salt, but its seeds held 44·5, and its bran 46·5 per cent. of it. M. Vauquelin obtained a result somewhat similar in his examination of the ashes of the oat plant; the seeds affording him 39·3 per cent. of phosphate of lime, but when he burnt the whole plant, seed and stalk together, he then found only 15 per cent.

The evidence, therefore, in favour of the absorbent theory, is certainly rather stronger than that in support of the excretory mode of explaining the phenomenon. Yet, in all probability, both causes may contribute to produce the effect. Davy, the chief of modern chemists, adopted the former mode of explaining the reluctance with which a crop grows for 2 years successively on the same land. (*Lectures*, p. 357.) Changes of all kind seem, in truth, ever to be grateful to vegetation—change of soil, of seed, of the course of cropping, of manure, &c. “Peas and beans,” said Davy, “in all instances, seem well adapted to prepare the ground for wheat; and in some rich lands, as in the alluvial soil of the Parret, and at the foot of the South Downs, in Sussex, they are raised in alternate crops for years together. Peas and beans contain a small quantity of a

matter analogous to albumen (hard white of egg); but it seems that the nitrogen which forms a constituent part of this matter is derived from the atmosphere. The dry bean leaf, when burnt, yields a smell approaching to that of decomposing animal matter; and in its decay in the soil may furnish principles capable of becoming a part of the gluten in wheat.

“Though the general composition of plants is very analogous, yet the specific difference in the products of many of them, and other well ascertained facts, prove that they must derive different materials from the soil; and though the vegetables, having the smallest systems of leaves, will proportionately most exhaust the soil of common nutritive matter, yet particular vegetables, when their produce is carried off, will require peculiar principles to be supplied to the land in which they grow. Strawberries and potatoes at first produce luxuriantly in virgin mould, recently turned up from pasture, but in a few years they degenerate and require a fresh soil; and the organization of these plants is such as to be constantly producing the migration of their layers. Thus, the strawberry, by its long shoots, is continually endeavouring to occupy a new soil; and the fibrous radicles of the potato produce bulbs at a considerable distance from the parent plant. The most remarkable instance of the powers of the plant to exhaust the soil of certain principles necessary to its growth, is found in certain fungi. Mushrooms are said never to rise in two successive seasons on the same spot; and the production of the phenomena called fairy rings, has been ascribed by Dr. Wollaston to the power of the peculiar fungus which forms it, to exhaust the soil of the nutriment necessary for the growth of the species. The consequence is that the ring annually extends, for no seeds will grow where their parents grew before them, and the interior part of the circle has been exhausted by preceding crops; but where the fungus has died, nourishment is supplied for grass, which usually rises within the circle, coarse, and of a dark-green colour.” “When cattle,” adds Davy, “are fed upon land not benefited by their manure, the effect is always an exhaustion of the soil: this is particularly the case where carrying-horses are kept on estates; they consume the pasture during the night, and drop the greatest part of their manure during their labour in the daytime. The exportation of corn from a country, unless some articles capable of becoming manure are introduced in compensation, must ultimately tend to exhaust the soil. Some of the spots, now desert sands in northern Africa and Asia Minor, were anciently fertile; Sicily was the granary of Italy, and the quantity of corn carried off from it by the Romans is probably a chief cause of its present sterility.”

The same theory is also supported by M. Liebig: in his excellent work on *Organic Chemistry*, p. 158, he remarks, “It is evident that two plants growing beside each other will mutually injure one another, if they withdraw the same food from the soil. Hence, it is not surprising that the *Matricaria chamomilla* and *Spartium scoparium* impede the growth of grain, when it is considered that both yield from 7 to 7.43

per cent. of ashes, which contain six-tenths of carbonate of potash. The dandelion and the *Eriogon acre* blossom and bear fruit at the same time as the wheat; so that, when growing mingled with it, they will partake of the component parts of the soil, and, in proportion to the vigour of their growth, that of the corn must decrease; for what one receives the others are deprived of. Plants will, on the contrary, thrive beside each other, either when the substances necessary for their growth, which they extract from the soil, are of different kinds, or when they themselves are not in the same stages of development at the same time. On a soil, for example, which contains potash, both wheat and tobacco may be reared in succession, because the latter plant does not require phosphates, salts which are invariably present in wheat, but requires only alkalies and food containing nitrogen. According to the analysis of Posselt and Reimann, 1000 parts of the leaves of the tobacco plant contain 16 parts of phosphate of lime, 8.8 parts of silica, and no magnesia; whilst an equal quantity of wheat-straw contains 47.3 parts; and the same quantity of the grain of wheat 99.45 parts of phosphates.”

The late George Sinclair took a similar view of the cause of the exhaustion of soils. “If,” he says, “a plant impoverishes a soil in proportion to the weight of vegetable matter it produces on a given space of ground, the following will be the order in which the under-mentioned plants exhaust the ground, being the proportion they bear to each other with respect to weight of produce:—

Mangel-wurzel	-	-	-	-	-	25
Cabbages	-	-	-	-	-	25
White turnip	-	-	-	-	-	16
Potatoes	-	-	-	-	-	15
Kohl-rabi (bulb-stalked cabbage)	-	-	-	-	-	14
Swedish turnip	-	-	-	-	-	13
Carrots	-	-	-	-	-	11

But when we take the weight of nutritive matter which a plant affords from a given space of ground, the results are very different, and will be found to agree with the daily experience in the garden and the farm.

The following figures represent the proportion in which they stand to each other with respect to the weight of nutritive matter per acre, and in exhausting the land:—

Potatoes	-	-	-	-	-	63
Cabbages	-	-	-	-	-	42
Mangel-wurzel	-	-	-	-	-	28
Carrots	-	-	-	-	-	24
Kohl-rabi	-	-	-	-	-	17
Swedish turnip	-	-	-	-	-	16
Common turnip	-	-	-	-	-	14

Change of crops also prevents very materially the increase of the predatory grub and insects which also more or less prey upon the farmer's crops. The parent of the English wire-worm, for instance, which is the larva of a small beetle, the *Elatér segetis*, may be seen in the summer months depositing its eggs on lawns or meadows abounding with the cerea. grasses; for instinct teaches it to place its eggs where the young wire-worm will meet with its natural food, which are the cereal grasses. Change of crops, therefore, not only checks the deposit of the eggs, but, by removing the natural food of the young vermin, it materially pre-

vents increase, or even their continuance; which otherwise, as is the case, for instance, with the wire-worm, might for 4 or 5 years be a pest to the soil. See BEETLE.

The ordinary course or rotation of crops under which the light lands of England are commonly cultivated, is either on what is denominated the four-course or shift system, or the five-course or shift.

The four-shift system commonly consists of fallow, manured; 1, turnips, fed off; 2, oats or barley; 3, grass seed; 4, wheat.

The five-shift system, which is in many situations a much more advantageous course of husbandry, is commonly fallow: 1, turnips; 2, oats, or barley; 3, clover; 4, peas; 5, wheat.

On clays the course varies: on some kinds of heavy clays it is usually fallow, with manure; wheat; beans; wheat, manured; clover; oats, or wheat.

On other clays the system pursued is fallow, with manure; wheat, or oats; clover; beans; wheat.

The variations, however, are of necessity exceedingly various. Thus, on some of the inferior adhesive clays of the midland counties, they adopt the four-course system.

Another system of moderately heavy soil husbandry is:—

	Acres.
1. Turnips - - - - -	20
Fallow - - - - -	20
2. Barley - - - - -	20
Oats - - - - -	20
3. Seeds - - - - -	20
Tares fed off - - - - -	20
4. Wheat - - - - -	40

There are endless variations, however, of this system, varying in their course from that practised in some of the heavy, rich Essex soils, of a two-shift system; viz., 1, wheat; 2, beans; 3, wheat; with an occasional fallow. And that more extensively used in the hundreds of that great agricultural county, of a five-shift system of fallow: 1, oats; 2, clover, dunged; 3, wheat; 4, beans; 5, wheat. To the nine-shift system of husbandry, sometimes practised, which is about the longest course with which I am acquainted, viz.:

- 20 acres fallow, or turnips manured.
- 20 acres oats or barley.
- 20 acres clover.
- 20 acres wheat, well hoed.
- 20 acres winter tares, sheep-fed.
- 20 acres wheat, hoed.
- 20 acres seeds, sheep-fed.
- 20 acres, 15 of beans and 5 of peas, dunged.
- 20 acres wheat, hoed.

The following course, which takes in every valuable crop, without in any instance violating the rules that science directs, seems to me the best, and is recommended by a Norfolk farmer for most clays not too wet. Say for a farm of 350 acres—100 acres of green crops, such as cabbages, turnips, rape, and tares, adapting the green crops to the nature of the land; 50 acres of peas or beans; 50 acres of barley or oats, laid down with clover; and 100 acres of wheat.

You will by this course have every year 200 acres of wheat and other corn, 50 of clover, and 100 of green crops, thus saving your land

from exhaustion by too frequent repetition of crops of the same genus. And white crops will in no instance succeed each other. The wheat stubbles are in this way sown with green crops, to be followed by 50 of barley and 50 of beans or peas; the barley sown with clover and followed by wheat, which will thus be 50 acres on clover, and 50 on the bean or pea stubble, taking care that the 50 acres of green crops, followed by beans or peas, when next coming in course for green crops, shall be sown with barley and clover, as by this means the clover comes only once in 7 years.

In whatever point of view, therefore, the farmer examines the rotation of crops best adapted to his land, the more highly interesting does the investigation appear. Long observation and the practice of ages have convinced the best English cultivators that sooner or later the soil is tired of or exhausted of something essential to its luxuriant produce by a repetition of the same crops; that the richest meadows gradually decrease in their produce; other soils become "clover-sick;" and it is now even pretty generally suspected that the land is in many districts gradually getting tired of turnips. To the examination, therefore, of this great question, let every farmer contribute his mite of practical observations: it is a theme whose investigation has long yielded a rich harvest to English agriculture; for amongst its fruits must be numbered the introduction of turnips, of mangel-wurzel, and other green crops; its examination led to the adoption of the four-shift system, and the banishment of that which for ages rested on the miserable plan of one crop and a fallow. It is idle, therefore, to contend that nothing more is to be effected by change of crops; for the experience of all periods is against so indolent and so erroneous an assumption. Let the farmer only remember what has been accomplished by the mere introduction of the turnip plant; what thousands of acres have been brought into cultivation by its means, and how many mouths are fed by the increased fertility of the land produced by the adoption of that four-shift system of rotation of which it is the first crop. Let him bring to mind what superior crops are now produced by the adoption of new seeds and novel courses, to those which a century since tenanted the lands of merry England; and he will then see abundant reason for hope, and for an energetic perseverance in a course of discovery, which has already rendered such an abundant harvest to the excellent cultivators of our soil. See M. Bonsingault on the "Rotation of Crops," *Quar. Jour. Agr.* vol. x. p. 251; *Liebig's Organ. Chem. of Agr., &c.*

To prevent the depreciation of soil and improve its productive capacity, a proper rotation of crops is indispensable. The same general principles upon which these objects may be most judiciously accomplished will apply to all countries, but the manner of carrying out these principles must vary with localities and peculiarities of climate and soil.

It was once thought that, after culture, it was necessary to allow the land to remain for one or more years at rest and idle, or fallow and

unused, in order that the soil might thus have its strength renovated. It has, however, been found that with judicious management land need never be suffered to lie idle, but cultivated every year in one or more crops with profit, and even with improvement of the soil. In other words, the system carried out on a small scale in gardens may be extended to farms. A large portion of Europe is at present cultivated without naked fallows, which are unknown in the vast productive agricultural operations of China.

In the United States, the rotations of crops vary considerably in different sections. In Massachusetts, one of the oldest settled portions of the Union, and the usages of which may perhaps represent those prevailing throughout the New England States, it would appear from Mr. Colman, that little of what may be called systematic husbandry prevails, the succession of crops being dictated rather by accident or convenience than by any well-considered principles. The following details from his 4th *Report on Agriculture*, will show how things are managed in different parts of Massachusetts.

The rotation of crops in Franklin county is very limited, as the crops cultivated are few. In Buckland, the first year the land is broken up, corn is planted and manured: the second year, oats are sowed without manure, and the land laid down to grass. It is continued in grass five years and then broken up, and the same course repeated. The first year of grass the produce is about two tons per acre, and when it yields not more than 1500 lbs. it is considered proper to break it up again. In Shelburne, on one of the best farms in the state, the course is, first year, Indian corn on green sward, manured; second year, spring wheat, and laid down to grass; the grass-seed sown with the wheat; one peck of herd's grass and one of red-top to the acre. The land remains in grass ordinarily five years. The average yield of grass is estimated at three tons to the acre,—which I think must be an over-estimate,—and the cost of getting the hay at \$2 per ton. For spring wheat, in the second year of the course, is sometimes substituted rye, or oats, or oats and peas, or oats and wheat.

In Whately, first year, Indian corn; second year, oats, and laid down with herd's grass (timothy) and clover, and remains in grass three years.

On much of the meadow land in Deerfield, the first year the land is in corn; the succeeding year peas and oats, and so on continually. The corn is manured in the hill. The land, after the corn is gathered, is sometimes sown with winter rye.

In some parts of Deerfield, the usual rotation is, first year, corn, usually manured in the hill; the second year, spring wheat, or wheat and oats, or peas and oats, or rye with southern clover; third year, clover; and then plough again.

The best farmers universally advise to sow the southern or June clover with grain, to be ploughed in with the stubble where the land is not to remain in grass, with a view to enrich the land. If the grain is winter grain, the

clover is usually sown in the spring before the snow has left the ground, at the rate of a bushel of clover chaff or clover-seed not cleaned, or else at the rate of 6 or 7 lbs. of cleaned seed. One of the most experienced farmers in the town has been accustomed to sow rye and clover together on the same land for a succession of years; in which case the clover and stubble were always ploughed in together for the purpose of enriching the land for the succeeding crop, and in this process he states that the condition of the land was continually growing better. The crops, however, at best were not large.

I think proper here to mention the statement of another farmer, a man of much intelligence and experience, in confirmation of the experience of two other farmers referred to in a former report, that it is much better that the clover should be withered or dead when it is ploughed in, rather than in a green or succulent state.

In some instances, as in Sunderland, for example, broom-corn is repeated several years in succession on the same land, and, as it is stated, without a diminution of product. In these cases, the crop is manured in the hill every year; and the corn-stalks, after the brush is gathered, are burnt upon the land.

In the oldest cultivated sections of Pennsylvania, the rotations seem to have been conducted with much good judgment, as is evinced by very successful results generally obtained. These, as well as the system highly approved by many of the most judicious farmers, are set forth in the following communication in the *Farmers' Cabinet* (vol. v. p. 94).

The example to which I refer, says the correspondent, is that of an old, practical, hard-working farmer, who commenced in the world as a day-labourer, and who is now worth at least \$100,000, not taking in the account many heavy pecuniary losses he has, at various times, sustained. This man, when 30 years of age, by the avails of his industry, added to a small legacy, was enabled to purchase and pay, in part, for a farm of 130 acres of land, 100 of which was under cultivation, but in a very low state. This farm is altogether upland, with a soil composed of lime, clay, and sand, in the chief of which the latter preponderates, the former being least considerable. When he commenced farming, he adopted a particular system of rotation, to which he has implicitly adhered from that time to the present, which is 40 years, and his success is the best comment on the worth of his experiment. His mode was as follows: having divided his farm into eight fields of equal size, as nearly as possible, three of these fields are sown with wheat each year, one with rye, one planted with corn, two in clover, and one an open fallow, on which corn had been raised the year previous. One of the two clover-fields is kept for mowing, the other for pasture, both of which are ploughed as soon after harvest as possible, and prepared for wheat in the fall. All the manure which is made on the farm for one year is hauled, in the spring, on the field intended for open fallow, which is then ploughed, and after one or two

cross-ploughings through the summer, is also sown with wheat in the fall. The field on which rye is sown, is that from which a crop of wheat had been taken the same year, and which had yielded three crops of wheat, alternating with crops of rye. Corn is planted on the field from which rye had been gathered the year previous, the stubbles of which are ploughed down in the fall. Clover-seed is sown early in the spring on two of the wheat fields, those which have been most recently manured. By this method, each field yields three crops of wheat, two of clover, one of rye, and one of corn, every eight years. Each field, in the mean time, has lain an open fallow, and received a heavy dressing of

manure, perhaps at an average of 15 four-horse loads per acre. His crop of wheat is seldom less than 1500 bushels, but often much more. His average rye-crop is about 450 bushels, and his corn crop, annually, about 500 bushels—all which grain, at the present low prices, would amount to more than \$2000 annually, and at former prices to double that amount; and his farm is withal very highly improved.

This system corresponds very nearly with that of which a tabular statement is presented in the same volume, by Mr. W. P. Kintzer, of Pequea, Lancaster county, Pennsylvania, as successfully practised by himself. It is as follows:—

	Field No. 1.	Field No. 2.	Field No. 3.	Field No. 4.	Field No. 5.	Field No. 6.	Field No. 7.	Field No. 8.
1st Year - - -	Wheat	Rye	Wheat	Clover	Corn	Wheat	Clover	Oats
2d " - - -	Rye	Clover	Corn	Wheat	Oats	Clover	Wheat	Wheat
3d " - - -	Clover	Wheat	Oats	Rye	Wheat	Wheat	Corn	Clover
4th " - - -	Wheat	Corn	Wheat	Clover	Clover	Rye	Oats	Wheat
5th " - - -	Corn	Oats	Clover	Wheat	Wheat	Clover	Wheat	Rye
6th " - - -	Oats	Wheat	Wheat	Corn	Rye	Wheat	Clover	Clover
7th " - - -	Wheat	Clover	Rye	Oats	Clover	Corn	Wheat	Wheat
8th " - - -	Clover	Wheat	Clover	Wheat	Wheat	Oats	Rye	Corn

In the county of Montgomery, where agriculture is in a very flourishing state,—the crops consisting of the ordinary grains and hay-grasses,—a *five-shift* rotation, from the division of the farm into five fields, is very much pursued. Commencing with Indian corn, the sod, which has been top-dressed with lime the previous season, is ploughed in the fall or spring. The corn is followed by oats, which being harvested, the stubble is turned under, manure spread upon the ground and wheat sown, with timothy-seed in the fall and red clover in the spring. The wheat has thus the important advantage of immediately succeeding two *cleansing crops*, and the ground, after harvesting the wheat, is left in fine condition for the hay grasses. The first year after the wheat is harvested, the grass is mown, the second year pastured, after which the sod is again turned under for corn, and the rotation recommences.

What is known in Pennsylvania as the Old York and Lancaster system, corresponds with the one last described, so far as the succession of grain crops and sowing of the grass-seeds are concerned, but differs in allowing the hay-grasses to occupy the field five years. The first two years are most productive in red clover, which, being a biennial and the root dying out, leaves the ground in possession of the timothy and other perennial grasses.

The following interesting view of the former and present Virginia modes of conducting rotations, and the improvements introduced and suggested, is from the able editor of the *Farmers' Register* (vol. vii.).

The first and most humble attempt at a rotation in this country, and the one which formerly was general on the greater part of most farms, and is even now in extensive use, is the *two-shift*; which, however, short as it is, had various grades of bad quality. This usually followed the *continual* cultivation of the land, in its newer condition, in tobacco, while rich enough for the crop, and afterwards in corn, every year.

The two-shift was most usually this:

1st year, corn—

2d, { wheat—or oats, if on land too light or too poor for wheat—
after harvest, grazed closely until next spring, when ploughed for corn again.

When too poor to bear any small grain crops, that part of the course was omitted on such poorer spots of the field, and afterwards on all; thus changing the rotation to

1st year, corn—

2d " natural cover of weeds, grazed.

When not grazed the second year, as was sometimes the case, for want of separate fencing, or some other cause, this rotation made a nearer approach to alternate and improving husbandry. It was then—

1st year, corn—

2d " weeds not grazed, and which (if not burnt off, as was done most usually) formed a very poor *manuring* crop.

The celebrated Eastern Shore rotation is of two shifts or fields, but of three crops in the two years. This is—

1st year, corn—

2d, { first crop, oats—
secondary crop, Magothy bay bean—a spontaneous and close cover immediately succeeding the oats, and which remains mostly or entirely untouched by the grazing stock, and is ploughed under for the next crop of corn. The interposition, by nature, and not by the design or industry of the cultivators, of this leguminous and manuring crop, is a most valuable feature in a rotation which otherwise would be altogether exhausting and destructive. The moisture of the air, no less than the sandiness of the soil, and the cleanness from other plants, give vigour to this bean, and make one-third of the whole course meliorating, to two-thirds of exhausting crops. The same moisture also nourishes the oats, and prevents that crop exhausting so much, as in dryer regions—and also by its greater bulk of straw, furnishing more materials for manure. These circumstances render this rotation, severe and barbarous as it is, less exhaust-

ing (or more improving, if much attention is paid to manuring) than the ordinary three-shift rotation. Except in the chance-made addition of the spontaneous bean crop, this rotation offends against every principle and rule which ought to govern.

The *three-shift* rotation was the next step in the supposed march of agricultural improvement, and even yet is that which many remaining two-shift or no-shift cultivators aspire to reach, as the limit of their farming and improving ambition, and their *ne plus ultra* of mild cultivation. This was

- 1st year, corn—
- 2d “ wheat, and afterwards the spontaneous grass and weeds grazed—
- 3d “ pasture, closely grazed.

The severity of the second year was generally moderated on the poorer parts, by the wheat being there necessarily omitted, which of course gave to those parts two years rest from tillage, in three; and, while the wheat was growing, a cessation from grazing also. With very few exceptions, such was the general system of the best cultivated farms in lower Virginia, when Taylor wrote; and it is on this kind of three-shift rotation that his denunciations were so deservedly cast. This rotation violates every sound principle and rule, and certainly deserved to be treated without mercy; but many have continued to denounce the three-shift rotation, even when rendered comparatively mild, as if the evil was in the *number three*, and not in circumstances more important than the mere number of shifts.

But, taken in the aspect above described, and which was the best then that was exhibited, the three-shift rotation had no merit whatever. It had no other than fibrous-rooted plants; no other than narrow-leaved crops; no root, leguminous, or even grass crop; for the close grazing merely served to prevent the scanty weeds and grass from growing; and while every year's crop was exhausting, the system furnished but small resources and materials for manure. For the grazing animals were as many as the land could keep alive, and scarcely any were fattened (by grazing alone) for home consumption or market; and their support served to diminish, instead of adding to, the fattening or manuring of the land. At that time it would have been difficult for a reading farmer to *comprehend* this undoubtedly sound maxim of English writers, “the more cattle kept, the more grain and other crops produced.” But the English farmer *keeps* no animal except for the profit it will yield; and all that are so kept, give their rich and abundant products of manure, as an additional profit to the soil. But when a stock of cattle, sheep, and hogs, can barely make out to keep alive through the year, and never fatten, except by stall and grain feeding, then keeping them certainly yields no clear profit to their owner, and their close grazing of the fields takes away more of fertilizing materials than their dung can possibly replace. An English or French farmer would be no less at a loss to comprehend the object (or even to believe in such a general practice) of keeping a large stock of animals which no net profit was obtained, or even

hoped for; and he would justly think that it would not be more absurd for a farmer to tend a crop of grain, and then leave it to rot on the field, than to give all his grass through summer to animals, and then lose the flesh so acquired, by starvation through the winter. Indeed, the general cattle management of this country would scarcely be believed in any good grazing or farming region. On the farms under the usual three-shift rotation, say of 400 acres of arable land, there would be from 40 to 60 head of grazing cattle, which furnished annually to the owner, at most, about as much milk and butter as two well-kept cows might supply, one or two passable beeves, with the aid of grain feeding, a few poor calves for veal, and a pretty large supply of *hides* from deaths by starvation in the spring. There were hogs enough to furnish the year's supply of bacon; but only by means of grain feeding, which alone was admitted to cost nearly or quite as much as the market price of the meat. A flock of poor sheep were on some farms also, of which, before shearing-time, half the wool of many was hanging on the briers, and the remaining fleeces filled with burs. This sort of grazing system accompanied the old three-shift rotation; and, inveterate as were old habits, and patient as we are of long-borne grievances, this evil was so great, that none could deny but that the mere expense of the dividing fences, necessary to keep the cattle from the fields of grain, cost more than all the returns from the grazing animals.

The *four-shift* rotation, recommended and practised by Col. Taylor, was—

- 1st year, corn—
- 2d “ wheat, and clover sown—or if too poor for wheat, left at rest, and not grazed—
- 3d “ clover (or weeds), not mown or grazed—
- 4th “ clover, not mown or grazed.

This rotation, as before stated, was the first introduction of manuring fields by their own vegetable cover, and this practice, and the admission of the opinions on which the new practice was founded, was a prodigious step towards agricultural improvement. It is true that even this rotation is opposed to the rules of good husbandry in most respects. But the giving of two and a half years out of four for vegetables to grow, that were to die and decay on, and be finally ploughed into the land, was a feature that compensated for every fault, and made the rotation decidedly meliorating, if on land capable of being enriched by the mere application of vegetable matters.

In the first of these numbers, it was stated incidentally to other matters why this rotation became of less benefit and more objectionable, in proportion to the time, and to the effect with which it operated; and if it improved the productive power of any land, that it also greatly increased the labours of tillage, and the destruction of products, by increasing weeds and noxious insects. In consequence of this objection, very few disciples of the great introducer of and advocate for this rotation, have continued long to pursue it strictly.

The *four-shift* and *clover fallow* rotation differs

widely from that of Col. Taylor. This has been, and I believe still is pursued with great success by Hill Carter, of Shirley, John A. Selden, of Westover, and has been on some other of the best lands on James River, where it has since, in other hands, been either neglected or abandoned, for some modification of the three-shift rotation. This four-shift system is

1st year, corn—

2d “ wheat, and clover sown, and not grazed—

3d “ clover, not grazed, and ploughed in deeply in August and September, and the field sown in wheat—

4th “ wheat, to be followed by corn, in recommencing the rotation next year.

A sufficient standing pasture was kept on other land. Mr. Carter, for a considerable length of time, substituted oats for corn in the first year.

The farmers above named (whose accounts of their systems and their products were reported at length in vol. i., *Far. Reg.*), and others also, undoubtedly made great crops, and great improvement of land, under this very severe rotation. But those results were due more to the excellence of their general management than to their rotation. None but admirable executive farmers can possibly overcome the great difficulties which accompany this rotation. He who, in our dry climate, on a stiff or even medium soil, can plough every August and September one-fourth of all his arable surface, to the depth of 8 or 10 inches, and turn in and cover effectually a heavy coat of clover—and this without failing in any year—shows thereby alone his ability to execute the most arduous undertakings, and to *do well* every thing which he may make a part of his general plan of operations. This rotation, in such hands as have directed it, has some admirable features; but it must be executed in the most perfect manner, or these best features are lost, and there will remain only the great evil of three fibrous-rooted, narrow-leaved, and exhausting grain crops, in succession.

The great merit of the four-shift rotation, in general, and considering it as embracing both of these very different varieties, is its easy adaptation to more mild or more severe cultivation, without any different arrangement or number of fields. Thus, Taylor's rotation may be rendered still milder (as is needed on the poorest lands) by omitting the wheat crop; and as the land improves, the richer spots may be thrown under the more severe cultivation of the other four-shift system, as practised by Mr. Carter or Mr. Selden. But, in any form, the rotation still remains objectionable, for the succession of grain crops (if there are even two in the course), as well as for other things, in one or the other variety, which have been already stated.

Every rotation yet known in Virginia is more or less objectionable, upon one or more of the following grounds:

The adoption of certain usual crops, without regard to the various qualities and the wants of the soils, or even to the demand of the market. Thus every farmer is sure to make

corn and wheat (or oats) his principal, if not his only crops. Thus, the fields are deprived universally of the most improving culture of roots, which dip into and draw from the soil deeply; and of pea crops, which feed on the air, and give the product to the soil as manure; and of all annual green manure crops, which would cleanse the soil by their getting in, their growth, and ploughing under, as well as manure it; and the store cattle and hogs suffer for the want of roots and other succulent food, and those which are necessarily well fed consume grain almost exclusively. Besides these and other objections, which any good practical farmer, or sound theorist, would make, I would further object to the great defect of the preparatory crop not serving to destroy the weeds which will obstruct, and the insects which will prey on the succeeding crop. Two great exceptions to this last general fault are presented when wheat follows clover, or tobacco, both of which are plants of the broad-leaved kind, unlike in all respects to the succeeding crop, and of such unlike conditions also, that it may be presumed that the growth of either has served well to destroy many of both the weeds and insect depredators, which are injurious to wheat. Accordingly, these two crops are the best forerunners of wheat; which after them always is an excellent crop for the land and the season.

Every well-informed farmer will agree to the importance of there being more meliorating crops introduced in our rotations—more grass, peas, roots, and broad-leaved vine crops. But the objection always is to making crops for which there is no sale or market demand. But suppose there is no direct sale and money profit made from hay or roots, they will yield as much profit by being used to feed and fatten (*not merely to keep alive*) the necessary farm-stock, and thus allow to be sold the corn and other grain which would be otherwise consumed by the animals, with less relish and less benefit.

While roots are totally wanting in our rotations, one important office is left unfilled, that is, the deep piercing of the soil and thorough opening of it by tap-rooted and tuberous-rooted plants. Another thing wanting, is the ploughing under of pea or other annual green crops, to cleanse, as well as to manure the soil. These properly introduced, and the grain crops separated by green crops, would produce rotations far more improving to the land than any yet known, and probably as much better for early annual income as for improvement of the land, the farmer's best capital.

ROWAN TREE (*Pyrus aucuparia*). The quicken tree, or mountain ash, as it is sometimes called, is a handsome tree, of slow growth, with a tough, cross-grained, not very hard wood, indigenous to our mountains, woods, and hedges. The leaves are pinnate scarcely a span long, composed of leaflets, uni form, serrated, smooth. The fruit is globose, scarlet, very juicy, sour, and bitter. They are eagerly devoured by birds of the thrush kind. The fruit, also, when the bitter is extracted by soaking it in water, may be made into a preserve.

RUBBING-POST. A stone pillar or post set up in a field for cattle, hogs, or other animals

to rub against, and for the protection of the gates, trees, and fences themselves.

RUDDLE or **RADDLE**. A kind of red earthy ochre, or ironstone, very easily reduced to powder, which is found in several parts of England, especially in Derbyshire; and is used in marking sheep.

RUE (*Ruta graveolens*). Rue thrives best in a poor brick earth, in which a portion of calcareous rubbish has been mixed. It will not endure the application of dung or a rich soil, for although this causes a luxuriant growth in summer, death is as certainly produced by severe frosts. It is propagated by slips and cuttings as well as from seeds; the first two modes being usually practised as being the most easy. It may be planted or sown any time during the spring.

RUNCINATE. A botanical term, applied to the lobes of leaves: a leaf is said to be runcinate when it is irregularly lobed, the lobes gradually diminishing to the base, and hooked backwards. The leaf of the dandelion (*Taraxacum*) is a good example of the runcinate leaf.

RUNT. A name given to a small kind of black cattle brought from Wales and Scotland. See **CATTLE**. It is also a term applied to the weak and stunted pigs of a litter; also several species of pigeons; as the Leghorn, Spanish, and Friesland runt.

RUSH (*Juncus*; Linnæus derived the name from *jungo*, to join; in allusion to the first ropes being made from rushes). This is an extensive genus of coarse plants, many of them aquatics, which are common on most wet lands. Rushes always intimate a deep, rich soil, and thrive best in land which is too cold and wet for other plants. The growth of these plants may be easily prevented by under or surface draining, which will prevent the stagnation of water on the soil; and by the application of saline or calcareous top-dressings, such as sand, lime ashes, and road-scrappings. All the species of rush do best cultivated in a moist situation, some of them entirely in water, and others in a peat soil; they may be increased by seeds, or dividing the roots. In Japan they cultivate the soft rush (*J. effusus*) for making floor-mats.

Sir J. E. Smith, in his *English Flora*, enumerates 23 indigenous species of rush. (Paxton's *Bot. Dict.*; Smith's *Eng. Flor.*)

Of the *scirpus* genus of plants, which includes the rushes, about 40 species have been found by botanists in the United States. Among these are the club-rush, or marsh *scirpus*; the bull-rush, which is also called tall club-rush or lake *scirpus*, which grows so luxuriantly along the shores of the Delaware; and the brown cotton-grass, or wool-bearing *scirpus*.

The species of club-rush commonly met with in the United States are the *Scirpus palustris*, *S. obtusis*, *S. tenuis*, which, with the common bull-rush, *S. Lacustris*, are all worthless occupants of low, wet grounds. (*Flora Cestrica.*)

RUST. See **MILDEW**.

RUTA BAGA. See **TURNIPS**.

RYE (*Secale cereale*; Germ. *roggen dut rog*). This species of grain is much more hardy, but incalculably less valuable in every respect than

wheat. It has been cultivated from time immemorial, and is supposed to be a native of the Caspian Caucasian desert. In England it is very little used as an article of food compared with wheat and oats, though in the north of Europe, and in Flanders, it forms a principal article of human subsistence, but generally mixed with wheat, and sometimes also with barley. The grains consist of 65.6 of meal, 24.2 of husk, and 10.2 of water. The preparation and culture of rye are essentially the same as for wheat; but the same quality of soil is not equally suited to each. Rye grows most luxuriantly for feeding when sown on hazel mould, but any poor, dry, sandy soil is fit for its production. It is sown either broadcast or in drills, in the autumn or spring; but the spring variety is that most hardy and most generally cultivated. The proportion of seed is about two or three bushels per acre when required for a crop, and three bushels and a half when it is intended to be fed off. The meal of rye is considered second only to wheat; it is often used alone or mixed with a proportion of wheat flour to make bread and gingerbread. In those unaccustomed to its use, it is apt to cause an acescent state of stomach and diarrhœa. Rye is liable to a disease called ergot, which depends on a fungus, which attacks and alters the character of the grain. It becomes long, of a deep violet hue externally, and pinkish-white within. The odour of the ergotted grain is fishy and fetid, the taste slightly acrid. Ergotted or spurred rye is poisonous, when it is baked into bread. It causes febrile symptoms, great debility, often paralysis, tremors, abscesses, gangrene, and death. Some of the epidemics which have occasionally nearly depopulated the north of Europe, have been traced to the use of the spurred rye. As green food for sheep, rye is not only valuable for its early produce, but as producing a flow of milk in the ewes. The straw is highly esteemed for Dunstable work, for thatching and litter; and is also used to stuff horse-collars. See **ERGOT**.

RYE-GRASS or **RAY-GRASS** (*Lolium perenne*), pl. 5, a. There has been much difference of opinion respecting the merits and comparative value of rye-grass. It produces an abundance of seed, which is easily collected and readily vegetates on most kinds of soil under circumstances of different management; it soon arrives at perfection, and produces in its first year of growth a good supply of early herbage, which is much liked by cattle. These merits have no doubt upheld it till the present day in practice, and will probably for some time to come continue it a favourite grass with many farmers. But the latter-math of rye-grass is very inconsiderable, and the plant impoverishes the soil in a high degree, if the culms, which are invariably left untouched by cattle, are not cut before the seed advances towards perfection. The spike of the *Lolium perenne* is awnless; calyx shorter than the spikelets; floret lanceolate. The varieties of this species are very numerous, such as the slender rye-grass (var. *tenuis*); compound or broad-spiked rye-grass (var. *compositum*); Pacey's rye-grass (var. *ramosum*); Russell's grass

(*Russellianum*); Whitworth's grass (*Whitworthiensis*); Stickney's grass (*Stickneiensis*): panicle rye-grass (*paniculatum*); double-flowered rye-grass (*monstrosum*); viviparous rye-grass (*viviparum*): all the varieties have a strong tendency to vary their form when sown on different soils. The annual species are common only to land under cultivation, under the alternate husbandry.

Rye-grass appears to have been cultivated previous to the year 1677 (*Woldridge's Husb.* 1st ed.), besides which, red clover, spurrey, trefoil, and nonsuch were the only plants then cultivated as grasses, or termed such; and it is only of late years that any other species of the natural grasses has been tried as a substitute for it in forming artificial pastures. One peck of rye-grass, with fourteen pounds of clover, per acre, is generally considered sufficient for sowing artificial pastures. Rye-grass, when not more than three years old, flowers in the second week of June, and ripens the seed in about 25 days after: as the plants become older they flower much later, sometimes so late as the beginning of August. See GRASSES.

A variety called the Italian rye-grass was some time since brought prominently into notice, and is well spoken of. One species of rye-grass, the bearded darnel (*Lolium temulentum*) is poisonous. Pl. 7, c. It is an annual, and flowers in July. The root is downy and fibrous; the culm leafy, smooth, about two feet high, with leaves of a bright-green, rough in the under disk. The spike is a span long, and roughish. The calyx of the flowers linear, flattish, many-ribbed, rising above the spikelets. The florets are six, with the outer valve of the corolla elliptical, concave, with a dorsal awn. The seeds are elliptical, flattened, and furnished with a furrow along its upper side. See DARNEL.

S.

SACCHARINE. A term applied to such substances as contain sugar. The plants in which this substance is abundant are in general highly nutritious and useful in the fattening of animals. See MOLASSES and SUGAR.

SACKS. The term sack, in the sense of a bag, is found in all the European and many Asiatic languages.

SAFFRON (*Crocus sativus*). The stigmata of this purple crocus are of a deep orange colour, and when in quantity have a peculiar and very characteristic odour; they are used in medicine, chiefly as a rich yellow or orange-colouring matter. Saffron is now chiefly imported from the south of Europe, especially Spain; it was formerly much cultivated in England in the vicinity of Saffron Walden, in Cambridgeshire.

Saffron is often largely adulterated with the petals of other plants, especially with those of the marigold. The English saffron is superior to that brought from Spain. It should never be compressed into cakes, but the stigmata left in a dry, shrivelled state, or, as it is termed, hay saffron. Where the stigmata are pale, the saf-

fron is bad. Saffron, as a medicine, is of little value. See CARTHAMUS and CROCUS.

SAFFRON, THE MEADOW. See COLCHICUM.

SAGE, GARDEN (*Salvia officinalis*; from *salveo*, to be safe, on account of the sanative properties with which it was supposed to be fraught). Sage is now used principally in culinary preparations. There are several varieties, as, 1. The common green. 2. Wormwood. 3. Green, with variegated leaves. 4. Red, with variegated leaves. 5. Painted, or parti-coloured. 6. Spanish, or lavender-leaved. 7. Red. A dry, moderately fertile soil, is best suited to their growth, in a rather sheltered situation. If the soil is rich, or super-abounding in moisture, they grow luxuriantly, but are apt to perish in winter. Sage is propagated by cuttings of the young shoots from the sides of the branches, sometimes also by rooted offsets, and likewise by seed. See CLARY.

SAGE, THE WOOD. See GERMANDER.

SAGO (Malay and Jav. *sagu*). A species of fecula or starch obtained from the cellular substance of a palm tree—the *Sagus farinifera*, Gærtn; *Sagus Rumphii*, Wild. In the early writers it is called *sagu*, *suga*, and *zaga*. In Java the word signifies bread. The sago which is procured from the above palm, and six other species of the same family, is the pith of the trunk. When the tree is of sufficient age it is cut down, split, and the pith extracted and reduced to powder, which is mixed with water and strained through a sieve. The sago is deposited from the fluid, and after two or three washings it is fit for use, and is called in this state, when dried, *sago-meal*. For the European market it is made into a paste and granulated, and is known in the trade under the name of pearl sago. The consumption of sago has undergone an almost incredible increase within the last twenty years, which is wholly ascribable to the reduction in the interval of the oppressive duties by which the article was formerly loaded. Sago has latterly been brought prominently into notice as food for domestic animals usually reared upon the farm, particularly horses and calves. Experience having decided in favour of its wholesomeness and economy, it will no doubt very soon become a general and staple article of food on all farms that rear young stock. From its emollient and nutritive properties, it appears to be admirably adapted for calves while on milk; for cows sometimes before and after calving; for young horses in winter, instead of much dry corn, or none at all, as is too frequently practised; and for young pet lambs, whose mothers have either died or forsaken them, in which events a serious encroachment is apt to be made on the milk intended for the calves. Sago seems peculiarly well adapted for horses for fast work, and for sporting dogs, since it is found to leave the wind unaffected; and with regard to fowls, the whole class of them might be rendered by it much more white in flesh and delicate for the table, than the food usually allowed them on farms.

Sago is most commonly used in a gelatinous state, and it is easily reduced to that state by boiling water.

As a drink for horses, after a severe run or burst in the field, sago gruel, consisting of about a pound of the mucilage or jelly, completely dissolved in two or three gallons of warm water, is found to be superior to any other kind of drink. For cows, the jelly should also be given in the shape of drink. Sago jelly mixed with new milk forms an excellent food for calves. Dogs should have the jelly poured over biscuit, bread, or potatoes. To pigs sago should be administered in the shape of drink, from 2 to 3 pounds being given to each pig once a day; and the jelly for fowls should be in warm balls, mixed up with barley meal.

Sago has been sometimes used as an ingredient of household bread, in the proportion of 1 part of sago to 3 of wheaten flour. It forms an excellent pudding for the convalescents from acute diseases. It is only moderately nutritious, consisting chiefly of starch; yet it is the bread, and may be termed the staff of life of natives of the Molucca islands.

SAINFOIN or **SAINTFOIN** (*Hedysarum onobrychis*). The Bourgogne or Esparette of the French. Pl. 8, g. Having been first introduced to the farmer from France, this plant brought its French name of saint-foin along with it; and cock's-head, by which it was before known as a native of England, is become obsolete. The stems of sainfoin are recumbent, 2 or 3 feet in length; leaves pinnate, nearly smooth; flower-stalks axillary, ascending, longer than the leaves, each bearing a dense tapering spike of handsome variegated crimson flowers. The fruit is a legume, erect, single-seeded, toothed at the margin and ribs. Sainfoin is a well-known object of cultivation as fodder for cattle, on dry, barren, especially chalky or marly ground, in open situations. From its not thriving well except the soil or subsoil be calcareous, sainfoin is not generally met with in England; it is most extensively cultivated on the Cotswold Hills, and on the chalk soils of Surrey, &c. Its nature, qualities, and treatment are similar to those of **LUCERN**, which see.

SAINT JOHN'S-WORT. See **JOHN'S-WORT.**

SAINT PETER'S-WORT. See **JOHN'S-WORT.**

SALAD, CORN. See **CORN SALAD.**

SALAL BERRY. A new fruit from the valley of the Columbia river. It is about the size of a common grape, of a dark purple colour, and possesses a sweet and pleasant flavour.

SALLOW. The common name of several species of *Salix*, which, unlike those known under the name of osiers, are not flexible, but form large trees or rough bushes, which grow in moist, marshy woods and hedges, in various parts of England. Sallows generally yield the best kind of charcoal for the manufacture of gunpowder, though all the species of *salix* are burnt for the preparation of this substance. Sir J. E. Smith particularizes, in England, nearly a dozen different native species of **sallow**. See **OSIER** and **WILLOW**.

SALLOW-THORN (*Hippophæ*, from *hippos*, a horse, and *phao*, to destroy; in reference to the supposed poisonous qualities of the seeds). The species are mostly ornamental trees or shrubs, growing in any common soil, and may

be readily increased by layers or cuttings of the roots. The common **sallow-thorn** or **sea-buckthorn** (*H. rhamnoides*) is a bushy, rigid shrub, 5 feet or more in height, with hard wood, and straight, spreading, leafy branches, each terminating in a thorn. The shrub is a native, being found growing wild on sandy cliffs on the eastern coast of England. The leaves are linear-lanceolate, scattered, deciduous, 1½ inch long, on short stalks, dark-green on the upper side, minutely dotted, beautifully silvery as well as scaly beneath.

SALSIFY (*Tragopogon porrifolius*). An ornamental plant, which, when grown in the kitchen garden, succeeds in any common soil. It is sown and treated in the same manner as carrots; the flavour of the root is mild and sweetish. When properly cooked, it has a flavour much resembling that of oysters, from which it often goes by the name of oyster plant.

SALSILLA (*Edible alstrameria*). A very herbaceous plant, a native of Peru. Its roots are eaten like the potato. It is cultivated in the West Indies, and may answer well in many parts of the United States. (*Kenrick*).

SALT, COMMON, as a manure (Germ. *salz*; It. *sale*). This salt is a compound of chlorine and a metal, the base of soda, called *sodium*; or, in chemical language, salt is a chloride of sodium. It is too well known to require description; but it may be proper to state that it dissolves equally well in cold and in hot water.

It would be, perhaps, difficult to name any other substance in the catalogue of modern fertilizers, whose powers have been so often and so warmly disputed as common salt; and for this controversy many reasons may be assigned. It has been generally employed with little scientific accuracy, and in far too loose a manner for any reliance to be placed upon the majority of the reports which have been furnished to us; and for many years a prohibitory duty in England rendered it inaccessible to the farmer—an impost which has not very long been removed, and which yet was the occasion of a great variety of blundering trials, miscalled experiments. The duty on salt was, indeed, one of long continuance. It originated as a war tax, in the ninth year of the reign of William III., and was not removed until after many an arduous debate, in the end of that of George III. The price of salt, in consequence of the duty, was raised from 6*d.* a bushel to more than 20*s.*; and was, therefore, during the continuance of the tax, too expensive a fertilizer to be employed by the English farmer; and it was only after being for a century and a half lost to agriculture, that it was again presented, in 1823, unshackled with duties, to the notice of the agriculturist. During that long interval, salt, as a manure, was known only in the traditions of the English farmers. Through these they learned, that it was formerly used to kill worms, and to destroy weeds; that it cleansed fallows, increased the produce of light, arable soils, and was good to sweeten grass. These reported advantages were rendered more probable by certain facts that had been forced, as it were, upon their attention. The gardener was well aware that the brine of the pickling tubs, when poured over his heaps of weeds, not

only killed every weed, every seed, and every grub, but that these heaps were then converted into so many parcels of the most fertilizing manure; the good effects of which, especially upon potatoes and carrots, were very decided. It was well known, too, that a single grain of salt placed upon an earthworm speedily destroyed it; that if brine were poured upon the lawn, all the earthworms were immediately ejected from that spot; and that if it were sprinkled about over a portion of the grass, to this salted portion all the deer, sheep, or the horses of the park constantly repaired, in preference to any other part of the field. Salt evidently, therefore, destroyed weeds and worms, and rendered grass more palatable to livestock; and, upon consulting the old agricultural writers, it was found that the notices of salt as a manure were many and important; and that salt had been employed in various agricultural operations from a very early period. Thus it is referred to in *St. Luke*, xiv. 34. Virgil reprobates a salt soil. Cato, 150 years B. C., commends it for cattle, hay, straw, &c.; as does Virgil, lib. 3, v. 394. The early German farmers knew of its value for sheep; and for the same purpose, in Spain, it has been employed from the earliest ages. In 1570, Conrad Heresbach commends it as being a certain prevention of the "murrain or rotte." In 1653, Sir Hugh Platt speaks of salt as a fertilizer in his usual visionary manner, and details the result of a very successful experiment on a "patch of ground" at Clapham; from which some late writers upon the uses of salt have led their readers into great blunders, by stating that this experiment was performed on an acre of land.

The use of salt by the cultivator, since the repeal of the duties in 1823, has been considerable, however, in many districts of England, in spite of these blundering instructions, ill-contrived experiments, and ignorant conclusions. If to this be added the natural difficulty of obtaining correct results in any experiments in which vegetable life is concerned, we need no longer be surprised that many contradictory statements have been made with regard, not only to salt, but to all other fertilizers.

Common salt is composed of 35.42 parts of chlorine, and 23.3 of sodium. This is not the place to enlarge upon its almost universal presence in almost all waters, soils, and situations, nor of the masses with which our country is endowed. Its fertilizing properties, when applied to land, may be described as five in number.

1. In *small proportions*, it promotes the decomposition of animal and vegetable substances—a fact first ascertained by Sir James Pringle and Dr. Macbride. Salt, therefore, promotes the rapid dissolution of the animal and vegetable remains contained in all cultivated soils. The recent discoveries of M. Macaire, with regard to the excretions of vegetables, impart considerable information as to the use of common salt in promoting the putrefaction of vegetable substances in the soil; since it has been shown by this gentleman that the brown excretory matter of a plant is extremely noxious to

those of its own species; the salt, therefore, by its presence in the soil, promoting the putrefaction of the excretion, naturally assists in removing the offending matter; and, in so doing, the excretion, as it decomposes, certainly affords nourishment to the plant which produced it. We are fully aware that this hypothesis may be disputed: we therefore offer it merely as an hypothesis. But it is true that salt, properly used, enables land which has been deteriorated by one crop to bear another with advantage.

2. It destroys vermin and kills weeds, which are thus converted into manure. 3. It is a direct constituent or food of some plants; and it has been clearly ascertained, that if salt is applied to a soil, the vegetables afterwards growing on that land are found to contain an increased proportion of common salt. (Mr. George Sinclair, *Prize Essay on Salt as a Manure*.) All marine plants contain it in considerable proportions. 4. Salt acts on vegetable substances as a stimulant. Dr. Priestley tried various experiments, all supporting this supposition. He added to phials, containing an ounce and a half of water, various proportions of common salt, from 1 to 12 grains, and in the solutions placed various sprigs of mint and other vegetables. In those solutions which contained more than 12 grains, the plants died immediately, and the rest died in their order, except that which contained 3 grains of salt, which seemed to grow as well as plants growing in simple water. It was remarkable, however, that this plant, as well as all those that died in the stronger solutions, seemed to flourish *at first* more than those which were growing in simple water, and that that which had 3 grains of salt, and that which had 1 grain only, continued to live after the plants in simple water were dead. (*Nat. Philos.* vol. i. p. 106.) That vegetable substances are capable of being stimulated by chemical solutions, is well known. A solution of chlorine in water will make certain seeds vegetate which would otherwise rot in the earth; and a mixture of camphor, &c., has been found to be very beneficial in restoring vitality to cuttings of various exotics too long delayed on their passage. 5. Salt preserves vegetables from injury by sudden transitions in the temperature of the atmosphere. That salted soils do not freeze so readily as usual when salt is applied to them, is well known; and that salt preserves crops of turnips, cabbages, &c., from injury by the frost, is equally well established. (Johnson's *Essay on Salt*, pp. 6—68.)

6. Salt renders earth more capable of absorbing the moisture of the atmosphere—a property of the first importance, since those soils which absorb the greatest proportion of moisture from the atmosphere are always the most valuable to the cultivator. "It affords," said the illustrious Davy, "one method of judging of the productiveness of land." (*Agr. Chem.* p. 184.) See EARTHS.

The impure picking of scalings of the salt-makers is usually to be obtained by the farmer at a very low rate, and from its being a mixture of common salt and gypsum (sulphate of lime), it is excellently adapted as a manure for the

grasses, such as clover, lucern, sainfoin, &c.; and, as such, I will give the chemical analysis, for the information of the cultivator, of the refuse of the marine and fossil salt-makers. The pan scale of the Lymington marine salt-makers consists, according to the analysis of Dr. Henry, of—

	Parts.
Muriate of magnesia - - -	29
Desiccated sulphate of magnesia - -	18
Carbonate of lime and magnesia - -	127
Sulphate of lime - - -	216
Muriate of soda (sea-salt) - - -	610
	1000

Of the pan scale of the fossil salt-refiners of Norwich, two specimens were examined by Dr. Henry; the first was composed of—

	Parts.
Common salt - - - -	950
Carbonate of lime - - - -	10
Sulphate of lime - - - -	40
	1000

The second variety was composed of—

	Parts.
Common salt - - - -	100
Carbonate of lime - - - -	110
Sulphate of lime - - - -	790
	1000

Salt, it should be remembered, rarely causes the wheat plant to grow larger or taller, but it fills up the ear better, and brings the weaker plants forward. Mr. Sinclair informs us, that "salt appears to lessen the produce of straw, and increase the weight of grain." I have never been able in my experiments, nor in any I have witnessed (with salt alone), to observe any increased quantity of straw, even in cases where there was an increased produce, by means of salt, of 6 bushels of wheat per acre. The salt should be applied some time before sowing the seed, not less than 10, and not more than 20 bushels per acre. In my own experiments upon a light gravelly soil, at Great Totham, in Essex, the use of this quantity of salt per acre (in 1819) produced an increase of 5½ bushels per acre. The following statement of the result of some trials in 1820, on a light and gravelly soil, will show how important may be the result to the country at large by its judicious application. I regret that incessant employment of a very different nature has hitherto prevented my continuing these experiments.

	Produce per Acre.	Bushels.	lbs.
No. 1. Soil without any manure for 4 years -		13	26
2. Soil manured with stable dung to the previous crop (potatoes) -		26	52
3. Soil with 5 bushels of salt per acre, and no other manure for 4 years -		26	12

The testimony of a plain Essex farmer corroborates these results. "The soil," says Mr. James Challis, of Panfield, "that I described to you to be of rather a loose, hollow description, had a dressing of salt in November, after the wheat was sown, about 14 or 15 bushels per acre: it produced at the rate of 6 bushels per acre more than that which was not dressed, and it may be stated to be 1l. per load of 40 bushels better in quality." (*Essay on Salt*, p. 45.)

It is a custom in most counties of England, to apply salt and water as a steep to prevent the ravages of the disease in wheat, called smut; the value of this is known to almost

every farmer. Recent experiments have suggested that it may even be of use, when employed in larger quantities, as a preventive of mildew; the most dreadful of the numerous diseases to which the cultivated grasses are exposed. The experiments of the late Rev. E. Cartwright strongly evidence, that when salt and water are sprinkled with a brush upon diseased plants, it effects a complete cure, even in apparently the most desperate cases. (*My Essay*, p. 49.) "The proportion, one pound to a gallon of water, laid on with a plasterer's brush, the operator making his casts as when sowing corn, is instant death to the fungus." The time and expense are trifling. It appeared, in the course of some inquiries made by the Board of Agriculture, that a Cornish farmer, Mr. Sickler, and also the Rev. R. Hoblin, were accustomed to employ refuse salt as a manure, and that their crops were never infected with the rust or blight. See MILDEW.

Experiments demonstrate the efficacy of salt on barley and oats. In 1820, on a good alluvial soil, at Heybridge, in Essex, in a field of barley, the results of two experiments were—

	Bushels.
1. Soil dressed with 6 bushels of salt per acre, and 20 loads of earth and stable dung, at turnip-time, produced per acre -	65
2. Soil dressed with 20 loads of dung and earth -	60

In the same year, at Sproughton, in Suffolk, on a sandy, barley soil, belonging to Mr. Ransome:—

	Bushels of Barley.
1. Soil without any manure produced, per acre -	30
2. Soil dressed with 16 bushels of salt per acre in March -	51

The following table contains the results of fourteen experiments, made in 1819, by the late Mr. George Sinclair, at Woburn, on the uses of salt to the barley crop. The soil had, the previous year, carried a crop of turnips, and was composed of three-fourths silicious sand:—

Kind of Manure, and Mode of applying it.	Quantity per Acre.		Produce.	
	Bushels of Salt.	Bushels of Lime.	Bush.	Weight per Bushel.
BARLEY.				
Soil without manure of any kind - - -	-	-	12	43½
Salt sown with the seed -	55	-	20	43½
Salt sown with the seed -	5½	-	20	42½
Salt applied before sowing -	33	-	28½	44½
Salt applied before sowing -	11	-	28½	43
Salt applied before sowing -	5½	-	23½	43
Lime and salt applied before sowing - - -	33	60	9	42½
Lime and salt applied before sowing - - -	11	60	22	42½
Lime and salt before sowing - - - -	16½	30	13½	43
Lime mixed and sown with seed - - - -	-	60	18½	43½
Lime mixed with soil previous to sowing - -	-	60	10½	43½
OATS.				
Sown without any manure - - -	-	-	28½	33
Salt with the seed - - -	44	-	17½	30½
Salt mixed with the soil -	44	-	27	27

In these experiments upon oats, the quantity of salt applied was evidently too great. Mr. Legrand states, that in his experiments upon barley, "it gradually advanced in its effects 16 bushels, and as gradually diminished bushels, when vegetation was stopped."

The following table contains the results of the experiments made at Woburn, 1818-19, by the late Mr. George Sinclair, with his usual scientific accuracy. I would direct the farmer's attention to this table, as containing a mass of valuable information.

The soil on which these experiments were made was sandy, and the plots each contained 36 square feet; the Talavera wheat was drilled into the soil November 5th, and reaped August 2d, 1818.

Kind of Manure, and Mode of applying it.	Manures, omitting Fractions. Quantity per Acre.				Produce.

As a Manure for Grass Land, Meadows, &c., salt has been used in all parts of England, with varying success. It always, however, sweetens the herbage. It has been employed at the rate of 6 to 16 bushels per acre, and where the primary object has been the destruction of the old turf, even 30 to 40 bushels have been successfully employed on the same extent of land. It has the effect of completely preventing worm-casts on lawns, &c.

In a letter with which I was favoured from Mr. Collins, of Kenton, Devonshire, 1826, he says—"One of my neighbours writes me, 'In using salt as a manure on grass land, I have found the salted portions not to be affected by severe frosty nights, when every blade of grass on the unsalted portions has been in a frozen state. I observe, too, that it is destructive to every kind of grub and worm; and I am convinced, where it has been used with judgment, that it has not failed.' Another intelligent neighbour," continues Mr. Collins, "whose farm is almost entirely a light black sand, writes, 'I have found salt answer my most sanguine expectations for barley, oats, potatoes, and turnips, both as to the increased quantity and improved quality of the crops, of which I can now give ocular demonstration: my barley and oats, which used to yield me only 15 to 20 bushels per acre, now yield from 40 to 45. My wheat is certainly much im-

proved in quality, but I expected more in quantity. I have had 35 bushels of wheat from an acre dressed with 10 bushels of salt; and from the same field last year, after the same quantity of salt, 140 bags of potatoes per acre. This year again, dressed with 10 bushels of salt, I have not more than 20 bushels of wheat per acre, but the quality very superior indeed, and the root of clover in it very fine and luxuriant. In every field I have salted, I find the grass very much superior to any produced before the use of salt.' I have since," adds Mr. Collins, "gone over his farm, and am astonished at the verdant pasturage, in what used to be coarse and rushy meadows. In this arable land, he never got more than 10 bushels of wheat per acre until he used salt; so that this is also a decided improvement."

In Suffolk, according to a statement furnished to me by Mr. Broke, of Capel, near Ipswich, "In the month of April, 1821, 6 bushels of salt manure were applied to half an acre of red clover; the soil good turnip land, not sharp; extent of the field 10 acres. The salted clover at first looked very yellow, and apparently injured, but it soon began to recover, and when mown, the increased produce was, at the very least, 10 cwt. per acre; and the aftermath proportionally good; the cattle eating it down closer, and in preference to any other part of the field."

SALT, COMMON.

With potatoes.—There have been various experiments made with salt as a manure for potatoes. The author of this work, in 1817, on a gravelly soil, at Great Totham, in Essex, made the following trials:—

	Bushels.
1. Soil simple, produce per acre	120
2. Soil with 20 bushels of salt in September	192
3. Soil with stable manure, 20 loads in the spring of the year	219
4. Soil with 20 loads of manure and 20 bushels of salt	234
5. Soil with 40 bushels of salt alone	192½
6. Soil with 40 bushels of salt and 20 loads of manure	244

The Rev. Edmund Cartwright, of Hollenden House, in Kent, in 1804, made various important trials of salt as a manure for potatoes. The soil on which the experiments were made consisted of three-fourths sand. See POTATOES.

“Of ten different manures,” said this agriculturist, “salt, a manure hitherto of an ambiguous character, is (one only excepted) superior to them all. The effect of the mixture of salt and soot is remarkable.” The writer of this witnessed the same result on carrots, at the rate of 16 bushels of each per acre.

Vermin.—With regard to the destruction of vermin by means of salt, we may safely assert, that there is, perhaps, no agricultural use of common salt more undoubted. The effect, too, is direct, and the result immediately apparent. For this purpose, from 5 to 10 bushels per acre are sufficient. The agriculturist need be under no apprehension that the salt will destroy his crop, for 20 bushels of salt per acre may be applied to young wheat with perfect safety: I have seen even 25 bushels used with advantage. See INSECTS.

In reference to Weeds.—Salt has been of late years used at the rate of from 20 to 40 bushels per acre, to kill weeds and to cleanse fallows, with great advantage; it also, in the large proportion we have named, will destroy coarse, sour grass, &c.; and though, for a time, all vegetation is destroyed, yet, in a short period, a much superior turf is produced. If the cultivator can collect weeds, parings of turf, ditches, banks, &c., of the most foul description, and spread evenly on the surface of the heap half a bushel of salt to every ton of the collection, he will find every weed, in the course of a few weeks, killed and dissolved away. This plan I have long followed myself, on a light, gravelly soil; and upon spreading this salted mixture, at the rate of 14 or 15 loads per acre, its beneficial effects can be traced to an inch. I have principally used it as a dressing for turnips and oats.

In the Garden.—Salt has been employed by the gardener for many purposes; most commonly on lawns, at the rate of 10 bushels per acre, to prevent worm-casts; and on gravel walks in a larger proportion, to kill weeds; it may be employed, however, as a fertilizer in gardens with decided advantage. I have witnessed the results of the following experiments made by my brother, Mr. George Johnson, at Great Totham; and I the more readily give them a place here, from knowing with what care they were made:—

The soil was composed of—

SALT, COMMON.

	Parts.
Stones and gravel	27
Vegetable fibre	15
Soluble matter	3
Carbonates of lime and magnesia	18
Oxide of iron	4
Animal and vegetable matter	1
Alumina	4.5
Silica	40
Loss	1
	<hr/> 100

Windsor beans were sown on it—

	Produce per Acre.
Soil treated with 20 bushels of salt per acre, bushels	217
Soil simple	135

Onions—

	Tons.	cwt.	qrs.	lbs.
Salt 20 bushel, manure 20 tons, per acre	3	12	3	12
Manure	2	10	2	19

Carrots—

1. Soil without any manure	13	4	0	0
2. Soil with 20 tons of manure	22	18	0	26
3. Soil with 20 bushels of salt	18	2	0	0
4. Soil with 20 bushels of salt, and 20 tons of manure	23	6	1	18

Parsnips—

1. Soil with 20 tons of manure, and 20 bushels of salt	6	15	0	0
2. Soil with 20 tons manure	6	11	1	1

Early potatoes—

1. Soil simple	308
2. Soil with 20 bushels of salt	584

Beets—

	Tons.	cwt.	qrs.
1. Soil simple	4	10	1
2. Soil with 20 bushels of salt	4	8	3
3. Soil with 20 tons of salt, and 20 tons of manure	7	0	0
4. Soil with 20 tons of manure	6	10	0

In preventing clubbing in the roots of some of the brassica tribe, Mr. Johnson found salt highly useful; he states, in some observations on this disease read to the Horticultural Society of London, October 16, 1821:—“Some cauliflowers were planted upon a light silicious soil, which had previously been manured with well-putrefied stable manure, and over one-third of the allotted space was sown salt, at the rate of 20 bushels per acre, immediately before planting in July, 1821. The previous crop had been broccoli. Fifty-four plants were set on the two-thirds unsalted, and 26 on the one-third salted: the result has been, that of the 54 unsalted, 15 have been diseased and unproductive, but of the 26 salted only 2.”

There is little doubt, but that salt might be much more extensively employed by florist than at present. A very small quantity of salt added to the water in which flowers are placed, adds considerably to their duration. There are many bulbous-rooted flowers which flourish best in the immediate vicinity of the sea. Mr. Edwin Greville remarked, in 1824, that some common salt applied at the rate of 16 bushels per acre to a portion of a bed of stocks, in his garden at Wyaston, in Derbyshire, made them grow most decidedly stronger and finer, and bloom much more perfectly than those growing in the same bed unsalted. “There was no possibility of error or doubt on the subject.” said my intelligent informant. I have given the experiments of Dr. Priestley upon various plants vegetating in salt and water. He found

that the use of salt materially protracted the existence of the plant. It is a common custom with the importers of exotic plants, to dip cuttings in salt-water. Before the adoption of this plan, they almost invariably perished in the passage.

Among the many excellent communications with which I have been favoured on the use of salt in the cultivation of plants, was one from an eminent florist, near Paddington, Mr. Thos. Hogg. "From the few experiments," he observes, "that I have tried with salt as a garden manure, I am fully prepared to bear testimony to its usefulness. In a treatise upon flowers, published about 6 years since, I remarked, that the application of salt, and its utility as a manure, was yet imperfectly understood. It is a matter of uncertainty, whether it acts directly as a manure, or only as a kind of spice or seasoning, thereby rendering the soil a more palatable food for plants. The idea that first suggested itself to my mind arose from contemplating the successful culture of hyacinths in Holland. This root, though not indigenous to the country, may be said to be completely naturalized in the neighbourhood of Haerlem, where it grows luxuriantly in a deep, sandy, alluvial soil; yet one great cause of its free growth, I considered, was owing to the saline atmosphere: this induced me to mix salt in the compost; and I am satisfied that no hyacinths will grow well at a distance from the sea, without it. I am also of opinion, that the numerous bulbous tribes of amaryllidaceæ, especially those from the Cape of Good Hope, ixias, alliums, which include onions, garlic, shalots, &c., anemones, various species of the lily, antholyza, colchicum, crinum, cyclamens, narcissus, iris, gladiolus, ranunculus, scilla, and many others, should either have salt or sea-sand in the mould used for them. I invariably use salt as an ingredient in my compost for carnations; a plant which, like wheat, requires substantial soil, and all the strength and heat of the summer, to bring it to perfection; and I believe I might say, without boasting, that few excel me in blooming that flower."

In the inundations of the sea, as in Friesland, for instance, in 1825, various curious effects were produced by the salt-water. The oak, the mulberry, pear, peach, and others with deep roots, did not suffer; neither did the asparagus, onions, celery, &c., for they were never finer, or more luxuriant. But the vines and gooseberries contracted a salt taste; and the apricots, apples, cherries, elms, poplars, beech, willows, &c., could not bear the over-dose of sea-water. They pushed out a few leaves, but speedily perished. (*Turner's Sacred Hist.* p. 117.) Similar results were noticed, after an inundation of the sea, in the garden of the late Richard Gower, Esq., near Ipswich, in Suffolk, in November, 1824. In this instance a portion of the garden remained 24 hours under the sea-water. The asparagus beds were materially improved in their produce. The cherry trees, in the following year, produced a numerous crop of cherries, which tasted, however, so very salt that they could not be eaten, although very fine in appearance. These trees all died in

the following year, 1826. (*Johnson on the Fertilizers*, p. 374.)

SALT, WITH OTHER MANURES.—Salt and Lime. With a mixture of salt and lime, a manure is gradually formed of a most powerful description. It promises now, through the successful example of Mr. Bennett and Sir C. Burrell, to be very generally adopted. It is difficult to account for the neglect of this manure, on any other ground than the difficulties which were so long thrown in the farmer's way, by the long-continued tax upon salt. That it is not a novel plan for enriching the land is quite certain. Glauber, a celebrated German chemist, one of the last of the alchemists, described it in the jargon of his craft nearly two centuries since, when he said "The *Sal mirabilis* (common salt), as it is of itself, is, by reason of its corroding virtues, which it as yet retains, plainly unfit for the multiplication of vegetable, for that being so used would prove more hurtful than profitable. Upon this account it is necessary that to one part of it be added two parts by weight of the best calyx vine (lime), which being moistened with water and made into balls, are to be well heated red-hot for an hour, that so all the corrosivity being introverted, the *sal mirabilis* may be *alkalized*, and used to vegetables for an universal medicine: for it conserves its attracting force, and loseth it not in the heating red-hot." (*Glauber's Works*, by *Packe*, pp. 2, 47.)

Christopher Packe, who, in 1688, published in English Glauber's folio volume, dwells at considerable length in his preface upon this mixture of salt and lime; "for the enriching of poor and barren land, it is the cheapest of all mixtures, and is most easy to be done; for any ploughman having but once seen it done may be presently able to manage it."

Salt and lime was used as a manure by Mr. Mitchell, of Ayr, many years since, and he, not knowing what others had done with this fertilizer before his time, considered himself to be the discoverer. He thus described his process:—Take 32 bushels of lime, and slack it with sea-water, previously boiled to the saturated state. This quantity is sufficient for an acre of ground, and may be either thrown out of the carts with a shovel over the land in the above state, or made into compost with 40 loads of moss or earth, in which state it will be found to pay fully for the additional labour, and is sufficient for an acre of fallow ground, though ever so reduced before. Its component parts are muriate and sulphate of lime, mineral alkali, in an uncombined state, also muriate and carbonate of soda. All the experiments have done well with it, but especially wheat and beans; and it has not been behind any manure with which it has been compared. There is one instance in which it was tried in comparison with 72 cart-loads of soaper's waste and dung; and although this was an extraordinary dressing, yet that with this salt and lime manure was fully above the average of the field. Mr. Mitchell calculates that 3000 gallons of sea-water, boiled down to about 600 gallons, will slack 64 bushels of shell lime. (These 3000 gallons of sea-water will contain about

lbs. of common salt.) A quantity sufficient for 2 acres. The expense of carrying the water from the sea, the evaporation, &c., he adds, will cost 20s. The 64 bushels of limestone cost him 40s., or 3*l.* for 2 acres.

The use of this mixture of salt and lime was also noticed in the year 1800, by Mr. Hollingshead, of Chorley, in Lancashire, who observes: "Lime prepared for manure should be slacked with salt-springs or salt-water: lime so slacked will have a double effect." And in 1816, Mr. James Manley, of Anderton, in Cheshire, when giving his evidence before a committee of the House of Commons on the salt duties, mentioned, that in getting marl (which is a mixture of carbonate of lime, alumina, and silica), he had found that, by mixing it with brine instead of water, the portion of the field on which the brined marl was used yielded 5 bushels of wheat per acre more than that portion on which the watered marl was employed; and it may be well to remember, that the celebrated salt sand of Padstow Harbour is composed of 64 per cent. of carbonate of lime; and that, in the experiments of the late Rev. Edmund Cartwright, upon potatoes, of 25 manures, or mixtures of manures, salt and lime were found superior in their product of potatoes to 19 others.

Every farmer has it in his power, even in the most inland situations, to procure this most excellent manure for the use of his farm, by means of a mixture of two parts of lime and one part of common salt, and suffering it to remain incorporated in a shady place, or covered with sods, for 2 or 3 months; a plan which I suggested some years since. (*Essay on Salt*, p. 32, 3d ed.) By this process a gradual decomposition takes place, muriate of lime and soda are formed, the whole mass speedily becoming encrusted with alkali. There is another advantage to be derived from the adoption of this process, besides the formation of soda, viz., that the muriate of lime is one of the most deliquescent or moisture-absorbing substances, with which we are acquainted; and, in consequence, whenever it exists in a soil, the warmth of the sun has, in summer, much less influence on it than it would otherwise have.

I would especially warn those who try the effect of a mixture of salt and lime, to attend carefully to the directions I have given, and not, as some farmers have done, to use the mixed salt and lime immediately, before any decomposition has taken place. After it has been well mixed together in a dry state, it should be allowed to remain 2 or 3 months undisturbed, and then applied at the rate of from 35 to 60 bushels per acre, either by sowing it out of a seed-basket, or mixed with earth, and spread in the usual way. It is necessary to give the mixture time, since the decomposition proceeds very slowly, and is not to be hastened by any simple process. See **LIME**.

Salt and Soot.—Salt has never been employed with other substances so extensively as it might. I have used it for potatoes, mixed with earth, ditch-scrapings, and with soot, with the most decided success; the places where it has been thus applied being much superior, both in appearance and in produce.

The mixture of salt with soot produces the most remarkable effects, especially when trenched into ground prepared for carrots. Mr. G. Sinclair found that when the soil, unmanured, produced twenty-three tons of carrots per acre, the same soil, fertilized with a mixture of only six bushels and a half of salt, and six and a half of soot, yielded forty tons per acre. Mr. Belfield describes the mixture as equally beneficial for wheat. And Mr. Cartwright found, that when the soil, without any addition, yielded per acre 157 bushels of potatoes, that, dressing the same land with a mixture of thirty bushels of soot and eight bushels of salt, made it produce per acre 240 bushels. (*Johnson on Fertilizers*.)

SALTS, *their uses to vegetation.* That peculiar saline substances exist in almost all vegetables, was an early observation made by the natural philosopher. The saline and alkaline taste perceivable in the ashes obtained by the combustion of these substances, very plainly indicated the fact. And although the skill of the chemist did not at first enable him to accurately discriminate between the salts, the alkalis, or even the earths contained in plants, with even tolerable accuracy, yet the progress of science has long since surmounted a mass of difficulties, and has detected a strange variety of salts in plants. A salt, he it remembered, is a substance produced by the combination of an acid with a base, that is, with an earth, an alkali, or a metallic oxide: the class of salts, therefore, is exceedingly numerous (they have been estimated at about 2000), and includes many substances which at first sight do not appear entitled to such a name; thus the union of the carbonic acid with the earth lime, which is an oxide of a metal, forms the salt carbonate of lime, or chalk, marble, &c. Sulphuric acid and lime form the salt sulphate of lime (gypsum), with phosphoric acid, phosphate of lime (earthy matter of bones), and many other earthy salts look to the mechanical eye as little like salts as these.

The farmer must avoid, in entering into this examination, the common error of supposing that the saline substances found in plants are not their essential constituents or food, but are merely there by chance; that their presence is unattended with benefit, and their absence totally unproductive of injury; for such is a most erroneous conclusion. Not only are certain salts, the phosphate and sulphate of lime, and the carbonate of potash, for instance, invariably present in certain plants, but without those salts are present in the soil in which they grow, they will not maintain a healthy vegetation. Under the head **EARTHS, GASES, WATER**, I have endeavoured to show how essential those substances are to vegetation, and what a great part they perform in the support of the farmer's crops; but still it will be found, that when a soil is carefully composed of all the pure earths discovered in plants, watered in abundance with pure water, and supplied with all the gases of putrefaction and of the atmosphere, that still all these are not sufficient by themselves to support a single ordinarily cultivated crop; but then it is found that where such a soil is supplied with various saline sub-

stances (for instance, with the various saline matters draining from a dunghill), that then every difficulty is removed. Neither must the cultivator suppose, that when saline substances are mixed with the soil, that then the plant growing upon it absorbs those salts as a matter of necessity, united with the moisture contained in that soil, without having the power of rejecting or separating it from its solution; for such an assumption has been proved to be contrary to the fact by several very accurate experiments. M. Saussure, for instance, found that plants had the power, when placed in saline solutions, foreign to their habits, of separating them from the water in which they were dissolved. These are researches fraught with instruction to the cultivator. He dissolved the following salts in water, in such proportions that each solution contained $\frac{1}{100}$ part of its weight of the salt—muriate of potash, muriate of soda (common salt), nitrate of lime, sulphate of soda (Glauber salt), muriate of ammonia (sal ammonia), acetate of lime, sulphate of copper (blue vitriol). In each of these solutions he put plants of *Polygonum Persicaria*, or of *Bidens cannabina*, furnished with their roots. The *Polygonum* grew for five weeks in the solution of muriate of potash, nitrate of lime, muriate of soda, and sulphate of soda, and its roots increased in them as usual. It languished in the solution of sal ammoniac, and the roots made no progress. It died in 8 or 9 days in the solution of acetate of lime, and in less than 3 days in the solution of sulphate of copper. When such a number of plants of *Polygonum* were put into the solutions as to absorb one-half of each in 2 days, the remaining half was found to have lost very different proportions of the salt which it had originally contained. Supposing the portion of salt at first in solution to be 100, the following table exhibits the quantity of each which had disappeared when one-half of the liquid was absorbed—

	Parts.
Muriate of potash - - - -	14·7
Muriate of soda - - - -	13
Nitrate of lime - - - -	4
Sulphate of soda - - - -	14·4
Muriate of ammonia - - - -	12
Acetate of lime - - - -	8
Sulphate of copper - - - -	47

The *Bidens* absorbed pretty nearly the same proportions, but in general did not vegetate so long as the *Polygonum*.

When various salts were dissolved at once in the same solution, and plants made to vegetate in them, it was found that different proportions of the salts were absorbed. The following table exhibits the results of these trials, supposing, as before, the original weight of each salt to have been 100, each solution contained $\frac{1}{100}$ part of its weight of each salt—

	Parts.
1. { Sulphate of soda - - - -	11·7
{ Muriate of soda - - - -	22
2. { Sulphate of soda - - - -	12
{ Muriate of potash - - - -	17
3. { Nitrate of lime - - - -	4·5
{ Muriate of ammonia - - - -	16·5
{ Acetate of lime - - - -	31
4. { Sulphate of copper - - - -	34
{ Acetate of lime - - - -	8
5. { Muriate of potash - - - -	17

	Parts.
6. { Nitrate of lime - - - -	17
{ Sulphate of copper - - - -	34
7. { Sulphate of soda - - - -	6
{ Muriate of soda - - - -	10
{ Acetate of lime - - - -	0

These experiments succeeded nearly equally with other plants, as the *Mentha piperita* and the Scotch fir. When the roots were cut or removed, the plants absorbed all solutions indiscriminately; on examining the plants, the salts absorbed were found in them unaltered. It being thus clearly established that plants possess a discriminating power, and that they do not absorb saline solutions merely because they happen to be dissolved in the soil, it next becomes an object of interest, as an illustration and guide for the operations of agriculture, to ascertain what salts are found by the researches of the chemist in commonly cultivated plants. And if, at the conclusion of our examination, we find that certain salts are found in abundance only in certain plants, and that these saline substances exist in them invariably in all soils and situations, and that without their presence the plant languishes and merely supports a sickly existence, we shall be almost driven to the conclusion, that these are as essentially the food of plants, as any of the other substances with which they abound.

For a lengthened period, the vegetable alkaline salt, carbonate of potash, has been obtained from plants. Procured at first by their combustion, in iron pots, it hence obtained its name. Dr. Thomson has given a table of the quantity of potash obtained from 100 parts of the ashes of various trees and plants. See **ALKALI.**

In general, says Dr. Thomson, three times as much ashes are obtained from shrubs as from trees. An equal weight of the branches of trees produce more ashes than the trunk, and the leaves more than the branches. Herbs arrived at maturity produce more ashes than at any other time. Green vegetables produce more ashes than dry. The salt which is obtained by the combustion of plants, although chiefly composed, does not consist wholly of potash: there are many salts mixed with it; these are usually sulphate of potash, muriate of potash, sulphate of lime, phosphate of lime, &c., but these bear in general but a small proportion to the potash.

Perhaps the most copious table of the alkaline and other salts obtained by the combustion of various plants has been given by M. Saussure in his chemical researches on vegetation. He obtained from 100 parts of the ashes of the—

	Parts.
Leaves of oak (<i>Quercus Robur</i>), May 10	47·
Do., September 27 - - - -	17·
Wood of a young oak, May 10 - - - -	7·
Bark of do. - - - -	7·
Perfect wood of oak - - - -	38·6
Albumen of do. - - - -	32·
Bark of do. - - - -	7·
Cortical layers of do. - - - -	7·
Extract of wood of do. - - - -	51·
Soil from the wood of do. - - - -	24·
Extract from do. - - - -	66·
Leaves of poplar (<i>Populus nigra</i>), May 10	36·
Do., September 12 - - - -	26·
Leaves of hazel - - - -	26·
Do., washed in cold water - - - -	8·2
Leaves of do., June 22 - - - -	22·7
Do., September 20 - - - -	11·

	Parts.
Wood of hazel, May 1	24.5
Bark of do.	12.5
Wood of mulberry, November	21.
Wood of horubeani, November	22.
Wood of horse-chestnut, May 10	9.5
Fruit of do., October 5	82.
Plants of peas (<i>Pisum sativum</i>) in flower	49.8
Do. ripe	34.25
Plants of vetches (<i>Vicia faba</i>) before flowering, May 23	55.5
Do. in flower	55.5
Do. ripe, July 23	50.
Seeds of do.	69.28
Do. in flower raised in distilled water	60.1
Plants of tansole, June 23	63.
Wheat, in flower	43.25
Do., seeds ripe	11.
Do. a month before flowering	60.
Do. in flower, June 14	41.
Do., seeds ripe	10.
Bran	44.16
Plants of maize or Indian corn	69.
Chaff of barley	20.
Seeds of do.	29.
Oats	1.
Leaves of fir (<i>Pinus abies</i>), raised on limestone	16.
Leaves of fir, raised on granite	15.
Branches of pine	15.

M. Vauquelin found 20 per cent. of potash in the ashes of the oat; and from his experiments it is probable that potash exists in plants in combination with the acetic and carbonic acids.

The mineral alkali soda, or carbonate of soda, is found in almost all the plants which are found growing in the sea, or on the shore, within reach of its influence. The amount of alkali which these produce, is considerably greater, in proportion to that produced by plants natives of inland places. Thus, 100 parts of the salsola soda yield 19.921 parts of ashes, and these contain 1.992 parts of soda and common salt. Many plants, the vegetable marrow and the vine, for instance, derive great benefit from the application of soda to their roots. Soap-suds are used as an excellent liquid manure by many gardeners.

Sea-weed, kelp-soda, barilla, and the common washing-soda of the shops, have all been used successfully as saline manures; and the well-known fertilizing mixture of salt and lime, after it has remained undisturbed for some time, contains chloride of lime and soda in abundance. Sea-weed abounds with a strange mixture of alkaline salts, and there is no green manure more powerful in its effects than this, especially when it is ploughed in as fresh as possible. Mr. Gaultier de Claubry found in the *Fucus saccharinus* and in the *Fucus digitatus* (which is much used in Scotland as a manure) the following substances—saccharine matter, mucilage, vegetable albumen, oxalate of potash, malate of potash, sulphate of potash, sulphate of soda, sulphate of magnesia, muriate of soda, muriate of potash, muriate of magnesia, carbonate of potash, carbonate of soda, hydriodate of potash, silica, phosphate of lime, phosphate of magnesia, oxide of iron, oxalate of lime. In the islands of Guernsey and Jersey they employ the ashes of the sea-weeds, which they call *vraic*. Half a bushel strewed over a perch of ground in winter, or the beginning of spring, is sufficient. It gives a full ear to the corn, and prevents it from being laid.

Phosphate of lime, which is composed, according to the experiments of M. Berzelius, of

phosphoric acid 100 parts, and lime 84.53, abounds in vegetable substances. It forms the basis of bones, from which, for the purposes of experiment, it is commonly procured. Obtained in this way it is always in the form of a white powder, without either taste or smell; is insoluble in water, and unaltered by exposure to the atmosphere. Phosphate of magnesia is composed of phosphoric acid and magnesia; is a salt soluble in 15 times its weight of water. These two salts have been found in a variety of vegetable substances by MM. Vauquelin, Saussure, and other able chemists. See BONES.
